Pro Angular: Build Powerful and Dynamic Web Apps

Adam Freeman
London, UK

Dedicated to my lovely wife, Jacqui Griffyth.
(And also to Peanut.)

Table of Contents

About the Author

Adam Freeman is an experienced IT professional who has held senior positions in a range of companies, most recently serving as chief technology officer and chief operating officer of a global bank. Now retired, he spends his time writing and long-distance running.

About the Technical Reviewer

Fabio Claudio Ferracchiati is a senior consultant and a senior analyst/developer using Microsoft technologies. He works for BluArancio (`www.bluarancio.com`). He is a Microsoft Certified Solution Developer for .NET, a Microsoft Certified Application Developer for .NET, a Microsoft Certified Professional, and a prolific author and technical reviewer. Over the past ten years, he's written articles for Italian and international magazines and coauthored more than ten books on a variety of computer topics.

CHAPTER 1

■ ■ ■

Getting Ready

Angular taps into some of the best aspects of server-side development and uses them to enhance HTML in the browser, creating a foundation that makes building rich applications simpler and easier. Angular applications are built around a clear design pattern that emphasizes creating applications that are

- *Extendable*: It is easy to figure out how even a complex Angular app works once you understand the basics—and that means you can easily enhance applications to create new and useful features for your users.

- *Maintainable*: Angular apps are easy to debug and fix, which means that long-term maintenance is simplified.

- *Testable*: Angular has good support for unit and end-to-end testing, meaning you can find and fix defects before your users do.

- *Standardized*: Angular builds on the innate capabilities of the web browser without getting in your way, allowing you to create standards-compliant web apps that take advantage of the latest HTML and features, as well as popular tools and frameworks.

Angular is an open-source JavaScript library that is sponsored and maintained by Google. It has been used in some of the largest and most complex web apps around. In this book, I show you everything you need to know to get the benefits of Angular in your projects.

THIS BOOK AND THE ANGULAR RELEASE SCHEDULE

Google has adopted an aggressive release schedule for Angular. This means there is an ongoing stream of minor releases and a major release every six months. Minor releases should not break any existing features and should largely contain bug fixes. The major releases can contain substantial changes and may not offer backward compatibility.

It doesn't seem fair or reasonable to ask readers to buy a new edition of this book every six months, especially since most Angular features are unlikely to change even in a major release. Instead, I am going to post updates following the major releases to the GitHub repository for this book, `https://github.com/Apress/pro-angular-5ed`.

This is an ongoing experiment for me (and for Apress), but the goal is to extend the life of this book by supplementing the examples it contains.

I am not making any promises about what the updates will be like, what form they will take, or how long I will produce them before folding them into a new edition of this book. Please keep an open mind and check the repository for this book when new Angular versions are released. If you have ideas about how the updates could be improved, then email me at adam@adam-freeman.com and let me know.

Understanding Where Angular Excels

Angular isn't the solution to every problem, and it is important to know when you should use Angular and when you should seek an alternative. Angular delivers the kind of functionality that used to be available only to server-side developers, but delivers it entirely in the browser. This means Angular has a lot of work to do each time an HTML document to which Angular has been applied is loaded—the HTML elements have to be compiled, the data bindings have to be evaluated, components and other building blocks need to be executed, and so on.

This kind of work takes time to perform, and the amount of time depends on the complexity of the HTML document, on the associated JavaScript code, and—critically—on the quality of the browser and the processing capability of the device. You won't notice any delay when using the latest browsers on a capable desktop machine, but old browsers on underpowered smartphones can slow down the initial setup of an Angular app.

The goal is to perform this setup as infrequently as possible and deliver as much of the app as possible to the user when it is performed. This means giving careful thought to the kind of web application you build. In broad terms, there are two kinds of web applications: *round-trip* and *single-page*.

Understanding Round-Trip and Single-Page Applications

For a long time, web apps were developed to follow a *round-trip* model. The browser requests an initial HTML document from the server. User interactions—such as clicking a link or submitting a form—led the browser to request and receive a completely new HTML document. In this kind of application, the browser is essentially a rendering engine for HTML content, and all of the application logic and data resides on the server. The browser makes a series of stateless HTTP requests that the server handles by generating HTML documents dynamically.

Some current web development is still for round-trip applications, not least because they require little from the browser, which ensures the widest possible client support. But there are some drawbacks to round-trip applications: they make the user wait while the next HTML document is requested and loaded, they require a large server-side infrastructure to process all the requests and manage all the application state, and they require more bandwidth because each HTML document has to be self-contained (leading to a lot of the same content being included in each response from the server).

Single-page applications take a different approach. An initial HTML document is sent to the browser, along with JavaScript code, but user interactions lead to Ajax requests for small fragments of HTML or data inserted into the existing set of elements being displayed to the user. The initial HTML document is never reloaded or replaced, and the user can continue to interact with the existing HTML while the Ajax requests are being performed asynchronously, even if that just means seeing a "data loading" message. The single-page application model is perfect for Angular.

> ■ **Tip** Another phrase you may encounter is *progressive web applications* (PWAs). Progressive applications continue to work even when disconnected from the network and have access to features such as push notifications. PWAs are not specific to Angular, but I demonstrate how to use simple PWA features in Chapter 8.

Comparing Angular to React and Vue.js

There are two main competitors to Angular: React and Vue.js. There are some low-level differences between them, but, for the most part, all of these frameworks are excellent, all of them work in similar ways, and all of them can be used to create rich and fluid client-side applications.

The main difference between these frameworks is the developer experience. Angular requires you to use TypeScript to be effective, for example. If you are used to using a language like C# or Java, then TypeScript will be familiar, and it addresses some of the oddities of the JavaScript language. Vue.js and React don't require TypeScript (although it is supported by both frameworks) but lean toward mixing HTML, JavaScript, and CSS content together in a single file, which not everyone likes.

My advice is simple: pick the framework that you like the look of the most and switch to one of the others if you don't get on with it. That may seem like an unscientific approach, but there isn't a bad choice to make, and you will find that many of the core concepts carry over between frameworks even if you switch.

What Do You Need to Know?

Before reading this book, you should be familiar with the basics of web development, have an understanding of how HTML and CSS work, and have a working knowledge of JavaScript. If you are a little hazy on some of these details, I provide primers for the HTML and TypeScript/JavaScript I use in this book in Chapters 3 and 4. You won't find a comprehensive reference for HTML elements and CSS properties, though, because there just isn't the space in a book about Angular to cover all of HTML.

What Is the Structure of This Book?

This book is split into three parts, each of which covers a set of related topics.

Part 1: Getting Started with Angular

Part 1 of this book provides the information you need to get ready for the rest of the book. It includes this chapter and primers/refreshers for key technologies, including HTML and TypeScript, which is a superset of JavaScript used in Angular development. I also show you how to build your first Angular application and take you through the process of building a more realistic application, called SportsStore.

Part 2: Angular in Detail

Part 2 of this book takes you through the building blocks provided by Angular for creating applications, working through each of them in turn. Angular includes a lot of built-in functionality, which I describe in-depth, and provides endless customization options, all of which I demonstrate.

5

Part 3: Advanced Angular Features

Part 3 of this book explains how advanced features can be used to create more complex and scalable applications. I demonstrate how to make asynchronous HTTP requests in an Angular application, how to use URL routing to navigate around an application, and how to animate HTML elements when the state of the application changes.

What Doesn't This Book Cover?

This book is for experienced web developers who are new to Angular. It doesn't explain the basics of web applications or programming, although there are primer chapters on HTML and TypeScript/JavaScript. I don't describe server-side development in any detail—see my other books if you want to create the back-end services required to support Angular applications.

And, as much as I like to dive into the detail in my books, not every Angular feature is useful in mainstream development, and I have to keep my books to a printable size. When I decide to omit a feature, it is because I don't think it is important or because the same outcome can be achieved using a technique that I do cover.

What Software Do I Need for Angular Development?

You will need a code editor and the tools described in Chapter 2. Everything required for Angular development is available without charge and can be used on Windows, macOS, and Linux.

How Do I Set Up the Development Environment?

Chapter 2 introduces Angular by creating a simple application, and, as part of that process, I tell you how to create a development environment for working with Angular.

What If I Have Problems Following the Examples?

The first thing to do is to go back to the start of the chapter and begin again. Most problems are caused by missing a step or not fully following a listing. Pay close attention to the emphasis in code listings, which highlight the changes that are required.

Next, check the errata/corrections list, which is included in the book's GitHub repository. Technical books are complex, and mistakes are inevitable, despite my best efforts and those of my editors. Check the errata list for the list of known errors and instructions to resolve them.

If you still have problems, then download the project for the chapter you are reading from the book's GitHub repository, `https://github.com/Apress/pro-angular-5ed`, and compare it to your project. I created the code for the GitHub repository by working through each chapter, so you should have the same files with the same contents in your project.

If you still can't get the examples working, then you can contact me at `adam@adam-freeman.com` for help. Please make it clear in your email which book you are reading and which chapter/example is causing the problem. Remember that I get a lot of emails and that I may not respond immediately.

What If I Find an Error in the Book?

You can report errors to me by email at adam@adam-freeman.com, although I ask that you first check the errata/corrections list for this book, which you can find in the book's GitHub repository at https://github. com/Apress/pro-angular-5ed, in case it has already been reported.

I add errors that are likely to confuse readers, especially problems with example code, to the errata/ corrections file on the GitHub repository, with a grateful acknowledgment to the first reader who reported it. I keep a list of less serious issues, which usually means errors in the text surrounding examples, and I use them when I write a new edition.

ERRATA BOUNTY

Apress has agreed to give a free ebook to readers who are the first to report errors that make it onto the GitHub errata list for this book. Readers can select any Apress ebook available through Springerlink. com, not just my books.

This is an entirely discretional and experimental program. Discretional means that only I decide which errors are listed in the errata and which reader is the first to make a report. Experimental means Apress may decide not to give away any more books at any time for any reason. There are no appeals, and this is not a promise or a contract or any kind of formal offer or competition. Put another way, this is a nice and informal way to say thank-you and to encourage readers to report mistakes that I have missed when writing this book.

Are There Lots of Examples?

There are *loads* of examples. The best way to learn Angular is by example, and I have packed as many of them as I can into this book. To maximize the number of examples in this book, I have adopted a simple convention to avoid listing the contents of files over and over. The first time I use a file in a chapter, I'll list the complete contents, just as I have in Listing 1-1. I include the name of the file in the listing's header and the folder in which you should create it. When I make changes to the code, I show the altered statements in bold.

Listing 1-1. A Complete Example Document

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule],
  providers: [],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

This listing is taken from Chapter 5. Don't worry about what it does; just be aware that this is a complete listing, which shows the entire contents of the file.

When I make a series of changes to the same file or when I make a small change to a large file, I show you just the elements that change, to create a *partial listing*. You can spot a partial listing because it starts and ends with an ellipsis (...), as shown in Listing 1-2.

Listing 1-2. A Partial Listing

```
...
class PaIteratorContext {
    odd: boolean; even: boolean;
    first: boolean; last: boolean;

    constructor(public $implicit: any,
            public index: number, total: number ) {

        this.odd = index % 2 == 1;
        this.even = !this.odd;
        this.first = index == 0;
        this.last = index == total - 1;

        setInterval(() => {
            this.odd = !this.odd; this.even = !this.even;
            this.$implicit.price++;
        }, 2000);
    }
}
...
```

Listing 1-2 is from a later chapter. You can see that just a section of the file is shown and that I have highlighted several statements. This is how I draw your attention to the part of the listing that has changed or emphasize the part of an example that shows the feature or technique I am describing. In some cases, I need to make changes to different parts of the same file, in which case I omit some elements or statements for brevity, as shown in Listing 1-3.

Listing 1-3. Omitting Statements for Brevity

```
import { Component, Input } from "@angular/core";
import { NgForm, FormControl, Validators } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;
```

```
nameField: FormControl = new FormControl("", {
    validators: [
        Validators.required,
        Validators.minLength(3),
        Validators.pattern("^[A-Za-z ]+$")
    ],
    updateOn: "change"
});

// ...constructor and methods omitted for brevity...
}
```

This convention lets me pack in more examples, but it does mean it can be hard to locate a specific technique. To this end, the chapters in which I describe Angular features in Parts 2 and 3 begin with a summary table that describes the techniques contained in the chapter and the listings that demonstrate how they are used.

Where Can You Get the Example Code?

You can download the example projects for all the chapters in this book from https://github.com/Apress/pro-angular-5ed.

How Do I Contact the Author?

You can email me at adam@adam-freeman.com. It has been a few years since I first published an email address in my books. I wasn't entirely sure that it was a good idea, but I am glad that I did it. I have received emails from around the world, from readers working or studying in every industry, and—for the most part, anyway—the emails are positive, polite, and a pleasure to receive.

I try to reply promptly, but I get many emails and sometimes I get a backlog, especially when I have my head down trying to finish writing a book. I always try to help readers who are stuck with an example in the book, although I ask that you follow the steps described earlier in this chapter before contacting me.

While I welcome reader emails, there are some common questions for which the answers will always be "no." I am afraid that I won't write the code for your new startup, help you with your college assignment, get involved in your development team's design dispute, or teach you how to program.

What If I Really Enjoyed This Book?

Please email me at adam@adam-freeman.com and let me know. It is always a delight to hear from a happy reader, and I appreciate the time it takes to send those emails. Writing these books can be difficult, and those emails provide essential motivation to persist at an activity that can sometimes feel impossible.

What If This Book Has Made Me Angry and I Want to Complain?

You can still email me at `adam@adam-freeman.com`, and I will still try to help you. Bear in mind that I can help only if you explain what the problem is and what you would like me to do about it. You should understand that sometimes the only outcome is to accept I am not the writer for you and that we will have closure only when you return this book and select another. I'll give careful thought to whatever has upset you, but after 25 years of writing books, I have come to understand that not everyone enjoys reading the books I like to write.

Summary

In this chapter, I outlined the content and structure of this book. The best way to learn Angular development is by example, so in the next chapter, I jump right in and show you how to set up your development environment and use it to create your first Angular application.

■ ■ ■

Jumping Right In

The best way to get started with Angular is to dive in and create a web application. In this chapter, I show you how to set up your development environment and take you through the process of creating a basic application. In Chapters 5–8, I show you how to create a more complex and realistic Angular application, but for now, a simple example will suffice to demonstrate the major components of an Angular app and set the scene for the other chapters in this part of the book.

Don't worry if you don't follow everything that happens in this chapter. Angular has a steep learning curve, so the purpose of this chapter is just to introduce the basic flow of Angular development and give you a sense of how things fit together. It won't all make sense right now, but by the time you have finished reading this book, you will understand every step I take in this chapter and much more besides.

Getting Ready

There is some preparation required for Angular development. In the sections that follow, I explain how to get set up and ready to create your first project. There is wide support for Angular in popular development tools, and you can pick your favorites.

Installing Node.js

Node.js is a JavaScript runtime for server-side applications and is used by most web application frameworks, including Angular.

The version of Node.js I have used in this book is 16.13.0, which is the current Long-Term Support (LTS) release at the time of writing. There may be a later version available by the time you read this, but you should stick to the 16.13.0 release for the examples in this book. A complete set of 16.13.0 releases, with installers for Windows and macOS and binary packages for other platforms, is available at `https://nodejs.org/dist/v16.13.0`.

Download and run the installer and ensure that the "npm package manager" option and the two Add to PATH options are selected, as shown in Figure 2-1.

Figure 2-1. *Installing Node.js*

When the installation is complete, open a new command prompt and run the command shown in Listing 2-1.

Listing 2-1. Running Node.js

```
node -v
```

If the installation has gone as it should, then you will see the following version number displayed:

```
v16.13.0
```

The Node.js installer includes the Node Package Manager (NPM), which is used to manage the packages in a project. Run the command shown in Listing 2-2 to ensure that NPM is working.

Listing 2-2. Running NPM

```
npm -v
```

If everything is working as it should, then you will see the following version number:

```
8.1.0
```

Installing an Editor

Angular development can be done with any programmer's editor, from which there is an endless number to choose. Some editors have enhanced support for working with Angular, including highlighting key terms and good tool integration.

When choosing an editor, one of the most important considerations is the ability to filter the content of the project so that you can focus on a subset of the files. There can be a lot of files in an Angular project, and many have similar names, so being able to find and edit the right file is essential. Editors make this possible in different ways, either by presenting a list of the files that are open for editing or by providing the ability to exclude files with specific extensions.

The examples in this book do not rely on any specific editor, and all the tools I use are run from the command line. If you don't already have a preferred editor for web application development, then I recommend using Visual Studio Code, which is provided without charge by Microsoft and has excellent support for Angular development. You can download Visual Studio Code from `https://code.visualstudio.com`.

Installing the Angular Development Package

The Angular team provides a complete set of command-line tools that simplify Angular development. These tools are distributed in a package named `@angular/cli`. Run the command shown in Listing 2-3 to install the Angular development tools.

Listing 2-3. Installing the Angular Development Package

```
npm install --global @angular/cli@13.0.3
```

Notice that there are two hyphens before the `global` argument. If you are using Linux or macOS, you may need to use `sudo`, as shown in Listing 2-4.

Listing 2-4. Using sudo to Install the Angular Development Package

```
sudo npm install --global @angular/cli@13.0.3
```

Choosing a Browser

The final choice to make is the browser that you will use to check your work during development. All the current-generation browsers have good developer support and work well with Angular. I have used Google Chrome throughout this book, and this is the browser I recommend you use as well.

Creating an Angular Project

Angular development is done as part of a project, which contains all of the files required to build and execute an application, along with configuration files and static content (like HTML and CSS files). To create a new project, open a command prompt, navigate to a convenient location, and run the command shown in Listing 2-5. Pay close attention to the use of double and single hyphens when typing this command.

Listing 2-5. Creating a New Angular Project

```
ng new todo --routing false --style css --skip-git --skip-tests
```

The ng command is part of the @angular-cli package, and ng new sets up a new project. The arguments configure the project, selecting options that are suitable for a first project (the configuration options are described in Chapter 9). The process of creating a new project can take some time because there are a large number of other packages required, all of which must be downloaded the first time you run the ng new command.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Opening the Project for Editing

Once the ng new command has finished, use your preferred code editor to open the todo folder that has been created and that contains the new project. The todo folder contains configuration files for the tools that are used in Angular development (described in Chapter 9), but it is the src/app folder that contains the application's code and content and is the folder in which most development is done. Figure 2-2 shows the initial content of the project folder as it appears in Visual Studio Code and highlights the src/app folder. You may see a slightly different view with other editors, some of which hide files and folders that are not often used directly during development, such as the node_modules folder, which contains the packages on which the Angular development tools rely.

Figure 2-2. *The initial contents of an Angular project*

Starting the Angular Development Tools

The final part of the setup process is to start the development tools, which will compile the placeholder content added to the project by the ng new command. To start the Angular development tools, use a command prompt to run the command shown in Listing 2-6 in the todo folder.

Listing 2-6. Starting the Angular Development Tools

```
ng serve
```

This command starts the Angular development tools, which include a compiler and a web server that is used to test the Angular application in the browser. The development tools go through an initial startup process, which can take a moment to complete. During the startup process, you will see messages like these displayed by the `ng serve` command:

```
Browser application bundle generation complete.
Initial Chunk Files   | Names         |      Size
vendor.js             | vendor        |   1.83 MB
polyfills.js          | polyfills     | 339.11 kB
styles.css, styles.js | styles        | 212.38 kB
main.js               | main          |  51.42 kB
runtime.js            | runtime       |   6.84 kB
                      | Initial Total |   2.43 MB
Build at: 2021-11-25T17:35:50.484Z - Hash: 8c7aa6b9cef0e8e7 - Time: 13641ms
** Angular Live Development Server is listening on localhost:4200, open your browser on
http://localhost:4200/ **
Compiled successfully.
```

Don't worry if you don't see the same output, just as long as you see the "compiled successfully" message at the end of the process. The integrated web server listens for requests on port 4200, so open a new browser window and request `http://localhost:4200`, which will show the placeholder content shown in Figure 2-3.

Figure 2-3. *The placeholder content in a new Angular project*

Adding Features to the Application

Now that the development tools are running, I am going to work through the process of creating a simple Angular application that will manage a to-do list. The user will be able to see the list of to-do items, check off items that are complete, and create new items. To keep the application simple, I assume that there is only one user and that I don't have to worry about preserving the state of the data in the application, which means that changes to the to-do list will be lost if the browser window is closed or reloaded. (Later examples, including the SportsStore application developed in Chapters 5–8, demonstrate persistent data storage.)

Creating a Data Model

The starting point for most applications is the data model, which describes the domain on which the application operates. Data models can be large and complex, but for my to-do application, I need to describe only two things: a to-do item and a list of those items.

Angular applications are written in TypeScript, which is a superset of JavaScript. I introduce TypeScript in Chapters 3 and 4, but its main advantage is that it supports static data types, which makes JavaScript development more familiar to C# and Java developers. (JavaScript has a prototype-based type system that many developers find confusing.) The ng new command includes the packages required to compile TypeScript code into pure JavaScript that can be executed by browsers.

To start the data model for the application, add a file called todoItem.ts to the todo/src/app folder with the contents shown in Listing 2-7. (TypeScript files have the .ts extension.)

Listing 2-7. The Contents of the todoItem.ts File in the src/app Folder

```
export class TodoItem {

  constructor(public task: string, public complete: boolean = false) {
      // no statements required
  }
}
```

The language features used in Listing 2-7 are a mix of standard JavaScript features and extra features that TypeScript provides. When the code is compiled, the TypeScript features are removed, and the result is JavaScript code that can be executed by browsers.

The export, class, and constructor keywords, for example, are standard JavaScript. Not all browsers support these features, so the build process for Angular applications can translate this type of feature into code that older browsers can understand, as I explain in Chapter 9.

The export keyword relates to JavaScript modules. When using modules, each TypeScript or JavaScript file is considered to be a self-contained unit of functionality, and the export keyword is used to identify data or types that you want to use elsewhere in the application. JavaScript modules are used to manage the dependencies that arise between files in a project. See Chapter 4 for details of how JavaScript modules are used.

The class keyword declares a class, and the constructor keyword denotes a class constructor. Unlike other languages, such as C#, JavaScript doesn't use the name of the class to denote the constructor.

■ **Tip** Don't worry if you are not familiar with these JavaScript/TypeScript features. Chapters 3 and 4 provide a primer for the JavaScript and TypeScript features that are most used in Angular development.

Other features in Listing 2-7 are provided by TypeScript. One of the most jarring features when you first start using TypeScript is its concise constructor feature, although you will quickly come to rely on it. The TodoItem class defines a constructor that receives two parameters, named task and complete. The values of these parameters are assigned to public properties of the same names. If no value is provided for the complete parameter, then a default value of false will be used:

```
...
constructor(public task: string, public complete: boolean = false) {
...
```

The concise constructor avoids a block of boilerplate code that would otherwise be required to define properties and assign them values that are received by the constructor.

The concise constructor syntax is helpful, but the headline TypeScript feature is static types. Both of the constructor parameters in Listing 2-7 are annotated with a data type:

```
...
constructor(public task: string, public complete: boolean = false) {
...
```

In standard JavaScript, values have types and can be assigned to any variable, which is a source of confusion to programmers who are used to variables that are defined to hold a specific data type. TypeScript adopts a more conventional approach to data types, and the TypeScript compiler will report an error if incompatible types are used. This may seem obvious if you are coming to Angular development from C# or Java, but it isn't the way that JavaScript usually works.

Creating the To-Do List Class

To create a class that represents a list of to-do items, add a file named todoList.ts to the src/app folder with the contents shown in Listing 2-8.

Listing 2-8. The Contents of the todoList.ts File in the src/app Folder

```
import { TodoItem } from "./todoItem";

export class TodoList {

    constructor(public user: string, private todoItems: TodoItem[] = []) {
        // no statements required
    }

    get items(): readonly TodoItem[]  {
        return this.todoItems;
    }

    addItem(task: string) {
        this.todoItems.push(new TodoItem(task));
    }
}
```

The import keyword declares a dependency on the TodoItem class. The TodoList class defines a constructor that receives the initial set of to-do items. I don't want to give unrestricted access to the array of TodoItem objects, so I have defined a property named items that returns a read-only array, which is done using the readonly keyword. The TypeScript compiler will generate an error for any statement that attempts to modify the contents of the array, and if you are using an editor that has good TypeScript support, such as Visual Studio Code, then the autocomplete features of the editor won't present methods and properties that would trigger a compiler error.

Displaying Data to the User

I need a way to display the data values in the model to the user. In Angular, this is done using a *template*, which is a fragment of HTML that contains expressions that are evaluated by Angular and that inserts the results into the content that is sent to the browser.

When the project was created, the ng new command added a template file named app.component.html to the src/app folder. Open this file for editing and replace the contents with those shown in Listing 2-9.

Listing 2-9. Replacing the Contents of the app.component.html File in the src/app Folder

```
<h3>
  {{ username }}'s To Do List
  <h6>{{ itemCount }} Items</h6>
</h3>
```

I'll add features to the template shortly, but this is enough to get started. Displaying data in a template is done using double braces—{{ and }}—and Angular evaluates whatever you put between the double braces to get the value to display.

The {{ and }} characters are an example of a *data binding*, which means they create a relationship between the template and a data value. Data bindings are an important Angular feature, and you will see more of them in this chapter as I add features to the example application (and I describe them in detail in Part 2 of this book). In this case, the data bindings tell Angular to get the value of the username and itemCount properties and insert them into the content of the h3 and div elements.

As soon as you save the file, the Angular development tools will try to build the project. The compiler will generate the following errors:

```
Error: src/app/app.component.html:2:6 - error TS2339: Property 'username' does not exist
on type 'AppComponent'.
2    {{ username }}'s To Do List
        ~~~~~~~~

  src/app/app.component.ts:5:16
    5    templateUrl: './app.component.html',
                      ~~~~~~~~~~~~~~~~~~~~~~~

    Error occurs in the template of component AppComponent.
Error: src/app/app.component.html:3:10 - error TS2339: Property 'itemCount' does not exist
on type 'AppComponent'.
3    <h6>{{ itemCount }} Items</h6>
             ~~~~~~~~~

  src/app/app.component.ts:5:16
    5    templateUrl: './app.component.html',
                      ~~~~~~~~~~~~~~~~~~~~~~~

    Error occurs in the template of component AppComponent.
```

These errors occur because the expressions within the data bindings rely on properties that don't exist. I'll fix this problem in the next section, but these errors show an important Angular characteristic, which is that templates are included in the compilation process and that any errors in the template are handled just like errors in regular code files.

Updating the Component

An Angular *component* is responsible for managing a template and providing it with the data and logic it needs. If that seems like a broad statement, it is because components are the part of an Angular application that does most of the heavy lifting. As a consequence, they can be used for all sorts of tasks.

In this case, I need a component to act as a bridge between the data model classes and the template so that I can create an instance of the TodoList class, populate it with some sample TodoItem objects, and, in doing so, provide the template with the username and itemCount properties it needs.

When the project was created, the ng new command added a file named app.component.ts to the src/app folder. As the name of the file suggests, this is a component. Apply the changes shown in Listing 2-10 to the app.component.ts file.

Listing 2-10. Editing the Contents of the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';
import { TodoList } from "./todoList";
import { TodoItem } from "./todoItem";
```

```
@Component({
    selector: 'app-root',
    templateUrl: './app.component.html',
    styleUrls: ['./app.component.css']
})
export class AppComponent {
    private list = new TodoList("Bob", [
        new TodoItem("Go for run", true),
        new TodoItem("Get flowers"),
        new TodoItem("Collect tickets"),
    ]);

    get username(): string {
        return this.list.user;
    }

    get itemCount(): number {
        return this.list.items
            .filter(item => !item.complete).length;
    }
}
```

The code in the listing can be broken into three main regions, as described in the following sections.

Understanding the Imports

The import keyword declares dependencies on JavaScript modules, both within the project and in third-party packages. The import keyword is used three times in Listing 2-10:

```
...
import { Component } from '@angular/core';
import { TodoList } from "./todoList";
import { TodoItem } from "./todoItem";
...
```

The first import statement is used in the listing to load the @angular/core module, which contains the key Angular functionality, including support for components. When working with modules, the import statement specifies the types that are imported between curly braces. In this case, the import statement is used to load the Component type from the module. The @angular/core module contains many classes that have been packaged together so that the browser can load them all in a single JavaScript file.

The other import statements are used to declare dependencies on the data model classes defined earlier. The target for this kind of import starts with ./, which indicates that the module is defined relative to the current file.

Notice that the import statements do not include file extensions. This is because the relationship between the target of an import statement and the file that is loaded by the browser is handled by the Angular build tools, which I explain in more detail in Chapter 9.

Understanding the Decorator

The oddest-looking part of the code in the listing is this:

```
...
@Component({
  selector: 'app-root',
  templateUrl: './app.component.html',
  styleUrls: ['./app.component.css']
})
...
```

This is an example of a *decorator*, which provides metadata about a class. This is the @Component decorator, and, as its name suggests, it tells Angular that this is a component. The decorator provides configuration information through its properties. This @Component decorator specifies three properties: selector, templateUrl, and styleUrls.

The selector property specifies a CSS selector that matches the HTML element to which the component will be applied.

When you request http://localhost:4200, the browser receives the contents of the index.html file, which was added to the src folder when the project was created. This file contains a custom HTML element, like this:

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Todo</title>
  <base href="/">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <link rel="icon" type="image/x-icon" href="favicon.ico">
</head>
<body>
  <app-root></app-root>
</body>
</html>
```

The Angular development tools automatically add script elements to this HTML, which instruct the browser to request the JavaScript files that provide the Angular framework and the custom features defined in the project.

When the Angular code is executed, the value of the selector property defined by the component is used to locate the specified element in the HTML document, and it is this element into which the content generated by the application is introduced. I am skipping over some details for brevity in this chapter, but I return to this topic in more detail in later chapters. For now, it is enough to understand that the value of the component decorator's selector property corresponds to the element in the HTML document.

The templateUrl property is to specify the component's template, which is the app.component.html file for this component and is the file edited in Listing 2-9.

The styleUrls property specifies one or more CSS stylesheets that are used to style the elements produced by the component and its template. The setting in this component specifies a file named app.component.css, which I use later in the chapter to create CSS styles.

Understanding the Class

The final part of the listing defines a class that Angular can instantiate to create the component.

```
...
export class AppComponent {
  private list = new TodoList("Bob", [
    new TodoItem("Go for run", true),
    new TodoItem("Get flowers"),
    new TodoItem("Collect tickets"),
  ]);

  get username(): string {
    return this.list.user;
  }

  get itemCount(): number {
    return this.list.items.filter(item => !item.complete).length;
  }
}
...
```

These statements define a class called AppComponent that has a private list property, which is assigned a TodoList object and is populated with an array of TodoItem objects. The AppComponent class defines read-only properties named username and itemCount that rely on the TodoList object to produce their values. The username property returns the value of the TodoList.user property, and the itemCount property uses the standard JavaScript array features to filter the Todoitem objects managed by the TodoList to select those that are incomplete and returns the number of matching objects it finds.

The value for the itemCount property is produced using a *lambda function*, also known as a *fat arrow function*, which is a more concise way of expressing a standard JavaScript function. The arrow in the lambda expressions is read as "goes to" such as "item goes to not item.complete."

When you save the changes to the TypeScript file, the Angular development tools will build the project. There should be no errors this time because the component has defined the properties that the template requires. The browser window will be automatically reloaded, showing the output in Figure 2-4.

Figure 2-4. *Generating content in the example application*

Styling the Application Content

To style the HTML content produced by the application, I am going to use the Angular Material package, which contains a set of components for use in Angular applications. Angular Material is as close as you can get to an "official" component library, and it has the advantage of being free to use, full of useful features, and well-integrated into the rest of the Angular framework.

■ **Note** Angular Material isn't the only component package available, and as you will see in later chapters, you don't need to use third-party components at all if that is your preference.

Use Control+C to stop the Angular development tools, and use the command prompt to run the command shown in Listing 2-11 in the todo folder.

Listing 2-11. Adding the Angular Material Package

```
ng add @angular/material@13.0.2 --defaults
```

When prompted, press Y to install the package. Once the package has been installed, open the app.module.ts file in the src folder and make the changes shown in Listing 2-12. These changes declare dependencies on the Angular Material features that are used in this chapter. Confusingly, this file is also called a *module*, which means that there are two types of modules in an Angular project: JavaScript modules and Angular modules. This is an example of an Angular module, which is described in more detail in Chapter 9. For this chapter, it is enough to know that this is how features from the Angular Material package are included in the example project.

Listing 2-12. Adding Dependencies in the app.module.ts File in the src Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { FormsModule } from '@angular/forms'
import { MatButtonModule } from '@angular/material/button';
import { MatToolbarModule } from '@angular/material/toolbar';
import { MatIconModule } from '@angular/material/icon';
import { MatBadgeModule } from '@angular/material/badge';
import { MatTableModule  } from '@angular/material/table';
import { MatCheckboxModule  } from '@angular/material/checkbox';
import { MatFormFieldModule    } from '@angular/material/form-field';
import { MatInputModule    } from '@angular/material/input';
import { MatSlideToggleModule } from '@angular/material/slide-toggle';

@NgModule({
  declarations: [
    AppComponent
  ],
```

```
  imports: [
    BrowserModule,
    BrowserAnimationsModule,
    FormsModule,
    MatButtonModule, MatToolbarModule, MatIconModule, MatBadgeModule,
    MatTableModule, MatCheckboxModule, MatFormFieldModule, MatInputModule,
    MatSlideToggleModule
  ],
  providers: [],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

Each feature used by the application increases the amount of JavaScript code that must be downloaded by the browser, which is why features are enabled individually. You must pay close attention to the changes shown in Listing 2-12 because errors will prevent the example application from working as expected. If you encounter issues, then compare your file with the one included in the GitHub repository for this book, which can be found at https://github.com/Apress/pro-angular-5ed.

Applying Angular Material Components

The next step is to use components contained in the Angular Material package to style the content produced by the application. Components are applied using HTML elements and attributes in the template file, as shown in Listing 2-13.

Listing 2-13. Applying Components in the app.components.html File in the src/app Folder

```
<mat-toolbar color="primary" class="mat-elevation-z3">
    <span>{{ username }}'s To Do List</span>
    <mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
</mat-toolbar>
```

The new template content relies on features from the Angular Material package, each of which is applied differently. The first feature is the toolbar, which is applied using the mat-toolbar element, with the contents of the toolbar contained within the opening and closing tag:

```
...
<mat-toolbar color="primary" class="mat-elevation-z3">
...
</mat-toolbar>
...
```

The color attribute is used to specify the color for the toolbar. The Angular Material package uses color themes, and the primary value used to configure the toolbar represents the predominant color of the theme.

The class that the mat-toolbar element has been assigned applies a style provided by the Angular Material package for creating a raised appearance for content:

```
...
<mat-toolbar color="primary" class="mat-elevation-z3">
...
```

25

The other features are an icon and a badge, which are used together to indicate how many incomplete items are in the user's to-do list. The icon is applied using the `mat-icon` element:

```
...
<mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
...
```

Icons are selected by specifying a name as the content of the `mat-icon` element. In this case, the `checklist` icon has been selected:

```
...
<mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
...
```

You can see the complete set of icons that are available by visiting https://fonts.google.com/icons ?selected=Material+Icons. Icons are distributed using font files, and the command used to add Angular Material to the project in Listing 2-13 adds the links required for these files to the `index.html` file in the `src` folder.

The badge is applied as an option to the `mat-icon` element using the `matBadge` and `matBadgeColor` attributes:

```
...
<mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
...
```

Badges are small circular status indicators, used to present the user with a number or characters, which makes them ideal for indicating how many to-do items there are. The value of the `matBadge` attribute sets the content of the badge, and the `matBadgeColor` attribute is used to set the color, which is `accent` in this case, denoting the theme color that is used for highlighting.

Save the changes to the template file and use the `ng serve` command to start the Angular development tools. Once the tool startup sequence is complete, use a browser to request `http://localhost:4200`, and you will see the content shown in Figure 2-5.

Figure 2-5. *Introducing Angular Material components*

I improve the layout in the next section, but the addition of the Angular Material components is already an improvement over the raw HTML content. Notice that the template in Listing 2-13 still contains the same data bindings introduced earlier in the chapter, and they still work in the same way, providing access to the data provided by the component.

Defining the Spacer CSS Style

The Angular Material package is generally comprehensive, but one omission is spacers to help position content. I want to position the span element that contains the user's name centrally within the title bar and have the icon and badge appear on the right. The first step is to create a CSS class that will configure HTML elements to grow to fill available space. As noted earlier, the decorator in the app.component.ts file contains a styleUrls property, which is used to select CSS files that are applied to the component's template. Add the style shown in Listing 2-14 to the app.component.css file, which is the file specified by default when the project is created.

Listing 2-14. Adding a CSS Style in the app.component.css File in the src/app Folder

```
.spacer { flex: 1 1 auto }
```

The addition in Listing 2-14 applies a style to any element assigned to a class named spacer. The style sets the flex property, which is part of the CSS *flexible box* feature, also known as *flexbox*. Flexbox is used to lay out HTML elements so they adapt to the space that is available and can respond to changes, such as when a browser window is resized or a device screen is rotated. The setting in Listing 2-14 configures an element to grow to fill any available space, and if there are multiple HTML elements in the same container assigned to the spacer class, then the available space will be allocated evenly between them. Add the elements shown in Listing 2-15 to the template file to introduce spacers into the layout.

Listing 2-15. Adding Elements in the app.component.html File in the src/app Folder

```
<mat-toolbar color="primary" class="mat-elevation-z3">
    <span class="spacer"></span>
    <span>{{ username }}'s To Do List</span>
    <span class="spacer"></span>
    <mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
</mat-toolbar>
```

When you save the file, the Angular development tools will detect the changes, recompile the project, and trigger a browser reload, producing the new layout shown in Figure 2-6.

Figure 2-6. *Adding spacers to the component layout*

Displaying the List of To-Do Items

The next step is to display the to-do items. Listing 2-16 adds a property to the component that provides access to the items in the list.

Listing 2-16. Adding a Property in the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';
import { TodoList } from "./todoList";
import { TodoItem } from "./todoItem";

@Component({
    selector: 'app-root',
    templateUrl: './app.component.html',
    styleUrls: ['./app.component.css']
})
export class AppComponent {
    private list = new TodoList("Bob", [
        new TodoItem("Go for run", true),
        new TodoItem("Get flowers"),
        new TodoItem("Collect tickets"),
    ]);

    get username(): string {
        return this.list.user;
    }

    get itemCount(): number {
        return this.list.items.filter(item => !item.complete).length;
    }

    get items(): readonly TodoItem[] {
      return this.list.items;
    }
}
```

To display details of each item to the user, I am going to use the Angular Material table component, as shown in Listing 2-17, which makes it easy to present the user with tabular data. (I explain how you can create your own equivalent to the table component in Part 2, using the same Angular features as the Angular Material package.)

Listing 2-17. Adding a Table in the app.component.html File in the src/app Folder

```
<mat-toolbar color="primary" class="mat-elevation-z3">
    <span class="spacer"></span>
    <span>{{ username }}'s To Do List</span>
    <span class="spacer"></span>
    <mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
</mat-toolbar>

<div class="tableContainer">
    <table mat-table [dataSource]="items" class="mat-elevation-z3 fullWidth">
```

```
    <ng-container matColumnDef="id">
        <th mat-header-cell *matHeaderCellDef>#</th>
        <td mat-cell *matCellDef="let i = index"> {{ i + 1 }} </td>
    </ng-container>

    <ng-container matColumnDef="task">
        <th mat-header-cell *matHeaderCellDef>Task</th>
        <td mat-cell *matCellDef="let item"> {{ item.task }} </td>
    </ng-container>

    <ng-container matColumnDef="done">
        <th mat-header-cell *matHeaderCellDef>Done</th>
        <td mat-cell *matCellDef="let item"> {{ item.complete }} </td>
    </ng-container>

    <tr mat-header-row *matHeaderRowDef="['id', 'task', 'done']"></tr>
    <tr mat-row *matRowDef="let row; columns: ['id', 'task', 'done'];"></tr>
  </table>
</div>
```

The Angular Material table component is applied by adding the mat-table attribute to a standard HTML table element, and the data the table will contain is specified using the dataSource attribute:

```
...
<table mat-table [dataSource]="items" class="mat-elevation-z3 fullWidth">
...
```

The square brackets (the [and] characters) denote an attribute binding, which is a data binding that is used to set an element attribute, providing the Angular Material table component with the data that it will display. Angular defines a range of data bindings for use in different situations, and these are all described in detail in Part 2. This binding configures the table to display the values returned by the items property defined in Listing 2-16.

The table component is configured by defining the columns that will be displayed to the user. The ng-container element is used to group content together, and, in this case, it is used to group the elements that define a header and a content cell for a column, like this:

```
...
<ng-container matColumnDef="task">
    <th mat-header-cell *matHeaderCellDef>Task</th>
    <td mat-cell *matCellDef="let item"> {{ item.task }} </td>
</ng-container>
...
```

This arrangement of elements defines the header and content table cells for a column named task. The header cell is defined using a th element to which the mat-header-cell and *matHeaderCellDef attributes have been applied:

```
...
<th mat-header-cell *matHeaderCellDef>Task</th>
...
```

The effect of the mat-header-cell attribute is to configure the appearance of the header cell so that it matches the rest of the table. The effect of the *matHeaderCellDef attribute is to configure the behavior of the cell.

■ **Note**   When you start working with Angular, the template syntax can feel arcane and impenetrable, with endless combinations of curly braces, square braces, and asterisks. All of these features are described in later chapters, but for now, make sure you don't omit the asterisks from the attributes when they are shown in the listings.

The content cell is defined using a td element to which the mat-cell and *matCellDef attributes are applied. The *matCellDef attribute is used to select the content that will be displayed in each table cell:

```
...
<td mat-cell *matCellDef="let item"> {{ item.task }} </td>
...
```

I explain how this feature works in detail in Part 2, but for the moment, it is enough to know that the expression assigned to the *matCellDef attribute will be evaluated for each element in the data source, which will be assigned to a variable named item, and this variable is used in a data binding to populate the table cell. In this case, the value of the task property will be displayed in the table cell.

The Angular Material table component provides additional context data as it creates table rows, including the index of the data item for which the current row is being created and which can be accessed like this:

```
...
<td mat-cell *matCellDef="let i = index"> {{ i + 1 }} </td>
...
```

The expression used for this table cell assigns the index value provided by the table component to a variable named i, which is used in the data binding to produce a simple counter.

The columns for the table header and body are selected by applying attributes to tr elements, like this:

```
...
<tr mat-header-row *matHeaderRowDef="['id', 'task', 'done']"></tr>
<tr mat-row *matRowDef="let row; columns: ['id', 'task', 'done'];"></tr>
...
```

These elements select the id, task, and done rows defined in Listing 2-17. It may seem odd that the columns are not applied automatically, but this approach is useful when you want to select different columns based on user input.

Defining Additional Styles

The final step of setting up the table is to define additional CSS styles, as shown in Listing 2-18.

Listing 2-18. Defining Styles in the app.component.css File in the src/app Folder

```
.spacer { flex: 1 1 auto }
.tableContainer { padding: 15px }
.fullWidth { width: 100% }
```

The first new style selects any element that has been assigned to the `tableContainer` class and applies padding around it. There is a `div` element in Listing 2-18 that I added to this class and that contains the `table` element. The second new style sets elements assigned to the `fullwidth` class to occupy 100 percent of the width available to them.

Save the changes, and the Angular development tools will compile the project and reload the browser, producing the content shown in Figure 2-7.

Figure 2-7. *Displaying the list of to-do items*

Creating a Two-Way Data Binding

At the moment, the template contains only *one-way data bindings*, which means they are used to display a data value but are unable to change it. Angular also supports *two-way data bindings*, which can be used to display a data value and change it, too. Two-way bindings are used with HTML form elements, and Listing 2-19 adds an Angular Material checkbox to the template that allows users to mark a to-do item as complete.

31

Listing 2-19. Adding a Checkbox in the app.component.html File in the src/app Folder

```
<mat-toolbar color="primary" class="mat-elevation-z3">
    <span class="spacer"></span>
    <span>{{ username }}'s To Do List</span>
    <span class="spacer"></span>
    <mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
</mat-toolbar>

<div class="tableContainer">
    <table mat-table [dataSource]="items" class="mat-elevation-z3 fullWidth">

        <ng-container matColumnDef="id">
            <th mat-header-cell *matHeaderCellDef>#</th>
            <td mat-cell *matCellDef="let i = index"> {{ i + 1 }} </td>
        </ng-container>

        <ng-container matColumnDef="task">
            <th mat-header-cell *matHeaderCellDef>Task</th>
            <td mat-cell *matCellDef="let item"> {{ item.task }} </td>
        </ng-container>

        <ng-container matColumnDef="done">
            <th mat-header-cell *matHeaderCellDef>Done</th>
            <td mat-cell *matCellDef="let item">
                <mat-checkbox [(ngModel)]="item.complete" color="primary">
                    {{ item.complete }}
                </mat-checkbox>
            </td>
        </ng-container>

        <tr mat-header-row *matHeaderRowDef="['id', 'task', 'done']"></tr>
        <tr mat-row *matRowDef="let row; columns: ['id', 'task', 'done'];"></tr>
    </table>
</div>
```

The mat-checkbox element applies the Angular Material checkbox component. The two-way binding is expressed using a special attribute:

```
...
<mat-checkbox [(ngModel)]="item.complete" color="primary">
...
```

The combination of brackets is known as the *banana-in-a-box* because the round brackets look like a banana contained in a box made by the square brackets. These brackets denote a two-way data binding, and ngModel is an Angular feature and is used to set up two-way bindings on form elements, such as checkboxes.

Save the changes to the file, and the Angular development tools will recompile the project and reload the browser to display the content shown in Figure 2-8. The effect is that the complete property of each to-do item is used to set a checkbox when it is displayed to the user. The appropriate complete property will also be updated when the user toggles the checkbox.

Figure 2-8. *Using two-way bindings*

I left the `true`/`false` values in the output to demonstrate an important aspect of how Angular deals with changes. Each time you toggle a checkbox, the corresponding text value changes and so does the counter displayed by the badge, as shown in Figure 2-9.

Figure 2-9. *Toggling a checkbox*

This behavior reveals an important Angular feature: the data model is *live*. This means data bindings— even one-way data bindings—are updated when the data model is changed. This simplifies web application development because it means you don't have to worry about ensuring that you display updates when the application state changes.

It can be easy to forget that underneath the templates and components and the live data model, Angular is using the browser's JavaScript API to create and display regular HTML elements. Right-click one of the checkboxes in the browser window and select Inspect or Inspect Element from the pop-up menu (the exact menu item will depend on your chosen browser). The browser's developer tools will open, and you can explore the HTML content displayed by the browser. You may have to dig around a little by expanding elements to see their contents, but you will see that the effect of applying an Angular Material checkbox in the template is a regular HTML checkbox, like this:

```
...
<input type="checkbox" class="mat-checkbox-input cdk-visually-hidden"
    id="mat-checkbox-1-input" tabindex="0" aria-checked="false">
...
```

If you find yourself confused by the way an Angular application behaves, then a good place to start is to examine the elements displayed by the browser, which reveals the effects created by your templates and components. There are other diagnostic tools available, as I explain in Chapter 9, but this is a simple and effective way to understand what an application is doing.

Filtering Completed To-Do Items

The checkboxes allow the data model to be updated, and the next step is to remove to-do items once they have been marked as done. Listing 2-20 changes the component's items property so that it filters out any items that have been completed.

Listing 2-20. Filtering To-Do Items in the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';
import { TodoList } from "./todoList";
import { TodoItem } from "./todoItem";

@Component({
    selector: 'app-root',
    templateUrl: './app.component.html',
    styleUrls: ['./app.component.css']
})
export class AppComponent {
    private list = new TodoList("Bob", [
        new TodoItem("Go for run", true),
        new TodoItem("Get flowers"),
        new TodoItem("Collect tickets"),
    ]);

    get username(): string {
        return this.list.user;
    }

    get itemCount(): number {
        return this.list.items.filter(item => !item.complete).length;
    }
```

```
    get items(): readonly TodoItem[] {
        return this.list.items.filter(item => !item.complete);
    }
}
```

The `filter` method is a standard JavaScript array feature. This is the same expression I used previously in the `itemCount` property. I could rework this property to avoid duplication, but I will add support for choosing whether completed tasks should be shown later in the chapter, which will require the `items` and `itemCount` properties to process the list of to-do items differently.

Since the data model is live and changes are reflected in data bindings immediately, checking the checkbox for an item removes it from view, as shown in Figure 2-10.

Figure 2-10. *Filtering the to-do items*

Adding To-Do Items

A to-do application isn't much use without the ability to add new items to the list. Listing 2-21 uses Angular Material components to present the user with an input element, into which a task description can be entered, and with a button that will use the description to create a new to-do item.

Listing 2-21. Adding Elements in the app.component.html File in the src/app Folder

```
<mat-toolbar color="primary" class="mat-elevation-z3">
    <span class="spacer"></span>
    <span>{{ username }}'s To Do List</span>
    <span class="spacer"></span>
    <mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
</mat-toolbar>

<div class="inputContainer">
    <mat-form-field class="fullWidth">
        <mat-label style="padding-left: 5px;">New To Do</mat-label>
        <input matInput placeholder="Enter to-do description" #todoText>
        <button matSuffix mat-raised-button color="accent" class="addButton"
            (click)="addItem(todoText.value); todoText.value = ''">
```

```
            Add
        </button>
    </mat-form-field>
</div>

<div class="tableContainer">
    <table mat-table [dataSource]="items" class="mat-elevation-z3 fullWidth">

        <ng-container matColumnDef="id">
            <th mat-header-cell *matHeaderCellDef>#</th>
            <td mat-cell *matCellDef="let i = index"> {{ i + 1 }} </td>
        </ng-container>

        <ng-container matColumnDef="task">
            <th mat-header-cell *matHeaderCellDef>Task</th>
            <td mat-cell *matCellDef="let item"> {{ item.task }} </td>
        </ng-container>

        <ng-container matColumnDef="done">
            <th mat-header-cell *matHeaderCellDef>Done</th>
            <td mat-cell *matCellDef="let item">
                <mat-checkbox [(ngModel)]="item.complete" color="primary">
                    {{ item.complete }}
                </mat-checkbox>
            </td>
        </ng-container>

        <tr mat-header-row *matHeaderRowDef="['id', 'task', 'done']"></tr>
        <tr mat-row *matRowDef="let row; columns: ['id', 'task', 'done'];"></tr>
    </table>
</div>
```

The new elements display an input element and a button element. The mat-form-field element and the mat* attributes on the other elements configure the Angular Material styling.

The input element has an attribute whose name starts with the # character, which is used to define a variable to refer to the element in the template's data bindings:

```
...
<input matInput placeholder="Enter to-do description" #todoText>
...
```

The name of the variable is todoText, and it is used by the binding that has been applied to the button element.

```
...
<button matSuffix mat-raised-button color="accent" class="addButton"
    (click)="addItem(todoText.value); todoText.value = ''">
...
```

This is an example of an *event binding*, and it tells Angular to invoke a component method called addItem, using the value property of the input element as the method argument, and then to clear the input element by setting its value property to the empty string.

Custom CSS styles are required to manage the layout of the new elements, as shown in Listing 2-22.

Listing 2-22. Defining Styles in the app.component.css File in the src/app Folder

```
.spacer { flex: 1 1 auto }
.tableContainer { padding: 15px  }
.fullWidth { width: 100% }
.inputContainer { margin: 15px 15px 5px }
.addButton { margin: 5px }
```

Listing 2-23 adds the method called by the event binding to the component.

■ **Tip** Don't worry about telling the bindings apart for now. I explain the different types of binding that Angular supports in Part 2 and the meaning of the different types of brackets or parentheses that each requires. They are not as complicated as they first appear, especially once you have seen how they fit into the rest of the Angular framework.

Listing 2-23. Adding a Method in the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';
import { TodoList } from "./todoList";
import { TodoItem } from "./todoItem";

@Component({
    selector: 'app-root',
    templateUrl: './app.component.html',
    styleUrls: ['./app.component.css']
})
export class AppComponent {
    private list = new TodoList("Bob", [
        new TodoItem("Go for run", true),
        new TodoItem("Get flowers"),
        new TodoItem("Collect tickets"),
    ]);

    get username(): string {
        return this.list.user;
    }

    get itemCount(): number {
        return this.list.items.filter(item => !item.complete).length;
    }

    get items(): readonly TodoItem[] {
        return this.list.items.filter(item => !item.complete);
    }
```

```
    addItem(newItem: string) {
        if (newItem != "") {
            this.list.addItem(newItem);
        }
    }
}
```

The addItem method receives the text sent by the event binding in the template and uses it to add a new item to the to-do list. The result of these changes is that you can create new to-do items by entering text in the input element and clicking the Add button, as shown in Figure 2-11.

Figure 2-11. *Creating a to-do item*

Finishing Up

The basic features are in place, and now it is time to wrap up the project. In Listing 2-24, I removed the true/false text from the Done column in the table from the template and added an option to show completed tasks.

Listing 2-24. Modifying the Template in the app.component.html File in the src/app Folder

```
<mat-toolbar color="primary" class="mat-elevation-z3">
    <span class="spacer"></span>
    <span>{{ username }}'s To Do List</span>
    <span class="spacer"></span>
    <mat-icon matBadge="{{ itemCount }}" matBadgeColor="accent">checklist</mat-icon>
</mat-toolbar>

<div class="inputContainer">
    <mat-form-field class="fullWidth">
        <mat-label style="padding-left: 5px;">New To Do</mat-label>
        <input matInput placeholder="Enter to-do description" #todoText>
```

```
        <button matSuffix mat-raised-button color="accent" class="addButton"
            (click)="addItem(todoText.value); todoText.value = ''">
            Add
        </button>
    </mat-form-field>
</div>

<div class="tableContainer">
    <table mat-table [dataSource]="items" class="mat-elevation-z3 fullWidth">

        <ng-container matColumnDef="id">
            <th mat-header-cell *matHeaderCellDef>#</th>
            <td mat-cell *matCellDef="let i = index"> {{ i + 1 }} </td>
        </ng-container>

        <ng-container matColumnDef="task">
            <th mat-header-cell *matHeaderCellDef>Task</th>
            <td mat-cell *matCellDef="let item"> {{ item.task }} </td>
        </ng-container>

        <ng-container matColumnDef="done">
            <th mat-header-cell *matHeaderCellDef>Done</th>
            <td mat-cell *matCellDef="let item">
                <mat-checkbox [(ngModel)]="item.complete" color="primary">
                    <!-- {{ item.complete }} -->
                </mat-checkbox>
            </td>
        </ng-container>

        <tr mat-header-row *matHeaderRowDef="['id', 'task', 'done']"></tr>
        <tr mat-row *matRowDef="let row; columns: ['id', 'task', 'done'];"></tr>
    </table>
</div>

<div class="toggleContainer">
    <span class="spacer"></span>
    <mat-slide-toggle [(ngModel)]="showComplete">
        Show Completed Items
    </mat-slide-toggle>
    <span class="spacer"></span>
</div>
```

The new elements present a toggle switch that has a two-way data binding for a property named showComplete. Listing 2-25 adds the definition for the showComplete property to the component and uses its value to determine whether completed tasks are displayed to the user.

Listing 2-25. Showing Completed Tasks in the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';
import { TodoList } from "./todoList";
import { TodoItem } from "./todoItem";

@Component({
  selector: 'app-root',
  templateUrl: './app.component.html',
  styleUrls: ['./app.component.css']
})
export class AppComponent {
  private list = new TodoList("Bob", [
    new TodoItem("Go for run", true),
    new TodoItem("Get flowers"),
    new TodoItem("Collect tickets"),
  ]);

  get username(): string {
    return this.list.user;
  }

  get itemCount(): number {
    return this.list.items.filter(item => !item.complete).length;
  }

  get items(): readonly TodoItem[] {
    return this.list.items.filter(item => this.showComplete || !item.complete);
  }

  addItem(newItem: string) {
    if (newItem != "") {
        this.list.addItem(newItem);
    }
  }

  showComplete: boolean = false;
}
```

Additional CSS styles are required to lay out the toggle switch, as shown in Listing 2-26.

Listing 2-26. Adding Styles in the app.component.css File in the src/app Folder

```
.spacer { flex: 1 1 auto }
.tableContainer { padding: 15px  }
.fullWidth { width: 100% }
.inputContainer { margin: 15px 15px 5px }
.addButton { margin: 5px }
.toggleContainer { margin: 15px; display: flex }
```

The result is that the user can decide whether to see completed tasks, as shown in Figure 2-12.

Figure 2-12. *Showing completed tasks*

Summary

In this chapter, I showed you how to create your first simple Angular app, which lets the user create new to-do items and mark existing items as complete. Don't worry if not everything in this chapter makes sense. What's important to understand at this stage is the general shape of an Angular application, which is built around a data model, components, and templates. If you keep these three key building blocks in mind and remember that the result is standard HTML elements, then you will have a solid foundation for everything that follows. In the next chapter, I put Angular in context and describe the structure of this book.

CHAPTER 3

■ ■ ■

Primer, Part 1

Developers come to the world of web app development via many paths and are not always grounded in the basic technologies that web apps rely on. In this chapter, I provide a brief overview of HTML, introduce the basics of JavaScript and TypeScript, and give you the foundation you need to understand the examples in the rest of the book, continuing with more advanced features in Chapter 4. If you are already familiar with HTML and TypeScript, you can jump right to Chapter 5, where I use Angular to create a more complex and realistic application.

Preparing the Example Project

To create the example project for this chapter, open a new command prompt, navigate to a convenient location, and run the command shown in Listing 3-1.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 3-1. Creating the Example Project

```
ng new Primer --routing false --style css --skip-git --skip-tests
```

This command creates a project called Primer that is set up for Angular development. I don't do any Angular development in this chapter, but I am going to use the Angular development tools as a convenient way to demonstrate different HTML, JavaScript, and TypeScript features.

Next, run the command shown in Listing 3-2 in the Primer folder to add the Bootstrap CSS package to the project. This is the package that I use to manage the appearance of content throughout this book.

Listing 3-2. Installing the Bootstrap CSS Package

```
npm install bootstrap@5.1.3
```

Run the command shown in Listing 3-3 to integrate Bootstrap into the application, taking care to enter the command as it is shown, without any extra spaces or quotes.

Listing 3-3. Changing the Application Configuration

```
ng config projects.example.architect.build.options.styles `
'[""src/styles.css"",
""node_modules/bootstrap/dist/css/bootstrap.min.css""]'
```

If you are using Windows, then use a PowerShell prompt to run the command shown in Listing 3-4 in the example folder.

Listing 3-4. Changing the Application Configuration Using PowerShell

```
ng config projects.Primer.architect.build.options.styles `
'[""src/styles.css"",
""node_modules/bootstrap/dist/css/bootstrap.min.css""]'
```

Run the command shown in Listing 3-5 in the Primer folder to start the Angular development compiler and HTTP server.

Listing 3-5. Starting the Development Tools

```
ng serve --open
```

After an initial build process, the Angular tools will open a browser window, which displays placeholder content added to the project when it was created, as shown in Figure 3-1.

Figure 3-1. *Running the example application*

Understanding HTML

Use your code editor to open the Primer folder and replace the contents of index.html in the src folder with the content shown in Listing 3-6.

Listing 3-6. Replacing the Contents of the index.html File in the src Folder

```
<!DOCTYPE html>
<html>
<head>
    <title>ToDo</title>
    <meta charset="utf-8" />
</head>
<body class="m-1">
    <h3 class="bg-primary text-white p-3">Adam's To Do List</h3>
    <div class="my-1">
        <input class="form-control" />
        <button class="btn btn-primary mt-1">Add</button>
    </div>
    <table class="table table-striped table-bordered">
        <thead>
            <tr>
                <th>Description</th>
                <th>Done</th>
            </tr>
        </thead>
        <tbody>
            <tr><td>Buy Flowers</td><td>No</td></tr>
            <tr><td>Get Shoes</td><td>No</td></tr>
            <tr><td>Collect Tickets</td><td>Yes</td></tr>
            <tr><td>Call Joe</td><td>No</td></tr>
        </tbody>
    </table>
</body>
</html>
```

Reload the browser and you will see the content shown in Figure 3-2. You will see some errors in the browser's JavaScript console if you have it open, but these can be ignored and will be resolved later in the chapter.

Figure 3-2. *Understanding HTML*

At the heart of HTML is the *element*, which tells the browser what kind of content each part of an HTML document represents. Here is an element from the example HTML document:

```
...
<td>Buy Flowers</td>
...
```

As illustrated in Figure 3-3, this element has three parts: the start tag, the end tag, and the content.

Figure 3-3. *The anatomy of a simple HTML element*

The *name* of this element (also referred to as the *tag name* or just the *tag*) is td, and it tells the browser that the content between the tags should be treated as a table cell. You start an element by placing the tag name in angle brackets (the < and > characters) and end an element by similarly using the tag, except that you also add a / character after the left-angle bracket (<). Whatever appears between the tags is the element's content, which can be text (such as Buy Flowers in this case) or other HTML elements.

Understanding Void Elements

The HTML specification includes elements that are not permitted to contain content. These are called *void* or *self-closing* elements, and they are written without a separate end tag, like this:

```
...
<input />
...
```

A void element is defined in a single tag, and you add a / character before the last angle bracket (the > character). The input element is the most used void element, and its purpose is to allow the user to provide input, through a text field, radio button, or checkbox. You will see lots of examples of working with this element in later chapters.

Understanding Attributes

You can provide additional information to the browser by adding *attributes* to your elements. Here is an element with an attribute from the example document:

```
...
<meta charset="utf-8" />
...
```

This is a meta element, and it describes the HTML document. There is one attribute, which I have emphasized so it is easier to see. Attributes are always defined as part of the start tag, and these attributes have a *name* and a *value*.

The name of the attribute in this example is charset. For the meta element, the charset attribute specifies the character encoding, which is UTF-8 in this case.

Applying Attributes Without Values

Not all attributes are applied with a value; just adding them to an element tells the browser that you want a certain kind of behavior. Here is an example of an element with such an attribute (not from the example document; I just made up this example element):

```
...
<input class="form-control" required />
...
```

This element has two attributes. The first is class, which is assigned a value just like the previous example. The other attribute is just the word required. This is an example of an attribute that doesn't need a value.

Quoting Literal Values in Attributes

Angular relies on HTML element attributes to apply a lot of its functionality. Most of the time, the values of attributes are evaluated as JavaScript expressions, such as with this element, taken from Chapter 2:

```
...
<td [ngSwitch]="item.complete">
...
```

The attribute applied to the td element tells Angular to read the value of a property called complete on an object that has been assigned to a variable called item. There will be occasions when you need to provide a specific value rather than have Angular read a value from the data model, and this requires additional quoting to tell Angular that it is dealing with a literal value, like this:

```
...
<td [ngSwitch]="'Apples'">
...
```

The attribute value contains the string Apples, which is quoted in both single and double quotes. When Angular evaluates the attribute value, it will see the single quotes and process the value as a literal string.

Understanding Element Content

Elements can contain text, but they can also contain other elements, like this:

```
...
<thead>
    <tr>
        <th>Description</th>
        <th>Done</th>
    </tr>
</thead>
...
```

The elements in an HTML document form a hierarchy. The html element contains the body element, which contains content elements, each of which can contain other elements, and so on. In the listing, the thead element contains tr elements that, in turn, contain th elements. Arranging elements is a key concept in HTML because it imparts the significance of the outer element to those contained within.

Understanding the Document Structure

There are some key elements that define the basic structure of an HTML document: the DOCTYPE, html, head, and body elements. Here is the relationship between these elements with the rest of the content removed:

```
<!DOCTYPE html>
<html>
<head>
    ...head content...
</head>
```

```
<body>
    ...body content...
</body>
</html>
```

Each of these elements has a specific role to play in an HTML document. The DOCTYPE element tells the browser that this is an HTML document and, more specifically, that this is an *HTML5* document. Earlier versions of HTML required additional information. For example, here is the DOCTYPE element for an HTML4 document:

```
...
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.01//EN"
    "http://www.w3.org/TR/html4/strict.dtd">
...
```

The html element denotes the region of the document that contains the HTML content. This element always contains the other two key structural elements: head and body. As I explained at the start of the chapter, I am not going to cover the individual HTML elements. There are too many of them, and describing HTML5 completely took me more than 1,000 pages in my HTML book. That said, Table 3-1 provides brief descriptions of the elements I used in the index.html file in Listing 3-2 to help you understand how elements tell the browser what kind of content they represent.

UNDERSTANDING THE DOCUMENT OBJECT MODEL

When the browser loads and processes an HTML document, it creates the *Document Object Model* (DOM). The DOM is a model in which JavaScript objects are used to represent each element in the document, and the DOM is the mechanism by which you can programmatically engage with the content of an HTML document.

You rarely work directly with the DOM in Angular, but it is important to understand that the browser maintains a live model of the HTML document represented by JavaScript objects. When Angular modifies these objects, the browser updates the content it displays to reflect the modifications. This is one of the key foundations of web applications. If we were not able to modify the DOM, we would not be able to create client-side web apps.

Table 3-1. *HTML Elements Used in the Example Document*

Element	Description
DOCTYPE	Indicates the type of content in the document
body	Denotes the region of the document that contains content elements
button	Denotes a button; often used to submit a form to the server
div	A generic element; often used to add structure to a document for presentation purposes
h3	Denotes a header
head	Denotes the region of the document that contains metadata
html	Denotes the region of the document that contains HTML (which is usually the entire document)
input	Denotes a field used to gather a single data item from the user
link	Imports content into the HTML document
meta	Provides descriptive data about the document, such as the character encoding
table	Denotes a table, used to organize content into rows and columns
tbody	Denotes the body of the table (as opposed to the header or footer)
td	Denotes a content cell in a table row
th	Denotes a header cell in a table row
thead	Denotes the header of a table
title	Denotes the title of the document; used by the browser to set the title of the window or tab
tr	Denotes a row in a table

Understanding CSS and the Bootstrap Framework

HTML elements tell the browser what kind of content they represent, but they don't provide any information about how that content should be displayed. The information about how to display elements is provided using *Cascading Style Sheets* (CSS). CSS consists of *properties* that can be used to configure every aspect of an element's appearance and *selectors* that allow those properties to be applied.

CSS is flexible and powerful, but it requires time and close attention to detail to get good, consistent results, especially as some legacy browsers implement features inconsistently. CSS frameworks provide a set of styles that can be easily applied to produce consistent effects throughout a project.

Throughout this book, I use the Bootstrap CSS framework, which consists of CSS classes that can be applied to elements to style them consistently, and JavaScript code that performs additional enhancements. I use the Bootstrap CSS styles in this book because they let me style my examples without having to define custom styles in each chapter. I don't use the Bootstrap JavaScript features at all in this book since the interactive parts of the examples are provided using Angular.

I don't go into detail about Bootstrap because it isn't the topic of this book, but you will see that many of the HTML elements used in examples throughout this book are assigned to classes like this:

```
...
<h3 class="bg-primary text-white p-3">Adam's To Do List</h3>
...
```

The bg-primary, text-white, and p-3 classes all apply styles defined by the Bootstrap framework, setting the background color, text color, and padding, respectively. Unless noted in the description of an example, you can ignore the classes to which elements are assigned. See https://getbootstrap.com for details of the Bootstrap framework.

Understanding TypeScript/JavaScript

Angular applications are written in TypeScript, which is a superset of JavaScript that adds support for static types. In this section, I describe the relationship between TypeScript and JavaScript and introduce the basic features that you will need to understand to begin Angular development, continuing in Chapter 4. This is not a comprehensive guide to TypeScript or JavaScript, but it addresses the basics, and it will give you the knowledge you need to get started.

Understanding the TypeScript Workflow

Angular projects are set up with the TypeScript compiler, which is used to generate the JavaScript code that will be sent to the browser. There is no Angular development in this chapter, but I am going to take advantage of the TypeScript support to demonstrate important language features. The key file for this process is named main.ts and is found in the src folder. Replace the contents of the main.ts file with the statements shown in Listing 3-7.

Listing 3-7. Replacing the Contents of the main.ts File in the src Folder

```
console.log("Hello");
```

The basic JavaScript building block is the *statement*. Each statement represents a single command, and statements are usually terminated by a semicolon (;). The semicolon is optional, but using them makes your code easier to read and allows for multiple statements on a single line.

When you save the file, the change is detected, and the Angular tools rebuild the project, sending the results to the browser to execute. The statement in Listing 3-7 calls the console.log function, which writes a message to the browser's JavaScript console. Open your browser's F12 developer tools (which is typically done by pressing the F12 key) and select the Console; you will see the output shown in Figure 3-4.

Figure 3-4. *A message in the JavaScript console*

The output from the statement in the `main.ts` file is displayed, along with additional messages generated by the automatic reloading process, which will automatically update the browser when a change is detected. Listing 3-8 adds another statement to the `main.ts` file.

Listing 3-8. Adding a Statement in the main.ts File in the src Folder

```
console.log("Hello");
console.log("Hello, World");
```

When you save the file, the project will be recompiled, and the browser will automatically reload, producing the following output in the JavaScript console:

```
Hello
Hello, World
```

Understanding JavaScript vs. TypeScript

JavaScript has an unusual approach to data types, which means that, for example, any variable can be assigned any value, regardless of type. As a simple demonstration, I am going to work outside of the Angular tools for a moment. Open a new command prompt, navigate to a convenient location, and create a file named `example.js` with the content shown in Listing 3-9. It doesn't matter where you put this file, as long as it isn't in the `Primer` project folder.

Listing 3-9. The Contents of the example.js File

```
function myFunction(param) {
    let result = param + 100;
    console.log("My result: " + result);
}
```

This listing defines a JavaScript function, which receives a value as a parameter, uses the addition operator to add 10 to the value, and then writes out the result to the JavaScript console. Notice that there are no data types specified in this code. The function, which is named myFunction, can receive any data type, as shown in Listing 3-10.

Listing 3-10. Invoking the Function in the example.js File

```javascript
function myFunction(param) {
    let result = param + 100;
    console.log("My result: " + result);
}

myFunction(1);
myFunction("London");
```

The first new statement invokes myFunction with a number, 10. The second new statement invokes myFunction with a string, London. Using the command prompt, execute the JavaScript code by running the command shown in Listing 3-11 in the folder in which you created the example.js file.

Listing 3-11. Executing the JavaScript Code

```
node example.js
```

This command will produce the following output as the JavaScript statements are executed:

```
My result: 101
My result: London100
```

When the function received a number, the addition operator combined one number, 1, with another number, 100, and produced the result 101. But when the function received a string, the addition operator was asked to combine values with two different data types. It produced its result by converting the number 100 into a string and concatenating it with the parameter value to produce the result London100. JavaScript does provide the means to check whether a value is of a specific type, as shown in Listing 3-12.

Listing 3-12. Checking a Type in the example.js File

```javascript
function myFunction(param) {
    if (typeof(param) == "number") {
        let result = param + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number: " + param)
    }
}

myFunction(1);
myFunction("London");
```

The typeof function is used to check that the parameter is a number value, and the throw keyword is used to create an error if it is not, which you can see by running the command in Listing 3-11 again, which produces the following output:

```
My result: 101
C:\javascript.js:6
        throw ("Expected a number: " + param)
        ^
Expected a number: London
(Use `node --trace-uncaught ...` to show where the exception was thrown)
```

The behavior of the function has changed so that it only accepts numbers, but this change is enforced at runtime, and there is no way for a programmer calling the function to know what it expects without reading the source code.

Compiling the Function with TypeScript

TypeScript is a superset of JavaScript that requires types to be specified so they can be checked by a compiler. Returning to the Angular project, replace the contents of the main.ts file with those shown in Listing 3-13.

Listing 3-13. Replacing the Contents of the main.ts File in the src Folder

```
function myFunction(param) {
    if (typeof(param) == "number") {
        let result = param + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number: " + param)
    }
}

myFunction(1);
myFunction("London");
```

This is the same code that I used in the JavaScript file in the previous section. When the file is saved, the Angular development tools detect the change and rebuild the project, which includes using the TypeScript compiler to compile files with the .ts extension. The compiler reports the following error:

```
Error: src/main.ts:1:21 - error TS7006: Parameter 'param' implicitly has an 'any' type.
1 function myFunction(param) {
                      ~~~~~
```

TypeScript is a layer on top of JavaScript but doesn't change the way that JavaScript works. So, TypeScript functions are allowed to accept any data type because that is how JavaScript functions work. The difference is that TypeScript requires the developer to explicitly declare that is the behavior that is required, as shown in Listing 3-14.

Listing 3-14. Specifying the Function Parameter Type in the main.ts File in the src Folder

```
function myFunction(param: any) {
    if (typeof(param) == "number") {
        let result = param + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number: " + param)
    }
}

myFunction(1);
myFunction("London");
```

The type for the parameter is specified after the name, separated by a colon, which is known as a *type annotation*. The type specified in this listing is any, which indicates that the function can accept any data type. The behavior of the function hasn't changed, but the any keyword satisfies the TypeScript compiler. When the file is saved, the code will be compiled, sent to the browser, and executed, producing the following output in the browser's JavaScript console:

```
My result: 101
Uncaught Expected a number: London
```

TypeScript features are erased during the compilation process so that pure JavaScript remains. Most F12 developer tools allow you to inspect the JavaScript code received by the browser, which reveals that the compilation process has removed the any keyword, as shown in Figure 3-5.

Figure 3-5. *Examining the compiled code*

Using a More Specific Type

TypeScript requires the any keyword to make sure that you really want the default JavaScript behavior. Most of the time, however, TypeScript code is written with more specific data types, as shown in Listing 3-15.

Listing 3-15. Specifying a Single Type in the main.ts File in the src Folder

```
function myFunction(param: number) {
    if (typeof(param) == "number") {
        let result = param + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number: " + param)
    }
}

myFunction(1);
myFunction("London");
```

JavaScript defines five core primitive types: `string`, `number`, `boolean`, `undefined`, and `null`. In Listing 3-15, I have changed the type annotation to replace any with the JavaScript primitive type `number`, which tells TypeScript that the function only expects to receive `number` values.

■ **Tip** There are also `bigint` and `symbol` primitive types, but I don't use them in this book. The `bigint` type is used to represent numbers expressed in arbitrary precision format, and the `symbol` type is used to represent unique token values.

The TypeScript compiler will report the following error when the code is compiled:

```
Error: src/main.ts:11:12 - error TS2345: Argument of type 'string' is not assignable to
parameter of type 'number'.
11 myFunction("London");
              ~~~~~~~~
```

The TypeScript compiler has inspected the types of the arguments used to invoke the function and determined that one of them doesn't match the `number` type annotation. The type annotation also allows me to simplify the function code, as shown in Listing 3-16, because I can rely on the TypeScript compiler to check types, rather than do so at runtime.

Listing 3-16. Simplifying the Function in the main.ts File in the src Folder

```
function myFunction(param: number) {
    //if (typeof(param) == "number") {
        let result = param + 100;
        console.log("My result: " + result);
    // } else {
    //     throw ("Expected a number: " + param)
    // }
}

myFunction(1);
//myFunction("London");
```

When the file is saved and compiled, the following output will be displayed in the browser's JavaScript console:

```
My result: 101
```

Using a Type Union

TypeScript is a compile-time gatekeeper that helps you make your use of types explicit so that problems that would otherwise cause runtime errors can be detected. And, since TypeScript compiles into pure JavaScript and doesn't change the way that JavaScript works, everything that can be done in JavaScript can be described in TypeScript. This is important because many developers assume that TypeScript is similar to languages such as C# or Java. That's not the case—TypeScript is just a layer, albeit a useful one, that allows the programmer to annotate JavaScript code to explain to the compiler what types are expected in a given section of code so that the compiler can warn the programmer when different types are used.

As an example, earlier examples in this section have covered two extreme situations: that `myFunction` can accept all parameter types (denoted with the any keyword) and `myFunction` can accept only `number` parameters (denoted with the `number` type). But it is possible to write JavaScript functions so they can deal with combinations of types, as shown in Listing 3-17.

Listing 3-17. Supporting Multiple Types in the main.ts File in the src Folder

```
function myFunction(param: number) {
    if (typeof(param) == "number" || typeof(param) == "string") {
        let result = param + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number or a string: " + param)
    }
}

myFunction(1);
//myFunction("London");
```

There is now a mismatch between the code in the function and its parameter type annotation. To describe situations where multiple types are acceptable, TypeScript supports type unions, as shown in Listing 3-18.

Listing 3-18. Using a Type Union in the main.ts File in the src Folder

```
function myFunction(param: number | string) {
    if (typeof(param) == "number" || typeof(param) == "string") {
        let result = param + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number or a string: " + param)
    }
}

myFunction(1);
myFunction("London");
```

Type unions combine multiple types with the | character so that the type annotation `number | string` tells the compiler that `myFunction` will accept both `number` and `string` values. But the TypeScript compiler is clever, and it knows that JavaScript will do different things when it applies the addition operator to two number values or a string and a number, which means that this statement produces an ambiguous result:

```
...
let result = param + 100;
...
```

TypeScript is designed to avoid ambiguity, and the compiler will generate the following error when compiling the code:

```
...
Error: src/main.ts:3:22 - error TS2365: Operator '+' cannot be applied to types 'string |
number' and 'number'.
...
```

Remember that the purpose of TypeScript is only to highlight potential problems, not to enforce any particular solution to a problem. There are several ways to resolve this ambiguity, but the one that I want to illustrate in this section is shown in Listing 3-19, which is to tell the TypeScript compiler that everything is going to be alright.

Listing 3-19. Addressing the Ambiguity in the main.ts File in the src Folder

```
function myFunction(param: number | string) {
    if (typeof(param) == "number" || typeof(param) == "string") {
        let result = (param as any) + 100;
        console.log("My result: " + result);
    } else {
        throw ("Expected a number or a string: " + param)
    }
}

myFunction(1);
myFunction("London");
```

The `as` keyword tells the TypeScript compiler that its knowledge of the `param` value is incomplete and that it should treat it as a type that I specify. In this case, I have specified the `any` type, which has the effect of telling the TypeScript that the ambiguity is expected and prevents it from producing an error. This code produces the following output in the browser's JavaScript console:

```
My result: 101
My result: London100
```

Using the `as` keyword should be done with caution because the TypeScript compiler is sophisticated and usually has a pretty solid understanding of how data types are being used. Equally, using the `any` type can be dangerous because it essentially stops the TypeScript compiler from checking types. And, it should go without saying, when you tell the TypeScript compiler that you know more about the code, then you need to make sure that you are right; otherwise, you will return to the runtime-error issue that led to the introduction of TypeScript in the first place.

Accessing Type Features

Unions are a useful way to describe combinations of types, but TypeScript will only allow the use of features that are shared by all of the types in the union. So, for example, for a value whose type is the union number | string, the TypeScript compiler will only allow the use of features that are defined by both the number *and* string types. To demonstrate, Listing 3-20 attempts to use the toFixed method, which is defined by the number type and which is not defined by the string type.

Listing 3-20. Accessing a Type Feature in the main.ts File in the src Folder

```
function myFunction(param: number | string) {
    if (typeof(param) == "number" || typeof(param) == "string") {
        let fixed = param.toFixed(2);
        console.log("My result: " + fixed);
    } else {
        throw ("Expected a number or a string: " + param)
    }
}

myFunction(1);
myFunction("London");
```

The TypeScript compiler is guarding against ambiguity again. It knows that the param value will be either a number or a string and that calling the toFixed method when the value is a string will cause an error. The compiler produces the following error when the code is compiled:

```
Error: src/main.ts:3:27 - error TS2339: Property 'toFixed' does not exist on type 'string
| number'.
```

To resolve this issue, either I can use only features that are available for both number and string values or I can check the type param value within the function to eliminate the ambiguity, as shown in Listing 3-21.

Listing 3-21. Checking a Type in the main.ts File in the src Folder

```
function myFunction(param: number | string) {
    if (typeof(param) == "number") {
        let numberResult = param.toFixed(2);
        console.log("My result: " + numberResult);
    } else {
        let stringResult = param + 100;
        console.log("My result: " + stringResult);
    }
}

myFunction(1);
myFunction("London");
```

I need to remove the ambiguity about the parameter value's type so that I call the `toFixed` method only when the function receives a `number`. This code produces the following output in the browser's JavaScript console when it is compiled and executed:

```
My result: 1.00
My result: London100
```

Understanding the Basic TypeScript/JavaScript Features

Now that you understand the relationship between TypeScript and JavaScript, it is time to describe the basic language features you will need to follow the examples in this book. This is not a comprehensive guide to either TypeScript or JavaScript, but it should be enough to get you started as you learn how the features provided by Angular fit together.

Defining Variables and Constants

The `let` keyword is used to define variables, and the `const` keyword is used to define a constant value that will not change, as shown in Listing 3-22.

Listing 3-22. Defining Variables and Constants in the main.ts File in the src Folder

```
let condition = true;
let person = "Bob";
const age = 40;
```

The TypeScript compiler infers the type of each variable or constant from the value it is assigned and will generate an error if a value of a different type is assigned. Types can be specified explicitly, as shown in Listing 3-23.

Listing 3-23. Specifying Types in the main.ts File in the src Folder

```
let condition: boolean = true;
let person: string = "Bob";
const age: number = 40;
```

Dealing with Unassigned and Null Values

In JavaScript, variables that have been defined but not assigned a value are assigned the special value `undefined`, whose type is `undefined`, as shown in Listing 3-24.

Listing 3-24. Defining a Variable Without a Value in the main.ts File in the src Folder

```
let condition: boolean = true;
let person: string = "Bob";
const age: number = 40;
```

```
let place;
console.log("Place value: " + place + " Type: " + typeof(place));
place = "London";
console.log("Place value: " + place + " Type: " + typeof(place));
```

This code produces the following output in the browser's JavaScript console:

```
Place value: undefined Type: undefined
Place value: London Type: string
```

This behavior may seem nonsensical in isolation, but it is consistent with the rest of JavaScript, where values have types, and any value can be assigned to a variable. JavaScript also defines a separate special value, null, which can be assigned to variables to indicate no value or result, as shown in Listing 3-25.

Listing 3-25. Assigning Null in the main.ts File in the src Folder

```
let condition: boolean = true;
let person: string = "Bob";
const age: number = 40;

let place;
console.log("Place value: " + place + " Type: " + typeof(place));
place = "London";
console.log("Place value: " + place + " Type: " + typeof(place));
place = null;
console.log("Place value: " + place + " Type: " + typeof(place));
```

I can generally provide a robust defense of the way that JavaScript features work, but there is an oddity of the null value that makes little sense, which can be seen in the output this code produces in the browser's JavaScript console:

```
Place value: undefined Type: undefined
Place value: London Type: string
Place value: null Type: object
```

The oddity is that the type of the special null value is object. I introduce the JavaScript support for objects in Chapter 4, but this JavaScript quirk dates back to the first version of JavaScript and hasn't been addressed because so much code has been written that depends on it.

Leaving aside this inconsistency, when the TypeScript compiler processes the code in Listing 3-25, it determines that values of different types are assigned to the place variable and infers the variable's type as any.

As I explained, the any type allows values of any type to be used, which effectively disables the TypeScript compiler's type checks. A type union can be used to restrict the values that can be used, while still allowing undefined and null to be used, as shown in Listing 3-26.

Listing 3-26. Using a Type Union in the main.ts File in the src Folder

```
let condition: boolean = true;
let person: string = "Bob";
const age: number = 40;

let place: string | undefined | null;
console.log("Place value: " + place + " Type: " + typeof(place));
place = "London";
console.log("Place value: " + place + " Type: " + typeof(place));
place = null;
console.log("Place value: " + place + " Type: " + typeof(place));
```

This type union allows the place variable to be assigned `string` values or `undefined` or `null`. Notice that `null` is specified by value in the type union. This listing produces the same output in the JavaScript console as Listing 3-26.

Using the JavaScript Primitive Types

As noted earlier, JavaScript defines a small set of primitive types: `string`, `number`, `boolean`, `undefined`, and `null`. This may seem like a short list, but JavaScript manages to fit a lot of flexibility into these three types.

Working with Booleans

The `boolean` type has two values: `true` and `false`. Listing 3-27 shows both values being used, but this type is most useful when used in conditional statements, such as an `if` statement. There is no console output from this listing.

Listing 3-27. Defining boolean Values in the main.ts File in the src Folder

```
let firstBool = true;
let secondBool = false;
```

Working with Strings

You define `string` values using either the double or single quote characters, as shown in Listing 3-28.

Listing 3-28. Defining string Variables in the main.ts File in the src Folder

```
let firstString = "This is a string";
let secondString = 'And so is this';
```

The quote characters you use must match. You can't start a string with a single quote and finish with a double quote, for example. There is no output from this listing.

JavaScript provides `string` objects with a basic set of properties and methods, the most useful of which are described in Table 3-2.

Table 3-2. *Useful string Properties and Methods*

Name	Description
length	This property returns the number of characters in the string.
charAt(index)	This method returns a string containing the character at the specified index.
concat(string)	This method returns a new string that concatenates the string on which the method is called and the string provided as an argument.
indexOf(term, start)	This method returns the first index at which term appears in the string or -1 if there is no match. The optional start argument specifies the start index for the search.
replace(term, newTerm)	This method returns a new string in which all instances of term are replaced with newTerm.
slice(start, end)	This method returns a substring containing the characters between the start and end indices.
split(term)	This method splits up a string into an array of values that were separated by term.
toUpperCase() toLowerCase()	These methods return new strings in which all the characters are uppercase or lowercase.
trim()	This method returns a new string from which all the leading and trailing whitespace characters have been removed.

Using Template Strings

A common programming task is to combine static content with data values to produce a string that can be presented to the user. The traditional way to do this is through string concatenation, which is the approach I have been using in the examples so far in this chapter, as follows:

```
...
console.log("Place value: " + place + " Type: " + typeof(place));
...
```

JavaScript also supports *template strings*, which allow data values to be specified inline, which can help reduce errors and result in a more natural development experience. Listing 3-29 shows the use of a template string.

Listing 3-29. Using a Template String in the main.ts File in the src Folder

```
let place: string | undefined | null;
console.log(`Place value: ${place} Type: ${typeof(place)}`);
```

Template strings begin and end with backticks (the ` character), and data values are denoted by curly braces preceded by a dollar sign. This string, for example, incorporates the value of the place variable and its type into the template string:

```
...
console.log(`Place value: ${place} Type: ${typeof(place)}`);
...
```

63

This example produces the following output:

```
Place value: undefined Type: undefined
```

Working with Numbers

The number type is used to represent both *integer* and *floating-point* numbers (also known as *real numbers*). Listing 3-30 provides a demonstration.

Listing 3-30. Defining number Values in the main.ts File in the src Folder

```
let daysInWeek = 7;
let pi = 3.14;
let hexValue = 0xFFFF;
```

You don't have to specify which kind of number you are using. You just express the value you require, and JavaScript will act accordingly. In the listing, I have defined an integer value, defined a floating-point value, and prefixed a value with 0x to denote a hexadecimal value. Listing 3-30 doesn't produce any output.

Working with Null and Undefined Values

The null and undefined values have no features, such as properties or methods, but the unusual approach taken by JavaScript means that you can only assign these values to variables whose type is a union that includes null or undefined, as shown in Listing 3-31.

Listing 3-31. Assigning Null and Undefined Values in the main.ts File in the src Folder

```
let person1 = "Alice";
let person2: string | undefined = "Bob";
```

The TypeScript compiler will infer the type of the person1 variable as string because that is the type of the value assigned to it. This variable cannot be assigned the null or undefined value.

The person2 variable is defined with a type annotation that specifies string or undefined values. This variable can be assigned undefined but not null, since null is not part of the type union.

Using the JavaScript Operators

JavaScript defines a largely standard set of operators. I've summarized the most useful in Table 3-3.

Table 3-3. *Useful JavaScript Operators*

Operator	Description
++, --	Pre- or post-increment and decrement
+, -, *, /, %	Addition, subtraction, multiplication, division, remainder
<, <=, >, >=	Less than, less than or equal to, more than, more than or equal to
==, !=	Equality and inequality tests
===, !==	Identity and nonidentity tests
&&, ||	Logical AND and OR
||,??	Null and null-ish coalescing operators
?	Optional chaining operator
=	Assignment
+	String concatenation
?:	Three-operand conditional statement

Using Conditional Statements

Many of the JavaScript operators are used in conjunction with conditional statements. In this book, I tend to use the if/else and switch statements. Listing 3-32 shows the use of both, which will be familiar if you have worked with pretty much any programming language.

Listing 3-32. Using the if/else and switch Conditional Statements in the main.ts File in the src Folder

```
let firstName = "Adam";

if (firstName == "Adam") {
    console.log("firstName is Adam");
} else if (firstName == "Jacqui") {
    console.log("firstName is Jacqui");
} else {
    console.log("firstName is neither Adam or Jacqui");
}

switch (firstName) {
    case "Adam":
        console.log("firstName is Adam");
        break;
    case "Jacqui":
        console.log("firstName is Jacqui");
        break;
    default:
        console.log("firstName is neither Adam or Jacqui");
        break;
}
```

The results from the listing are as follows:

```
firstName is Adam
firstName is Adam
```

The Equality Operator vs. the Identity Operator

In JavaScript, the equality operator (==) will attempt to coerce (convert) operands to the same type to assess equality. This can be a useful feature, but it is widely misunderstood and often leads to unexpected results. Listing 3-33 shows the equality operator in action.

Listing 3-33. Using the Equality Operator in the main.ts File in the src Folder

```
let firstVal: any = 5;
let secondVal: any = "5";

if (firstVal == secondVal) {
    console.log("They are the same");
} else {
    console.log("They are NOT the same");
}
```

The output from this script is as follows:

```
They are the same
```

JavaScript is converting the two operands into the same type and comparing them. In essence, the equality operator tests that values are the same irrespective of their type.

If you want to test to ensure that the values *and* the types are the same, then you need to use the identity operator (===, three equal signs, rather than the two of the equality operator), as shown in Listing 3-34.

Listing 3-34. Using the Identity Operator in the main.ts File in the src Folder

```
let firstVal: any = 5;
let secondVal: any = "5";

if (firstVal === secondVal) {
    console.log("They are the same");
} else {
    console.log("They are NOT the same");
}
```

In this example, the identity operator will consider the two variables to be different. This operator doesn't coerce types. The result from this script is as follows:

```
They are NOT the same
```

To demonstrate how JavaScript works, I had to use the `any` type when declaring the `firstVal` and `secondVal` variables, because TypeScript restricts the use of the equality operator so that it can be used only on two values of the same type. Listing 3-35 removes the variable type annotations and allows TypeScript to infer the types from the assigned values.

Listing 3-35. Removing the Type Annotations in the main.ts File in the src Folder

```
let firstVal = 5;
let secondVal = "5";

if (firstVal === secondVal) {
    console.log("They are the same");
} else {
    console.log("They are NOT the same");
}
```

The TypeScript compiler detects that the variable types are not the same and generates the following error:

```
Error: src/main.ts:4:5 - error TS2367: This condition will always return 'false' since the
types 'number' and 'string' have no overlap.
```

UNDERSTANDING TRUTHY AND FALSY

The comparison operator presents another pitfall for the unwary, which is that expressions can be *truthy* or *falsy*. The following results are always falsy:

- The `false` (boolean) value
- The `0` (number) value
- The empty string (`""`)
- `null`
- `undefined`
- NaN (a special number value)

All other values are truthy, which can be confusing. For example, `"false"` (a string whose content is the word `false`) is truthy. The best way to avoid confusion is to only use expressions that evaluate to the `boolean` values `true` and `false`.

Explicitly Converting Types

The string concatenation operator (+) has higher precedence than the addition operator (also +), which means JavaScript will concatenate variables in preference to adding. This can confuse because JavaScript will also convert types freely to produce a result—and not always the result that is expected, as shown in Listing 3-36.

Listing 3-36. String Concatenation Operator Precedence in the main.ts File in the src Folder

```
let myData1 = 5 + 5;
let myData2 = 5 + "5";

console.log(`Result 1: ${myData1}, Type: ${typeof(myData1)}`);
console.log(`Result 2: ${myData2}, Type: ${typeof(myData2)}`);
```

This code produces the following output in the browser's JavaScript console:

```
Result 1: 10, Type: number
Result 2: 55, Type: string
```

The second result is the kind that confuses. What might be intended to be an addition operation is interpreted as string concatenation through a combination of operator precedence and type conversion. The TypeScript compiler understands the way the JavaScript operators behave and correctly infers the data types it produces, but, unlike the equally confusing equality operator, TypeScript doesn't prevent the type conversion.

To avoid this, you can explicitly convert the types of values to ensure you perform the right kind of operation, as described in the following sections.

Converting Numbers to Strings

If you are working with multiple number variables and want to concatenate them as strings, then you can convert the numbers to strings with the toString method, as shown in Listing 3-37.

Listing 3-37. Using the number.toString Method in the main.ts File in the src Folder

```
let myData1 = (5).toString() + String(5);
let myData2 = 5 + "5";

console.log(`Result 1: ${myData1}, Type: ${typeof(myData1)}`);
console.log(`Result 2: ${myData2}, Type: ${typeof(myData2)}`);
```

Notice that I placed the numeric value in parentheses, and then I called the toString method. This is because you have to allow JavaScript to convert the literal value into a number before you can call the methods that the number type defines. I have also shown an alternative approach to achieve the same effect, which is to call the String function and pass in the numeric value as an argument. Both of these techniques have the same effect, which is to convert a number to a string, meaning that the + operator is used for string concatenation and not addition. The output from this script is as follows:

```
Result 1: 55, Type: string
Result 2: 55, Type: string
```

Other methods allow you to exert more control over how a number is represented as a string. I briefly describe these methods in Table 3-4. All of the methods shown in the table are defined by the number type.

Table 3-4. *Useful Number-to-String Methods*

Method	Description
`toString()`	This method returns a string that represents a number in base 10.
`toString(2)` `toString(8)` `toString(16)`	This method returns a string that represents a number in binary, octal, or hexadecimal notation.
`toFixed(n)`	This method returns a string representing a real number with the n digits after the decimal point.
`toExponential(n)`	This method returns a string that represents a number using exponential notation with one digit before the decimal point and n digits after.
`toPrecision(n)`	This method returns a string that represents a number with n significant digits, using exponential notation if required.

Converting Strings to Numbers

The complementary technique is to convert strings to numbers so that you can perform addition rather than concatenation, as shown in Listing 3-38.

Listing 3-38. Converting Strings to Numbers in the main.ts File in the src Folder

```
let myData1 = (5).toString() + String(5);
let myData2 = Number("5") + parseInt("5");

console.log(`Result 1: ${myData1}, Type: ${typeof(myData1)}`);
console.log(`Result 2: ${myData2}, Type: ${typeof(myData2)}`);
```

The output from this script is as follows:

```
Result 1: 55, Type: string
Result 2: 10, Type: number
```

The `Number` function is strict in the way that it parses string values, but there are two other functions you can use that are more flexible and will ignore trailing non-number characters. These functions are `parseInt` and `parseFloat`. I have described all three methods in Table 3-5.

Table 3-5. *Useful String to Number Methods*

Method	Description
`Number(str)`	This method parses the specified string to create an integer or real value.
`parseInt(str)`	This method parses the specified string to create an integer value.
`parseFloat(str)`	This method parses the specified string to create an integer or real value.

Using the Null and Nullish Coalescing Operators

The logical OR operator (||) has been traditionally used as a null coalescing operator in JavaScript, allowing a fallback value to be used in place of null or undefined values, as shown in Listing 3-39.

■ **Note** If you move the mouse pointer over the variable in code editors such as Visual Studio Code, you will see that the TypeScript compiler is smart enough to infer when the variables in the next few examples are null or undefined. This is because all of the statements in the main.ts file are executed in sequence, allowing the compiler to use a more specific combination of types than have been used in the type annotations. This doesn't happen in real projects, where code is defined in functions or methods.

Listing 3-39. Using the Null Coalescing Operator in the main.ts File in the src Folder

```
let val1: string | undefined;
let val2: string | undefined = "London";

let coalesced1 = val1 || "fallback value";
let coalesced2 = val2 || "fallback value";

console.log(`Result 1: ${coalesced1}`);
console.log(`Result 2: ${coalesced2}`);
```

The || operator returns the left-hand operand if it evaluates as truthy and otherwise returns the right-hand operand. When the operator is applied to val1, the right-hand operand is returned because no value has been assigned to the variable, meaning that it is undefined. When the operator is applied to val2, the left-hand operand is returned because the variable has been assigned the string London, which evaluates as truthy. This code produces the following output in the browser's JavaScript console:

```
Result 1: fallback value
Result 2: London
```

The problem with using the || operator this way is that truthy and falsy values can produce unexpected results, as shown in Listing 3-40.

Listing 3-40. An Unexpected Null Coalescing Result in the main.ts File in the src Folder

```
let val1: string | undefined;
let val2: string | undefined = "London";
let val3: number | undefined = 0;

let coalesced1 = val1 || "fallback value";
let coalesced2 = val2 || "fallback value";
let coalesced3 = val3 || 100;

console.log(`Result 1: ${coalesced1}`);
console.log(`Result 2: ${coalesced2}`);
console.log(`Result 3: ${coalesced3}`);
```

The new coalescing operation returns the fallback value, even though the val3 variable is neither null nor undefined, because 0 evaluates as falsy. The code produces the following results in the browser's JavaScript console:

```
Result 1: fallback value
Result 2: London
Result 3: 100
```

The nullish-coalescing operator (??) addresses this issue by returning the right-hand operand only if the left-hand operand is null or undefined, as shown in Listing 3-41.

Listing 3-41. Using the Nullish-Coalescing Operator in the main.ts File in the src Folder

```
let val1: string | undefined;
let val2: string | undefined = "London";
let val3: number | undefined = 0;

let coalesced1 = val1 ?? "fallback value";
let coalesced2 = val2 ?? "fallback value";
let coalesced3 = val3 ?? 100;

console.log(`Result 1: ${coalesced1}`);
console.log(`Result 2: ${coalesced2}`);
console.log(`Result 3: ${coalesced3}`);
```

The nullish operator doesn't consider truthy and falsy outcomes and looks only for the null and undefined values. This code produces the following output in the browser's JavaScript console:

```
Result 1: fallback value
Result 2: London
Result 3: 0
```

Using the Optional Chaining Operator

As explainer earlier, TypeScript won't let null or undefined to be assigned to variables unless they have been defined with a suitable type union. Further, TypeScript will only allow methods and properties defined by all of the types in the union to be used. This combination of features means that you have to guard against null or undefined values before you can use the features provided by any other type in a union, as demonstrated in Listing 3-42.

Listing 3-42. Guarding Against Null or Undefined Values in the main.ts File in the src Folder

```
let count: number | undefined | null = 100;
if (count != null && count != undefined) {
    let result1: string = count.toFixed(2);
    console.log(`Result 1: ${result1}`);
}
```

To invoke the `toFixed` method, I have to make sure that the `count` variable hasn't been assigned `null` or `undefined`. The TypeScript compiler understands the meaning of the expressions in the `if` statement and knows that excluding `null` and `undefined` values means that the value assigned to `count` must be a `number`, meaning that the `toFixed` method can be used safely. This code produces the following output in the browser's JavaScript console:

```
Result 1: 100.00
```

The optional chaining operator (the ? character) simplifies the guarding process, as shown in Listing 3-43.

Listing 3-43. Using the Optional Chaining Operator in the main.ts File in the src Folder

```
let count: number | undefined | null = 100;
if (count != null && count != undefined) {
    let result1: string = count.toFixed(2);
    console.log(`Result 1: ${result1}`);
}

let result2: string | undefined = count?.toFixed(2);
console.log(`Result 2: ${result2}`);
```

The operator is applied between the variable and the method call and will return `undefined` if the value is `null` or `undefined`, preventing the method from being invoked:

```
...
let result2: string | undefined = count?.toFixed(2);
...
```

If the value isn't `null` or `undefined`, then the method call will proceed as normal. The result from an expression that includes the optional chaining operator is a type union of undefined and the result from the method. In this case, the union will be `string | undefined` because the `toFixed` method returns a `string`. The code in Listing 3-43 produces the following output in the browser's JavaScript console:

```
Result 1: 100.00
Result 2: 100.00
```

Summary

In this chapter, I described some of the basic features of the foundation on which Angular is built. I described the basic structure of HTML elements and explained the relationship between JavaScript and TypeScript, before introducing the basic JavaScript/TypeScript features. In the next chapter, I continue to describe useful JavaScript and TypeScript features and provide a brief overview of an important JavaScript library that you will encounter in Angular development.

CHAPTER 4

■ ■ ■

Primer, Part 2

In this chapter, I continue to describe the basic features of TypeScript and JavaScript that are required for Angular development and briefly touch on the RxJS package, which is used extensively by Angular and is required for some advanced features.

Preparing for This Chapter

This chapter uses the Primer project created in Chapter 4. No changes are required for this chapter. Open a new command prompt, navigate to the Primer folder, and run the command shown in Listing 4-1 to start the Angular development tools.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 4-1. Starting the Development Tools

```
ng serve --open
```

After an initial build process, the Angular tools will open a browser window and display the content shown in Figure 4-1.

Figure 4-1. *Running the example application*

This chapter continues to use the browser's JavaScript console. Press F12 to open the browser's developers tools and switch to the console; you will see the following results (you may have to reload the browser):

```
Result 1: 100.00
Result 2: 100.00
```

Defining and Using Functions

When the browser receives JavaScript code, it executes the statements it contains in the order in which they have been defined. In common with most languages, JavaScript allows statements to be grouped into a function, which won't be executed until a statement that invokes the function is executed, as shown in Listing 4-2.

Listing 4-2. Defining a Function in the main.ts File in the src Folder

```
function writeValue(val: string | null) {
    console.log(`Value: ${val ?? "Fallback value"}`)
}

writeValue("London");
writeValue(null);
```

Functions are defined with the `function` keyword and are given a name. If a function defines parameters, then TypeScript requires type annotations, which are used to enforce consistency in the use of the function. The function in Listing 4-2 is named `writeValue`, and it defines a parameter that will accept `string` or `null` values. The statement inside of the function isn't executed until the browser reaches a statement that invokes the function. The code in Listing 4-2 produces the following output in the browser's JavaScript console:

```
Value: London
Value: Fallback value
```

Defining Optional Function Parameters

By default, TypeScript will allow functions to be invoked only when the number of arguments matches the number of parameters the function defines. This may seem obvious if you are used to other mainstream languages, but a function can be called with any number of arguments in pure JavaScript, regardless of how many parameters have been defined. The ? character is used to denote an optional parameter, as shown in Listing 4-3.

Listing 4-3. Defining an Optional Parameter in the main.ts File in the src Folder

```
function writeValue(val?: string) {
    console.log(`Value: ${val ?? "Fallback value"}`)
}

writeValue("London");
writeValue();
```

The ? operator has been applied to the `val` parameter, which means that the function can be invoked with zero or one argument. Within the function, the parameter type is `string | undefined`, because the value will be undefined if the function is invoked without an argument.

■ **Note** Don't confuse `val?: string`, which is an optional parameter, with `val: string | undefined`, which is a type union of `string` and `undefined`. The type union requires the function to be invoked with an argument, which may be the value `undefined`, whereas the optional parameter allows the function to be invoked without an argument.

The code in Listing 4-3 produces the following output in the browser's JavaScript console:

```
Value: London
Value: Fallback value
```

Defining Default Parameter Values

Parameters can be defined with a default value, which will be used when the function is invoked without a corresponding argument. This can be a useful way to avoid dealing with undefined values, as shown in Listing 4-4.

Listing 4-4. Defining a Default Parameter Value in the main.ts File in the src Folder

```
function writeValue(val: string = "default value") {
    console.log(`Value: ${val}`)
}

writeValue("London");
writeValue();
```

The default value will be used when the function is invoked without an argument. This means that the type of the parameter in the example will always be string, so I don't have to check for undefined values. The code in Listing 4-4 produces the following output in the browser's JavaScript console:

```
Value: London
Value: default value
```

Defining Rest Parameters

Rest parameters are used to capture any additional arguments when a function is invoked with additional arguments, as shown in Listing 4-5.

Listing 4-5. Using a Rest Parameter in the main.ts File in the src Folder

```
function writeValue(val: string, ...extraInfo: string[]) {
    console.log(`Value: ${val}, Extras: ${extraInfo}`)
}

writeValue("London", "Raining", "Cold");
writeValue("Paris", "Sunny");
writeValue("New York");
```

The rest parameter must be the last parameter defined by the function, and its name is prefixed with an ellipsis (three periods, ...). The rest parameter is an array to which any extra arguments will be assigned. In the listing, the function prints out each extra argument to the console, producing the following results:

```
Value: London, Extras: Raining,Cold
Value: Paris, Extras: Sunny
Value: New York, Extras:
```

Defining Functions That Return Results

You can return results from functions by declaring the return data type and using the return keyword within the function body, as shown in Listing 4-6.

Listing 4-6. Returning a Result in the main.ts File in the src Folder

```
function composeString(val: string) : string {
    return `Composed string: ${val}`;
}

function writeValue(val?: string) {
    console.log(composeString(val ?? "Fallback value"));
}

writeValue("London");
writeValue();
```

The new function defines one parameter, which is a string, and returns a result, which is also a string. The type of the result is defined using a type annotation after the parameters:

```
...
function composeString(val: string) : string {
...
```

TypeScript will check the use of the return keyword to ensure that the function returns a result and that the result is of the expected type. This code produces the following output in the browser's JavaScript console:

```
Composed string: London
Composed string: Fallback value
```

Using Functions as Arguments to Other Functions

JavaScript functions are values, which means you can use one function as the argument to another, as demonstrated in Listing 4-7.

Listing 4-7. Using a Function as an Argument to Another Function in the main.ts File in the src Folder

```
function getUKCapital() : string {
    return "London";
}

function writeCity(f: () => string)  {
    console.log(`City: ${f()}`)
}

writeCity(getUKCapital);
```

The `writeCity` function defines a parameter called `f`, which is a function that it invokes to get the value to insert into the string that it writes out. TypeScript requires the function parameter to be described so that the types of its parameters and results are declared:

```
...
function writeCity(f: () => string)  {
...
```

This is the arrow syntax, also known as fat arrow syntax or the lambda expression syntax. There are three parts to an arrow function: the input parameters surrounded by parentheses, then an equal sign and a greater-than sign (the "arrow"), and finally the function result. The parameter function doesn't define any parameters, so the parentheses are empty. This means that the type of the parameter `f` is a function that accepts no parameters and returns a `string` result. The parameter function is invoked within a template string:

```
...
console.log(`City: ${f()}`)
...
```

Only functions with the specified combination of parameters and result can be used as an argument to `writeCity`. The `getUKCapital` function has the correct characteristics:

```
...
writeCity(getUKCapital);
...
```

Notice that only the name of the function is used as the argument. If you follow the function name with parentheses, `writeCity(getUKCapital())`, then you are telling JavaScript to invoke the `getUKCapital` function and pass the result to the `writeCity` function. TypeScript will detect that the result from the `getUKCapital` function doesn't match the parameter type defined by the `writeCity` function and will produce an error when the code is compiled. The code in Listing 4-7 produces the following output in the browser's JavaScript console:

```
City: London
```

Defining Functions Using the Arrow Syntax

The arrow syntax can also be used to define functions, not just to describe them, and this is a useful way to define functions inline, as shown in Listing 4-8.

Listing 4-8. Defining an Arrow Function in the main.ts File in the src Folder

```
function getUKCapital() : string {
    return "London";
}

function writeCity(f: () => string)  {
    console.log(`City: ${f()}`)
}
```

```
writeCity(getUKCapital);
writeCity(() => "Paris");
```

This inline function receives no parameters and returns the literal string value Paris, allowing me to define a function that can be used as an argument to the writeCity function. The code in Listing 4-8 produces the following output in the browser's JavaScript console:

```
City: London
City: Paris
```

Understanding Value Closure

Functions can access values that are defined in the surrounding code, using a feature called *closure*, as demonstrated in Listing 4-9.

Listing 4-9. Using a Closure in the main.ts File in the src Folder

```
function getUKCapital() : string {
    return "London";
}

function writeCity(f: () => string)  {
    console.log(`City: ${f()}`)
}

writeCity(getUKCapital);
writeCity(() => "Paris");
let myCity = "Rome";
writeCity(() => myCity);
```

The new arrow function returns the value of the variable named myCity, which is defined in the surrounding code. This is a powerful feature that means you don't have to define parameters on functions to pass around data values, but caution is required because it is easy to get unexpected results when using common variable names like counter or index, where you may not realize that you are reusing a variable name from the surrounding code. This example produces the following output in the browser's JavaScript console:

```
City: London
City: Paris
City: Rome
```

Working with Arrays

JavaScript arrays work like arrays in most other programming languages. Listing 4-10 demonstrates how to create and populate an array.

Listing 4-10. Creating an Populating an Array in the main.ts File in the src Folder

```
let myArray = [];
myArray[0] = 100;
myArray[1] = "Adam";
myArray[2] = true;
```

I have created a new and empty array using the literal syntax, which uses square brackets, and assigned the array to a variable named myArray. In the subsequent statements, I assign values to various index positions in the array. (There is no console output from this listing.)

There are a couple of things to note in this example. First, I didn't need to declare the number of items in the array when I created it. JavaScript arrays will resize themselves to hold any number of items. The second point is that I didn't have to declare the data types that the array will hold. Any JavaScript array can hold any mix of data types. In the example, I have assigned three items to the array: a number, a string, and a boolean. The TypeScript compiler infers the type of the array as any[], denoting any array that can hold values of all types. The example can be written with the type annotation shown in Listing 4-11.

Listing 4-11. Using a Type Annotation in the main.ts File in the src Folder

```
let myArray: any[] = [];
myArray[0] = 100;
myArray[1] = "Adam";
myArray[2] = true;
```

Arrays can be restricted to hold values of specific types, as shown in Listing 4-12.

Listing 4-12. Restricting Array Value Types in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [];
myArray[0] = 100;
myArray[1] = "Adam";
myArray[2] = true;
```

The type union restricts the array so that it can hold only number, string, and boolean values. Notice that I have put the type union in parentheses because the union number | string | boolean[] denotes a value that can be assigned a number, a string, or an array of boolean values, which is not what is intended.

Arrays can be defined and populated in a single statement, as shown in Listing 4-13.

Listing 4-13. Populating a New Array in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [100, "Adam", true];
```

If you omit the type annotation, TypeScript will infer the array type from the values used to populate the array. You should rely on this feature with caution for arrays that are intended to hold multiple types because it requires that the full range of types is used when creating the array.

Reading and Modifying the Contents of an Array

You read the value at a given index using square braces ([and]), placing the index you require between the braces, as shown in Listing 4-14.

Listing 4-14. Reading the Data from an Array Index in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [100, "Adam", true];

let val = myArray[0];
console.log(`Value: ${val}`);
```

The TypeScript compiler infers the type of values in the array so that the type of the val variable in Listing 4-14 is number | string | boolean. This code produces the following output in the browser's JavaScript console:

```
Value: 100
```

You can modify the data held in any position in a JavaScript array simply by assigning a new value to the index, as shown in Listing 4-15. The TypeScript compiler will check that the type of the value you assign matches the array element type.

Listing 4-15. Modifying the Contents of an Array in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [100, "Adam", true];

myArray[0] = "Tuesday";

let val = myArray[0];
console.log(`Value: ${val}`);
```

In this example, I have assigned a string to position 0 in the array, a position that was previously held by a number. This code produces the following output in the browser's JavaScript console:

```
Value: Tuesday
```

Enumerating the Contents of an Array

You enumerate the content of an array using a for loop or using the forEach method, which receives a function that is called to process each element in the array. Listing 4-16 shows both approaches.

Listing 4-16. Enumerating the Contents of an Array in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [100, "Adam", true];

for (let i = 0; i < myArray.length; i++) {
    console.log("Index " + i + ": " + myArray[i]);
}

console.log("---");

myArray.forEach((value, index) => console.log("Index " + index + ": " + value));
```

The JavaScript `for` loop works just the same way as loops in many other languages. You determine how many elements there are in the array using its `length` property.

The function passed to the `forEach` method is given two arguments: the value of the current item to be processed and the position of that item in the array. In this listing, I have used an arrow function as the argument to the `forEach` method, which is the kind of use for which they excel (and you will see used throughout this book). The output from the listing is as follows:

```
Index 0: 100
Index 1: Adam
Index 2: true
---
Index 0: 100
Index 1: Adam
Index 2: true
```

Using the Spread Operator

The spread operator is used to expand an array so that its contents can be used as function arguments or combined with other arrays. In Listing 4-17, I used the spread operator to expand an array so that its items can be combined into another array.

Listing 4-17. Using the Spread Operator in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [100, "Adam", true];
let otherArray = [...myArray, 200, "Bob", false];

// for (let i = 0; i < myArray.length; i++) {
//     console.log("Index " + i + ": " + myArray[i]);
// }

// console.log("---");

otherArray.forEach((value, index) => console.log("Index " + index + ": " + value));
```

The spread operator is an ellipsis (a sequence of three periods), and it causes the array to be unpacked.

```
...
let otherArray = [...myArray, 200, "Bob", false];
...
```

Using the spread operator, I can specify `myArray` as an item when I define `otherArray`, with the result that the contents of the first array will be unpacked and added as items to the second array. This example produces the following results:

```
Index 0: 100
Index 1: Adam
Index 2: true
Index 3: 200
Index 4: Bob
Index 5: false
```

Using the Built-in Array Methods

JavaScript arrays define a number of methods, the most useful of which are described in Table 4-1.

Table 4-1. *Useful Array Methods*

Method	Description
concat(otherArray)	This method returns a new array that concatenates the array on which it has been called with the array specified as the argument. Multiple arrays can be specified.
join(separator)	This method joins all the elements in the array to form a string. The argument specifies the character used to delimit the items.
pop()	This method removes and returns the last item in the array.
shift()	This method removes and returns the first element in the array.
push(item)	This method appends the specified item to the end of the array.
unshift(item)	This method inserts a new item at the start of the array.
reverse()	This method returns a new array that contains the items in reverse order.
slice(start,end)	This method returns a section of the array.
sort()	This method sorts the array. An optional comparison function can be used to perform custom comparisons.
splice(index, count)	This method removes count items from the array, starting at the specified index. The removed items are returned as the result of the method.
unshift(item)	This method inserts a new item at the start of the array.
every(test)	This method calls the test function for each item in the array and returns true if the function returns true for all of them and false otherwise.
some(test)	This method returns true if calling the test function for each item in the array returns true at least once.
filter(test)	This method returns a new array containing the items for which the test function returns true.
find(test)	This method returns the first item in the array for which the test function returns true.
findIndex(test)	This method returns the index of the first item in the array for which the test function returns true.
foreach(callback)	This method invokes the callback function for each item in the array, as described in the previous section.
includes(value)	This method returns true if the array contains the specified value.
map(callback)	This method returns a new array containing the result of invoking the callback function for every item in the array.
reduce(callback)	This method returns the accumulated value produced by invoking the callback function for every item in the array.

Since many of the methods in Table 4-1 return a new array, these methods can be chained together to process a filtered data array, as shown in Listing 4-18.

Listing 4-18. Processing a Data Array in the main.ts File in the src Folder

```
let myArray: (number | string | boolean)[] = [100, "Adam", true];
let otherArray = [...myArray, 200, "Bob", false];

let sum: number = otherArray
    .filter(val => typeof(val) == "number")
    .reduce((total: number, val) => total + (val as number), 0)

console.log(`Sum: ${sum}`);
```

I use the filter method to select the number in the array and use the reduce method to determine the total, producing the following output in the browser's JavaScript console:

```
Sum: 300
```

Notice that I have had to give the TypeScript compiler some help with a type annotation and the as keyword. The compiler is sophisticated but doesn't always correctly infer the types in this type of operation.

Working with Objects

JavaScript objects are a collection of properties, each of which has a name and value. The simplest way to create an object is to use the literal syntax, as shown in Listing 4-19.

Listing 4-19. Creating an Object in the main.ts File in the src Folder

```
let hat = {
    name: "Hat",
    price: 100
};

let boots = {
    name: "Boots",
    price: 100
}

console.log(`Name: ${hat.name}, Price: ${hat.price}`);
console.log(`Name: ${boots.name}, Price: ${boots.price}`);
```

The literal syntax uses braces to contain a list of property names and values. Names are separated from their values with colons and from other properties with commas. Two objects are defined in Listing 4-19 and assigned to variables named hat and boots. The properties defined by the object can be accessed through the variable name, as shown in this statement:

```
...
console.log(`Name: ${hat.name}, Price: ${hat.price}`);
...
```

The code in Listing 4-19 produces the following output:

```
Name: Hat, Price: 100
Name: Boots, Price: 100
```

Understanding Literal Object Types

When the TypeScript encounters a literal object, it infers its type, using the combination of property names and the values to which they are assigned. This combination can be used in type annotations, allowing the shape of objects to be described as, for example, function parameters, as shown in Listing 4-20.

■ **Tip** In Angular development, you will most frequently create objects using classes, which are described in the "Defining Classes" section.

Listing 4-20. Describing an Object Type in the main.ts File in the src Folder

```
let hat = {
    name: "Hat",
    price: 100
};

let boots = {
    name: "Boots",
    price: 100
}

function printDetails(product : { name: string, price: number}) {
    console.log(`Name: ${product.name}, Price: ${product.price}`);
}

printDetails(hat);
printDetails(boots);
```

The type annotation specifies that the product parameter can accept objects that define a string property called name, and a number property named price. This example produces the same output as Listing 4-19.

A type annotation that describes a combination of property names and types just sets out a minimum threshold for objects, which can define additional properties and still be conform to the type, as shown in Listing 4-21.

Listing 4-21. Adding a Property in the main.ts File in the src Folder

```
let hat = {
    name: "Hat",
    price: 100
};
```

85

```
let boots = {
    name: "Boots",
    price: 100,
    category: "Snow Gear"
}

function printDetails(product : { name: string, price: number}) {
    console.log(`Name: ${product.name}, Price: ${product.price}`);
}

printDetails(hat);
printDetails(boots);
```

The listing adds a new property to the objects assigned to the boots variable, but since the object defines the properties described in the type annotation, this object can still be used as an argument to the printDetails function. This example produces the same output as Listing 4-19.

Defining Optional Properties in a Type Annotation

A question mark can be used to denote an optional property, as shown in Listing 4-22, allowing objects that don't define the property to still conform to the type.

Listing 4-22. Defining an Optional Property in the main.ts File in the src Folder

```
let hat = {
    name: "Hat",
    price: 100
};

let boots = {
    name: "Boots",
    price: 100,
    category: "Snow Gear"
}

function printDetails(product : { name: string, price: number, category?: string}) {
    if (product.category != undefined) {
        console.log(`Name: ${product.name}, Price: ${product.price}, ` +
            `Category: ${product.category}`);
    } else {
        console.log(`Name: ${product.name}, Price: ${product.price}`);
    }
}

printDetails(hat);
printDetails(boots);
```

The type annotation adds an optional category property, which is marked as optional. This means that the type of the property is string | undefined, and the function can test to see if a category value has been provided using the language features described in Chapter 3. This code produces the following output in the browser's JavaScript console:

```
Name: Hat, Price: 100
Boots, Price: 100, Category: Snow Gear
```

Defining Classes

Classes are templates used to create objects, providing an alternative to the literal syntax. Support for classes is a recent addition to the JavaScript specification and is intended to make working with JavaScript more consistent with other mainstream programming languages. Listing 4-23 defines a class and uses it to create objects.

Listing 4-23. Defining a Class in the main.ts File in the src Folder

```
class Product {

    constructor(name: string, price: number, category?: string) {
        this.name = name;
        this.price = price;
        this.category = category;
    }

    name: string
    price: number
    category?: string
}

let hat = new Product("Hat", 100);

let boots = new Product("Boots", 100, "Snow Gear");

function printDetails(product : { name: string, price: number, category?: string}) {
    if (product.category != undefined) {
        console.log(`Name: ${product.name}, Price: ${product.price}, ` +
            `Category: ${product.category}`);
    } else {
        console.log(`Name: ${product.name}, Price: ${product.price}`);
    }
}

printDetails(hat);
printDetails(boots);
```

JavaScript classes will be familiar if you have used another mainstream language such as Java or C#. The class keyword is used to declare a class, followed by the name of the class, which is Product in this example.

The constructor function is invoked when a new object is created using the class, and it provides an opportunity to receive data values and do any initial setup that the class requires. In the example, the constructor defines name, price, and category parameters that are used to assign values to properties defined with the same names.

The new keyword is used to create an object from a class, like this:

```
...
let hat = new Product("Hat", 100);
...
```

This statement creates a new object using the Product class as its template. Product is used as a function in this situation, and the arguments passed to it will be received by the constructor function defined by the class. The result of this expression is a new object that is assigned to a variable called hat.

Notice that the objects created from the class can still be used as arguments to the printDetails function. Introducing a class has changed the way that objects are created, but those objects have the same combination of property names and types and still match the type annotation for the function parameters. The code in Listing 4-23 produces the following output in the browser's JavaScript console:

```
Name: Hat, Price: 100
Name: Boots, Price: 100, Category: Snow Gear
```

Adding Methods to a Class

I can simplify the code in the example by moving the functionality defined by the printDetails function into a method defined by the Product class, as shown in Listing 4-24.

Listing 4-24. Defining a Method in the main.ts File in the src Folder

```
class Product {

    constructor(name: string, price: number, category?: string) {
        this.name = name;
        this.price = price;
        this.category = category;
    }

    name: string
    price: number
    category?: string

    printDetails() {
        if (this.category != undefined) {
            console.log(`Name: ${this.name}, Price: ${this.price}, ` +
                `Category: ${this.category}`);
        } else {
            console.log(`Name: ${this.name}, Price: ${this.price}`);
        }
    }
}
```

```
let hat = new Product("Hat", 100);

let boots = new Product("Boots", 100, "Snow Gear");

// function printDetails(product : { name: string, price: number, category?: string}) {
//     if (product.category != undefined) {
//         console.log(`Name: ${product.name}, Price: ${product.price}, ` +
//             `Category: ${product.category}`);
//     } else {
//         console.log(`Name: ${product.name}, Price: ${product.price}`);
//     }
// }

hat.printDetails();
boots.printDetails();
```

Methods are invoked through the object, like this:

```
...
hat.printDetails();
...
```

The method accesses the properties defined by the object through the this keyword:

```
...
console.log(`Name: ${this.name}, Price: ${this.price}`);
...
```

This example produces the following output in the browser's JavaScript console:

```
Name: Hat, Price: 100
Name: Boots, Price: 100, Category: Snow Gear
```

Access Controls and Simplified Constructors

TypeScript provides support for access controls using the public, private, and protected keywords. The public class gives unrestricted access to the properties and methods defined by a class, meaning they can be accessed by any other part of the application. The private keyword restricts access to features so they can be accessed only within the class that defines them. The protected keyword restricts access so that features can be accessed within the class or a subclass.

By default, the features defined by a class are accessible by any part of the application, as though the public keyword has been applied. You won't see the access control keywords applied to methods and properties in this book because access controls are not essential in an Angular application. But there is a related feature that I use often, which allows classes to be simplified by applying the access control keyword to the constructor parameters, as shown in Listing 4-25.

Listing 4-25. Simplifying the Class in the main.ts File in the src Folder

```
class Product {

    constructor(public name: string, public price: number, public category?: string) {
        // this.name = name;
        // this.price = price;
        // this.category = category;
    }

    // name: string
    // price: number
    // category?: string

    printDetails() {
        if (this.category != undefined) {
            console.log(`Name: ${this.name}, Price: ${this.price}, ` +
                `Category: ${this.category}`);
        } else {
            console.log(`Name: ${this.name}, Price: ${this.price}`);
        }
    }
}

let hat = new Product("Hat", 100);

let boots = new Product("Boots", 100, "Snow Gear");

hat.printDetails();
boots.printDetails();
```

Adding one of the access control keywords to a constructor parameter has the effect of creating a property with the same name, type, and access level. So, adding the `public` keyword to the `price` parameter, for example, creates a `public` property named `price`, which can be assigned `number` values. The value received through the constructor is used to initialize the property. This is a useful feature that eliminates the need to copy parameter values to initialize properties, and it is a feature that I wish other languages would adopt. The code in Listing 4-25 produces the same output as Listing 4-24, and only the way that the `name`, `price`, and `category` properties are defined has changed.

Using Class Inheritance

Classes can inherit behavior from other classes using the extends keyword, as shown in Listing Listing 4-26.

Listing 4-26. Using Class Inheritance in the main.ts File in the src Folder

```
class Product {

    constructor(public name: string, public price: number, public category?: string) {
    }
```

```
    printDetails() {
        if (this.category != undefined) {
            console.log(`Name: ${this.name}, Price: ${this.price}, ` +
                `Category: ${this.category}`);
        } else {
            console.log(`Name: ${this.name}, Price: ${this.price}`);
        }
    }
}

class DiscountProduct extends Product {

    constructor(name: string, price: number, private discount: number) {
        super(name, price - discount);
    }
}

let hat = new DiscountProduct("Hat", 100, 10);

let boots = new Product("Boots", 100, "Snow Gear");

hat.printDetails();
boots.printDetails();
```

The extends keyword is used to declare the class that will be inherited from, known as the *superclass* or *base class*. In the listing, DiscountProduct inherits from Product. The super keyword is used to invoke the superclass's constructor and methods. The DiscountProduct builds on the Product functionality to add support for a price reduction, producing the following results in the browser's JavaScript console:

```
Name: Hat, Price: 90
Name: Boots, Price: 100, Category: Snow Gear
```

Checking Object Types

When applied to an object, the typeof function will return object. To determine whether an object has been derived from a class, the instanceof keyword can be used, as shown in Listing 4-27.

Listing 4-27. Checking an Object Type in the main.ts File in the src Folder

```
class Product {

    constructor(public name: string, public price: number, public category?: string) {
    }

    printDetails() {
        if (this.category != undefined) {
            console.log(`Name: ${this.name}, Price: ${this.price}, ` +
                `Category: ${this.category}`);
```

```
        } else {
            console.log(`Name: ${this.name}, Price: ${this.price}`);
        }
    }
}

class DiscountProduct extends Product {

    constructor(name: string, price: number, private discount: number) {
        super(name, price - discount);
    }
}

let hat = new DiscountProduct("Hat", 100, 10);

let boots = new Product("Boots", 100, "Snow Gear");

// hat.printDetails();
// boots.printDetails();

console.log(`Hat is a Product? ${hat instanceof Product}`);
console.log(`Hat is a DiscountProduct? ${hat instanceof DiscountProduct}`);
console.log(`Boots is a Product? ${boots instanceof Product}`);
console.log(`Boots is a DiscountProduct? ${boots instanceof DiscountProduct}`);
```

The instanceof keyword is used with an object value and a class, and the expression returns true if the object was created from the class or a superclass. The code in Listing 4-27 produces the following output in the browser's JavaScript console:

```
Hat is a Product? True
Hat is a DiscountProduct? True
Boots is a Product? True
Boots is a DiscountProduct? false
```

Working with JavaScript Modules

JavaScript modules are used to manage the dependencies in a web application, which means you don't need to manage a large set of individual code files to ensure that the browser downloads all the code for the application. Instead, during the compilation process, all of the JavaScript files that the application requires are combined into a larger file, known as a *bundle*, and it is this that is downloaded by the browser.

Creating and Using Modules

Each TypeScript or JavaScript file that you add to a project is treated as a module. To demonstrate, I created a folder called modules in the src folder, added to it a file called NameAndWeather.ts, and added the code shown in Listing 4-28.

Listing 4-28. The Contents of the NameAndWeather.ts File in the src/modules Folder

```
export class Name {
    constructor(public first: string, public second: string) {}

    get nameMessage() {
        return `Hello ${this.first} ${this.second}`;
    }
}

export class WeatherLocation {
    constructor(public weather: string, public city: string) {}

    get weatherMessage() {
        return `It is ${this.weather} in ${this.city}`;
    }
}
```

The classes, functions, and variables defined in a JavaScript or TypeScript file can be accessed only within that file by default. The export keyword is used to make features accessible outside of the file so that they can be used by other parts of the application. In the example, I have applied the export keyword to the Name and WeatherLocation classes, which means they are available to be used outside of the module.

■ **Tip** I have defined two classes in the NameAndWeather.ts file, which has the effect of creating a module that contains two classes. The convention in Angular applications is to put each class into its own file, which means that each class is defined in its own module.

The import keyword is used to declare a dependency on the features that a module provides. In Listing 4-29, I have used the Name and WeatherLocation classes in the main.ts file, and that means I have to use the import keyword to declare a dependency on them and the module they come from.

Listing 4-29. Importing Specific Types in the main.ts File in the src Folder

```
import { Name, WeatherLocation } from "./modules/NameAndWeather";

let name = new Name("Adam", "Freeman");
let loc = new WeatherLocation("raining", "London");

console.log(name.nameMessage);
console.log(loc.weatherMessage);
```

This is the way that I use the import keyword in most of the examples in this book. The keyword is followed by curly braces that contain a comma-separated list of the features that the code in the current files depends on, followed by the from keyword, followed by the module name. In this case, I have imported the Name and WeatherLocation classes from the NameAndWeather module in the modules folder. Notice that the file extension is not included when specifying the module.

When the `main.ts` file is compiled, the Angular development tools detect the dependency on the code in the `NameAndWeather.ts` file. This dependency ensures that the `Name` and `WeatherLocation` classes are included in the JavaScript bundle file, and you will see the following output in the browser's JavaScript console, showing that code in the module was used to produce the result:

```
Hello Adam Freeman
It is raining in London
```

Notice that I didn't have to include the `NameAndWeather.ts` file in a list of files to be sent to the browser. Just using the `import` keyword is enough to declare the dependency and ensure that the code required by the application is included in the JavaScript file sent to the browser.

UNDERSTANDING MODULE RESOLUTION

You will see two different ways of specifying modules in the `import` statements in this book. The first is a relative module, in which the name of the module is prefixed with `./`, like this example from Listing 4-29:

```
...
import { Name, WeatherLocation } from "./modules/NameAndWeather";
...
```

This statement specifies a module located relative to the file that contains the `import` statement. In this case, the `NameAndWeather.ts` file is in the `modules` directory, which is in the same directory as the `main.ts` file. The other type of import is nonrelative. Here is an example of a nonrelative import from Chapter 2 and one that you will see throughout this book:

```
...
import { Component } from "@angular/core";
...
```

The module in this `import` statement doesn't start with `./`, and the build tools resolve the dependency by looking for a package in the `node_modules` folder. In this case, the dependency is on a feature provided by the `@angular/core` package, which is added to the project when it is created by the `ng new` command.

Working with Reactive Extensions

Angular relies on a package named RxJS, also known as *Reactive Extensions*, or *ReactiveX*. The Reactive Extensions library is useful in Angular applications because it provides a simple and unambiguous system for sending and receiving notifications. It doesn't sound like a huge achievement, but it underpins most of the built-in Angular functionality, which needs to change the HTML content displayed to the user when the state of the application changes.

You won't often need to work with RxJS directly, but there are some features described in this book that rely on RxJS, and a basic knowledge of the building blocks RxJS provides can be useful. (See https://rxjs.dev for a full description of the features provided by the RxJS package.)

Understanding Observables

The key Reactive Extensions building block is an `Observable<T>`, which represents an observable sequence of events that occur over a period of time. This is most often encountered when using the Angular support for making HTTP requests, described in Chapter 23, where the outcome of the request is presented through an `Observable<T>` object. The generic type argument `<T>` denotes the type of event that the observable produces so that an `Observable<string>` will produce a series of `string` values, for example.

An object can subscribe to an `Observable` and receive a notification each time an event occurs, allowing it to respond only when the event has been observed. In the case of an HTTP request, for example, the use of the `Observable` allows the response to be handled when it arrives, without the handler code needing to periodically check whether the request has completed.

■ **Note**   If you are familiar with JavaScript, you may wonder if an `Observable` is the same as a `Promise`, which is the typical way of dealing with asynchronous operations. The key difference is that an `Observable` represents a series of events, rather than a single result, which better suits the way that Angular works. HTTP requests can be handled equally well with an `Observable` or a `Promise`, but other Angular features require ongoing notifications, which is where RxJS excels.

The basic method provided by an `Observable` is `subscribe`, which accepts an object whose properties are set to functions that respond to the sequence of events. The property names and the purpose of the functions are described in Table 4-2. If you only need to specify a function that receives events, then you can pass that function as the argument to the `subscribe` method.

Table 4-2. *The Observable subscribe Argument Properties*

Name	Description
next	This function is invoked when a new event occurs.
error	This function is invoked when an error occurs.
complete	This function is invoked when the sequence of events ends.

Listing 4-30 defines a function that receives an `Observable<string>` and writes out the sequence of `string` values that are received.

Listing 4-30. Using an Observable in the main.ts File in the src Folder

```
import { Observable } from "rxjs";

function recieveEvents(observable: Observable<string>) {
    observable.subscribe({
        next: str => {
            console.log(`Event received: ${str}`);
        },
        complete: () => console.log("Sequence ended")
    });
}
```

The RxJS package is added to the project when it is created. The recieveEvents function defines an Observable<string> parameter and calls the subscribe method, providing functions that write out messages when an event is received and when the event sequence ends.

Understanding Observers

The Reactive Extensions Observer<T> class provides the mechanism by which updates are created, using the methods described in Table 4-3.

Table 4-3. *The Observer Methods*

Name	Description
next(value)	This method creates a new event using the specified value.
error(errorObject)	This method reports an error, described using the argument, which can be any object.
complete()	This method ends the sequence, indicating that no further events will be sent.

Listing 4-31 defines a function that receives an Observer<string> and uses it to send a series of events before calling the complete method.

Listing 4-31. Using an Observer in the main.ts File in the src Folder

```
import { Observable, Observer } from "rxjs";

function recieveEvents(observable: Observable<string>) {
    observable.subscribe({
        next: str => {
            console.log(`Event received: ${str}`);
        },
        complete: () => console.log("Sequence ended")
    });
}

function sendEvents(observer: Observer<string>) {
    let count = 5;
    for (let i = 0; i < count; i++) {
        observer.next(`${i + 1} of ${count}`);
    }
    observer.complete();
}
```

Understanding Subjects

The Reactive Extensions library provides the Subject<T> class, which implements both the Observer and Observable functionality. A Subject is useful when you are working with RxJS in your own code, rather than using an Observer or Observable provided through the Angular API. In Listing 4-32, I have created a Subject<string> and used it as the argument to invoke the functions defined in the previous sections.

THE DIFFERENT TYPES OF SUBJECT

Listing 4-32 uses the `Subject` class, which is the simplest way to create an object that is both an `Observer` and an `Observable`. Its main limitation is that when a new subscriber is created using the `subscribe` method, it won't receive an event until the next time the `next` method is called. This can be unhelpful if you are creating instances of components or directives dynamically and you want them to have some context data as soon as they are created.

The Reactive Extensions library includes some specialized implementations of the `Subject` class that can be used to work around this problem. The `BehaviorSubject` class keeps track of the last event it processed and sends it to new subscribers as soon as they call the `subscribe` method. The `ReplaySubject` class does something similar, except that it keeps track of all of its events and sends them all to new subscribers, allowing them to catch up with any events that were sent before they subscribed.

Listing 4-32. Using a Subject in the main.ts File in the src Folder

```
import { Observable, Observer, Subject } from "rxjs";

function recieveEvents(observable: Observable<string>) {
    observable.subscribe({
        next: str => {
            console.log(`Event received: ${str}`);
        },
        complete: () => console.log("Sequence ended")
    });
}

function sendEvents(observer: Observer<string>) {
    let count = 5;
    for (let i = 0; i < count; i++) {
        observer.next(`${i + 1} of ${count}`);
    }
    observer.complete();
}

let subject = new Subject<string>();
recieveEvents(subject);
sendEvents(subject);
```

The new statements connect together the functions, and the `Subject<string>` acts as the conduit that carries the events between functions, producing the following output in the browser's JavaScript console:

```
Event received: 1 of 5
Event received: 2 of 5
Event received: 3 of 5
Event received: 4 of 5
Event received: 5 of 5
Sequence ended
```

Summary

In this chapter, I continued to describe the key features provided by TypeScript and JavaScript, including functions, arrays, objects, and modules. I also briefly described the RxJS package, which is used for some of the advanced features described later in the book.

CHAPTER 5

■ ■ ■

SportsStore: A Real Application

In Chapter 2, I built a quick and simple Angular application. Small and focused examples allow me to demonstrate specific Angular features, but they can lack context. To help overcome this problem, I am going to create a simple but realistic e-commerce application.

My application, called SportsStore, will follow the classic approach taken by online stores everywhere. I will create an online product catalog that customers can browse by category and page, a shopping cart where users can add and remove products, and a checkout where customers can enter their shipping details and place their orders. I will also create an administration area that includes create, read, update, and delete (CRUD) facilities for managing the catalog—and I will protect it so that only logged-in administrators can make changes. Finally, I show you how to prepare and deploy an Angular application.

My goal in this chapter and those that follow is to give you a sense of what real Angular development is like by creating as realistic an example as possible. I want to focus on Angular, of course, and so I have simplified the integration with external systems, such as the data store, and omitted others entirely, such as payment processing.

The SportsStore example is one that I use in a few of my books, not least because it demonstrates how different frameworks, languages, and development styles can be used to achieve the same result. You don't need to have read any of my other books to follow this chapter, but you will find the contrasts interesting if you already own my *Pro ASP.NET Core 3* book, for example.

The Angular features that I use in the SportsStore application are covered in-depth in later chapters. Rather than duplicate everything here, I tell you just enough to make sense of the example application and refer you to other chapters for in-depth information. You can either read the SportsStore chapters from end to end to get a sense of how Angular works or jump to and from the detailed chapters to get into the depth of each feature. Either way, don't expect to understand everything right away—Angular has lots of moving parts, and the SportsStore application is intended to show you how they fit together without diving too deeply into the details that I spend the rest of the book describing.

Preparing the Project

To create the SportsStore project, open a command prompt, navigate to a convenient location, and run the following command:

```
ng new SportsStore --routing false --style css --skip-git --skip-tests
```

The `angular-cli` package will create a new project for Angular development, with configuration files, placeholder content, and development tools. The project setup process can take some time since there are many NPM packages to download and install.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Installing the Additional NPM Packages

Additional packages are required for the SportsStore project, in addition to the core Angular packages and build tools set up by the `ng new` command. Run the following commands to navigate to the SportsStore folder and add the required packages:

```
cd SportsStore
npm install bootstrap@5.1.3
npm install @fortawesome/fontawesome-free@6.0.0
npm install --save-dev json-server@0.17.0
npm install --save-dev jsonwebtoken@8.5.1
```

It is important to use the version numbers shown in the listing. You may see warnings about unmet peer dependencies as you add the packages, but you can ignore them. Some of the packages are installed using the `--save-dev` argument, which indicates they are used during development and will not be part of the SportsStore application.

Adding the CSS Style Sheets to the Application

Once the packages have been installed, run the command shown in Listing 5-1 in the SportsStore folder to add the Bootstrap CSS stylesheet to the project.

Listing 5-1. Changing the Application Configuration

```
ng config projects.SportsStore.architect.build.options.styles \
'["src/styles.css",'\
'"node_modules/@fortawesome/fontawesome-free/css/all.min.css",'\
'"node_modules/bootstrap/dist/css/bootstrap.min.css"]'
```

If you are using Windows, then use a PowerShell prompt to run the command shown in Listing 5-2 in the example folder.

Listing 5-2. Changing the Application Configuration Using PowerShell

```
ng config projects.SportsStore.architect.build.options.styles `
'[""src/styles.css"",
""node_modules/@fortawesome/fontawesome-free/css/all.min.css"",
""node_modules/bootstrap/dist/css/bootstrap.min.css""]'
```

Run the command shown in Listing 5-3 in the SportsStore folder to ensure the configuration changes have been applied correctly.

Listing 5-3. Checking the Configuration Changes

```
ng config projects.SportsStore.architect.build.options.styles
```

The output from this command should contain the three files listed in Listing 5-1 and Listing 5-2, like this:

```
[
  "src/styles.css",
  "node_modules/@fortawesome/fontawesome-free/css/all.min.css",
  "node_modules/bootstrap/dist/css/bootstrap.min.css"
]
```

Preparing the RESTful Web Service

The SportsStore application will use asynchronous HTTP requests to get model data provided by a RESTful web service. As I describe in Chapter 23, REST is an approach to designing web services that uses the HTTP method or verb to specify an operation and the URL to select the data objects that the operation applies to.

I added the json-server package to the project in the previous section. This is an excellent package for creating web services from JSON data or JavaScript code. Add the statement shown in Listing 5-4 to the scripts section of the package.json file so that the json-server package can be started from the command line.

Listing 5-4. Adding a Script in the package.json File in the SportsStore Folder

```
...
"scripts": {
  "ng": "ng",
  "start": "ng serve",
  "build": "ng build",
  "watch": "ng build --watch --configuration development",
  "test": "ng test",
  "json": "json-server data.js -p 3500 -m authMiddleware.js"
},
...
```

To provide the json-server package with data to work with, I added a file called data.js in the SportsStore folder and added the code shown Listing 5-5, which will ensure that the same data is available whenever the json-server package is started so that I have a fixed point of reference during development.

■ **Tip** It is important to pay attention to the filenames when creating the configuration files. Some have the .json extension, which means they contain static data formatted as JSON. Other files have the .js extension, which means they contain JavaScript code. Each tool required for Angular development has expectations about its configuration file.

Listing 5-5. The Contents of the data.js File in the SportsStore Folder

```
module.exports = function () {
    return {
        products: [
            { id: 1, name: "Kayak", category: "Watersports",
                description: "A boat for one person", price: 275 },
            { id: 2, name: "Lifejacket", category: "Watersports",
                description: "Protective and fashionable", price: 48.95 },
            { id: 3, name: "Soccer Ball", category: "Soccer",
                description: "FIFA-approved size and weight", price: 19.50 },
            { id: 4, name: "Corner Flags", category: "Soccer",
                description: "Give your playing field a professional touch",
                price: 34.95 },
            { id: 5, name: "Stadium", category: "Soccer",
                description: "Flat-packed 35,000-seat stadium", price: 79500 },
            { id: 6, name: "Thinking Cap", category: "Chess",
                description: "Improve brain efficiency by 75%", price: 16 },
            { id: 7, name: "Unsteady Chair", category: "Chess",
                description: "Secretly give your opponent a disadvantage",
                price: 29.95 },
            { id: 8, name: "Human Chess Board", category: "Chess",
                description: "A fun game for the family", price: 75 },
            { id: 9, name: "Bling King", category: "Chess",
                description: "Gold-plated, diamond-studded King", price: 1200 }
        ],
        orders: []
    }
}
```

This code defines two data collections that will be presented by the RESTful web service. The `products` collection contains the products for sale to the customer, while the `orders` collection will contain the orders that customers have placed (but which is currently empty).

The data stored by the RESTful web service needs to be protected so that ordinary users can't modify the products or change the status of orders. The `json-server` package doesn't include any built-in authentication features, so I created a file called `authMiddleware.js` in the `SportsStore` folder and added the code shown in Listing 5-6.

Listing 5-6. The Contents of the authMiddleware.js File in the SportsStore Folder

```
const jwt = require("jsonwebtoken");

const APP_SECRET = "myappsecret";
const USERNAME = "admin";
const PASSWORD = "secret";

const mappings = {
    get: ["/api/orders", "/orders"],
    post: ["/api/products", "/products", "/api/categories", "/categories"]
}
```

```
function requiresAuth(method, url) {
    return (mappings[method.toLowerCase()] || [])
        .find(p => url.startsWith(p)) !== undefined;
}

module.exports = function (req, res, next) {
    if (req.url.endsWith("/login") && req.method == "POST") {
        if (req.body && req.body.name == USERNAME && req.body.password == PASSWORD) {
            let token = jwt.sign({ data: USERNAME, expiresIn: "1h" }, APP_SECRET);
            res.json({ success: true, token: token });
        } else {
            res.json({ success: false });
        }
        res.end();
        return;
    } else if (requiresAuth(req.method, req.url)) {
        let token = req.headers["authorization"] || "";
        if (token.startsWith("Bearer<")) {
            token = token.substring(7, token.length - 1);
            try {
                jwt.verify(token, APP_SECRET);
                next();
                return;
            } catch (err) { }
        }
        res.statusCode = 401;
        res.end();
        return;
    }
    next();
}
```

This code inspects HTTP requests sent to the RESTful web service and implements some basic security features. This is server-side code that is not directly related to Angular development, so don't worry if its purpose isn't immediately obvious. I explain the authentication and authorization process in Chapter 7, including how to authenticate users with Angular.

■ **Caution** Don't use the code in Listing 5-6 other than for the SportsStore application. It contains weak passwords that are hardwired into the code. This is fine for the SportsStore project because the emphasis is on client-side development with Angular, but this is not suitable for real projects.

Preparing the HTML File

Every Angular web application relies on an HTML file that is loaded by the browser and that loads and starts the application. Edit the index.html file in the SportsStore/src folder to remove the placeholder content and to add the elements shown in Listing 5-7.

Listing 5-7. Preparing the index.html File in the src Folder

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>SportsStore</title>
  <base href="/">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <link rel="icon" type="image/x-icon" href="favicon.ico">
</head>
<body class="p-2">
  <app>SportsStore Will Go Here</app>
</body>
</html>
```

The HTML document includes an app element, which is the placeholder for the SportsStore functionality. There is also a base element, which is required by the Angular URL routing features, which I add to the SportsStore project in Chapter 6.

Creating the Folder Structure

An important part of setting up an Angular application is to create the folder structure. The ng new command sets up a project that puts all of the application's files in the src folder, with the Angular files in the src/app folder. To add some structure to the project, create the additional folders shown in Table 5-1.

Table 5-1. *The Additional Folders Required for the SportsStore Project*

Folder	Description
SportsStore/src/app/model	This folder will contain the code for the data model.
SportsStore/src/app/store	This folder will contain the functionality for basic shopping.
SportsStore/src/app/admin	This folder will contain the functionality for administration.

Running the Example Application

Make sure that all the changes have been saved, and run the following command in the SportsStore folder:

```
ng serve --open
```

This command will start the development tools set up by the ng new command, which will automatically compile and package the code and content files in the src folder whenever a change is detected. A new browser window will open and show the content illustrated in Figure 5-1.

Figure 5-1. *Running the example application*

The development web server will start on port 4200, so the URL for the application will be http://
localhost:4200. You don't have to include the name of the HTML document because index.html is the
default file that the server responds with. (You will see errors in the browser's JavaScript console, which can
be ignored for the moment.)

Starting the RESTful Web Service

To start the RESTful web service, open a new command prompt, navigate to the SportsStore folder, and run
the following command:

```
npm run json
```

The RESTful web service is configured to run on port 3500. To test the web service request, use
the browser to request the URL http://localhost:3500/products/1. The browser will display a JSON
representation of one of the products defined in Listing 5-5, as follows:

```
{
  "id": 1,
  "name": "Kayak",
  "category": "Watersports",
  "description": "A boat for one person",
  "price": 275
}
```

Preparing the Angular Project Features

Every Angular project requires some basic preparation. In the sections that follow, I replace the placeholder
content to build the foundation for the SportsStore application.

Updating the Root Component

The root component is the Angular building block that will manage the contents of the app element in the HTML document from Listing 5-7. An application can contain many components, but there is always a root component that takes responsibility for the top-level content presented to the user. I edited the file called app.component.ts in the SportsStore/src/app folder and replaced the existing code with the statements shown in Listing 5-8.

Listing 5-8. Replacing the Contents of the app.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
  selector: "app",
  template: `<div class="bg-success p-2 text-center text-white">
                  This is SportsStore
             </div>`
})
export class AppComponent { }
```

The @Component decorator tells Angular that the AppComponent class is a component, and its properties configure how the component is applied. All the component properties are described in Chapter 15, but the properties shown in the listing are the most basic and most frequently used. The selector property tells Angular how to apply the component in the HTML document, and the template property defines the HTML content the component will display. Components can define inline templates, like this one, or they use external HTML files, which can make managing complex content easier.

There is no code in the AppComponent class because the root component in an Angular project exists just to manage the content shown to the user. Initially, I'll manage the content displayed by the root component manually, but in Chapter 6, I use a feature called *URL routing* to adapt the content automatically based on user actions.

Inspecting the Root Module

There are two types of Angular modules: feature modules and the root module. Feature modules are used to group related application functionality to make the application easier to manage. I create feature modules for each major functional area of the application, including the data model, the store interface presented to users, and the administration interface.

The root module is used to describe the application to Angular. The description includes which feature modules are required to run the application, which custom features should be loaded, and the name of the root component. The conventional name of the root module file is app.module.ts, which is created in the SportsStore/src/app folder. No changes are required to this file for the moment; Listing 5-9 shows its initial content.

Listing 5-9. The Initial Contents of the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';

@NgModule({
```

```
  declarations: [AppComponent],
  imports: [BrowserModule],
  providers: [],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

Similar to the root component, there is no code in the root module's class. That's because the root module only really exists to provide information through the @NgModule decorator. The imports property tells Angular that it should load the BrowserModule feature module, which contains the core Angular features required for a web application.

The declarations property tells Angular that it should load the root component, the providers property tells Angular about the shared objects used by the application, and the bootstrap property tells Angular that the root component is the AppComponent class. I'll add information to this decorator's properties as I add features to the SportsStore application, but this basic configuration is enough to start the application.

Inspecting the Bootstrap File

The next piece of plumbing is the bootstrap file, which starts the application. This book is focused on using Angular to create applications that work in web browsers, but the Angular platform can be ported to different environments. The bootstrap file uses the Angular browser platform to load the root module and start the application. No changes are required for the contents of the main.ts file, which is in the SportsStore/src folder, as shown in Listing 5-10.

Listing 5-10. The Contents of the main.ts File in the src Folder

```
import { enableProdMode } from '@angular/core';
import { platformBrowserDynamic } from '@angular/platform-browser-dynamic';

import { AppModule } from './app/app.module';
import { environment } from './environments/environment';

if (environment.production) {
  enableProdMode();
}

platformBrowserDynamic().bootstrapModule(AppModule)
  .catch(err => console.error(err));
```

The development tools detect the changes to the project's file, compile the code files, and automatically reload the browser, producing the content shown in Figure 5-2.

Figure 5-2. *Starting the SportsStore application*

Starting the Data Model

The best place to start any new project is the data model. I want to get to the point where you can see some Angular features at work, so rather than define the data model from end to end, I am going to put some basic functionality in place using dummy data. I'll use this data to create user-facing features and then return to the data model to wire it up to the RESTful web service in Chapter 6.

Creating the Model Classes

Every data model needs classes that describe the types of data that will be contained in the data model. For the SportsStore application, this means classes that describe the products sold in the store and the orders that are received from customers.

Being able to describe products will be enough to get started with the SportsStore application, and I'll create other model classes to support features as I implement them. I created a file called `product.model.ts` in the `SportsStore/src/app/model` folder and added the code shown in Listing 5-11.

Listing 5-11. The Contents of the product.model.ts File in the src/app/model Folder

```
export class Product {

    constructor(
        public id?: number,
        public name?: string,
        public category?: string,
        public description?: string,
        public price?: number) { }
}
```

The `Product` class defines a constructor that accepts `id`, `name`, `category`, `description`, and `price` properties, which correspond to the structure of the data used to populate the RESTful web service. The question marks (the ? characters) that follow the parameter names indicate that these are optional parameters that can be omitted when creating new objects using the `Product` class, which can be useful when writing applications where model object properties will be populated using HTML forms.

Creating the Dummy Data Source

To prepare for the transition from dummy to real data, I am going to feed the application data using a data source. The rest of the application won't know where the data is coming from, which will make the switch to getting data using HTTP requests seamless.

I added a file called `static.datasource.ts` to the `SportsStore/src/app/model` folder and defined the class shown in Listing 5-12.

Listing 5-12. The Contents of the static.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { Observable, from } from "rxjs";

@Injectable()
export class StaticDataSource {
    private products: Product[] = [
        new Product(1, "Product 1", "Category 1", "Product 1 (Category 1)", 100),
        new Product(2, "Product 2", "Category 1", "Product 2 (Category 1)", 100),
        new Product(3, "Product 3", "Category 1", "Product 3 (Category 1)", 100),
        new Product(4, "Product 4", "Category 1", "Product 4 (Category 1)", 100),
        new Product(5, "Product 5", "Category 1", "Product 5 (Category 1)", 100),
        new Product(6, "Product 6", "Category 2", "Product 6 (Category 2)", 100),
        new Product(7, "Product 7", "Category 2", "Product 7 (Category 2)", 100),
        new Product(8, "Product 8", "Category 2", "Product 8 (Category 2)", 100),
        new Product(9, "Product 9", "Category 2", "Product 9 (Category 2)", 100),
        new Product(10, "Product 10", "Category 2", "Product 10 (Category 2)", 100),
        new Product(11, "Product 11", "Category 3", "Product 11 (Category 3)", 100),
        new Product(12, "Product 12", "Category 3", "Product 12 (Category 3)", 100),
        new Product(13, "Product 13", "Category 3", "Product 13 (Category 3)", 100),
        new Product(14, "Product 14", "Category 3", "Product 14 (Category 3)", 100),
        new Product(15, "Product 15", "Category 3", "Product 15 (Category 3)", 100),
    ];

    getProducts(): Observable<Product[]> {
        return from([this.products]);
    }
}
```

The `StaticDataSource` class defines a method called `getProducts`, which returns the dummy data. The result of calling the `getProducts` method is an `Observable<Product[]>`, which is an `Observable` that produces arrays of `Product` objects.

The `Observable` class is provided by the Reactive Extensions package, which is used by Angular to handle state changes in applications, as described in Chapter 4. An `Observable` object represents an asynchronous task that will produce a result at some point in the future. Angular exposes its use of `Observable` objects for some features, including making HTTP requests, and this is why the `getProducts` method returns an `Observable<Product[]>` rather than simply returning the data synchronously.

The `@Injectable` decorator has been applied to the `StaticDataSource` class. This decorator is used to tell Angular that this class will be used as a service, which allows other classes to access its functionality through a feature called *dependency injection*, which is described in Chapters 17 and 18. You'll see how services work as the application takes shape.

■ **Tip**   Notice that I have to import Injectable from the @angular/core JavaScript module so that I can apply the @Injectable decorator. I won't highlight all the different Angular classes that I import for the SportsStore example, but you can get full details in the chapters that describe the features they relate to.

Creating the Model Repository

The data source is responsible for providing the application with the data it requires, but access to that data is typically mediated by a *repository*, which is responsible for distributing that data to individual application building blocks so that the details of how the data has been obtained are kept hidden. I added a file called product.repository.ts in the SportsStore/src/app/model folder and defined the class shown in Listing 5-13.

Listing 5-13.   The Contents of the product.repository.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";

@Injectable()
export class ProductRepository {
    private products: Product[] = [];
    private categories: string[] = [];

    constructor(private dataSource: StaticDataSource) {
        dataSource.getProducts().subscribe(data => {
            this.products = data;
            this.categories = data.map(p => p.category ?? "(None)")
                .filter((c, index, array) => array.indexOf(c) == index).sort();
        });
    }

    getProducts(category?: string): Product[] {
        return this.products
            .filter(p => category == undefined || category == p.category);
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => p.id == id);
    }

    getCategories(): string[] {
        return this.categories;
    }
}
```

When Angular needs to create a new instance of the repository, it will inspect the class and see that it needs a StaticDataSource object to invoke the ProductRepository constructor and create a new object. The repository constructor calls the data source's getProducts method and then uses the subscribe method on the Observable object that is returned to receive the product data.

Creating the Feature Module

I am going to define an Angular feature model that will allow the data model functionality to be easily used elsewhere in the application. I added a file called model.module.ts in the SportsStore/src/app/model folder and defined the class shown in Listing 5-14.

■ **Tip**   Don't worry if all the filenames seem similar and confusing. You will get used to the way that Angular applications are structured as you work through the other chapters in the book, and you will soon be able to look at the files in an Angular project and know what they are all intended to do.

Listing 5-14. The Contents of the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { ProductRepository } from "./product.repository";
import { StaticDataSource } from "./static.datasource";

@NgModule({
    providers: [ProductRepository, StaticDataSource]
})
export class ModelModule { }
```

The @NgModule decorator is used to create feature modules, and its properties tell Angular how the module should be used. There is only one property in this module, providers, and it tells Angular which classes should be used as services for the dependency injection feature, which is described in Chapters 17 and 18. Feature modules—and the @NgModule decorator—are described in Chapter 19.

Starting the Store

Now that the data model is in place, I can start to build out the store functionality, which will let the user see the products for sale and place orders for them. The basic structure of the store will be a two-column layout, with category buttons that allow the list of products to be filtered and a table that contains the list of products, as illustrated by Figure 5-3.

Figure 5-3. *The basic structure of the store*

In the sections that follow, I'll use Angular features and the data in the model to create the layout shown in the figure.

Creating the Store Component and Template

As you become familiar with Angular, you will learn that features can be combined to solve the same problem in different ways. I try to introduce some variety into the SportsStore project to showcase some important Angular features, but I am going to keep things simple the moment in the interest of being able to get the project started quickly.

With this in mind, the starting point for the store functionality will be a new component, which is a class that provides data and logic to an HTML template, which contains data bindings that generate content dynamically. I created a file called store.component.ts in the SportsStore/src/app/store folder and defined the class shown in Listing 5-15.

Listing 5-15. The Contents of the store.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";

@Component({
    selector: "store",
    templateUrl: "store.component.html"
})
export class StoreComponent {

    constructor(private repository: ProductRepository) { }

    get products(): Product[] {
        return this.repository.getProducts();
    }
```

```
    get categories(): string[] {
        return this.repository.getCategories();
    }
}
```

The @Component decorator has been applied to the StoreComponent class, which tells Angular that it is a component. The decorator's properties tell Angular how to apply the component to HTML content (using an element called store) and how to find the component's template (in a file called store.component.html).

The StoreComponent class provides the logic that will support the template content. The constructor receives a ProductRepository object as an argument, provided through the dependency injection feature described in Chapters 17 and 18. The component defines products and categories properties that will be used to generate HTML content in the template, using data obtained from the repository. To provide the component with its template, I created a file called store.component.html in the SportsStore/src/app/store folder and added the HTML content shown in Listing 5-16.

Listing 5-16. The Contents of the store.component.html File in the src/app/store Folder

```html
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
    <div class="row text-white">
        <div class="col-3 bg-info p-2">
            {{categories.length}} Categories
        </div>
        <div class="col-9 bg-success p-2">
            {{products.length}} Products
        </div>
    </div>
</div>
```

The template is simple, just to get started. Most of the elements provide the structure for the store layout and apply some Bootstrap CSS classes. There are only two Angular data bindings at the moment, which are denoted by the {{ and }} characters. These are *string interpolation* bindings, and they tell Angular to evaluate the binding expression and insert the result into the element. The expressions in these bindings display the number of products and categories provided by the store component.

Creating the Store Feature Module

There isn't much store functionality in place yet, but even so, some additional work is required to wire it up to the rest of the application. To create the Angular feature module for the store functionality, I created a file called store.module.ts in the SportsStore/src/app/store folder and added the code shown in Listing 5-17.

Listing 5-17. The Contents of the store.module.ts File in the src/app/store Folder

```typescript
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule } from "@angular/forms";
```

```
import { ModelModule } from "../model/model.module";
import { StoreComponent } from "./store.component";

@NgModule({
    imports: [ModelModule, BrowserModule, FormsModule],
    declarations: [StoreComponent],
    exports: [StoreComponent]
})
export class StoreModule { }
```

The @NgModule decorator configures the module, using the imports property to tell Angular that the store module depends on the model module as well as BrowserModule and FormsModule, which contain the standard Angular features for web applications and for working with HTML form elements. The decorator uses the declarations property to tell Angular about the StoreComponent class, and the exports property tells Angular the class can be also used in other parts of the application, which is important because it will be used by the root module.

Updating the Root Component and Root Module

Applying the basic model and store functionality requires updating the application's root module to import the two feature modules and also requires updating the root module's template to add the HTML element to which the component in the store module will be applied. Listing 5-18 shows the change to the root component's template.

Listing 5-18. Adding an Element in the app.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "app",
    template: "<store></store>"
})
export class AppComponent { }
```

The store element replaces the previous content in the root component's template and corresponds to the value of the selector property of the @Component decorator in Listing 5-15. Listing 5-19 shows the change required to the root module so that Angular loads the feature module that contains the store functionality.

Listing 5-19. Importing Feature Modules in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { StoreModule } from "./store/store.module";

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, StoreModule],
  providers: [],
```

114

```
    bootstrap: [AppComponent]
})
export class AppModule { }
```

When you save the changes to the root module, Angular will have all the details it needs to load the application and display the content from the store module, as shown in Figure 5-4.

If you don't see the expected result, then stop the Angular development tools and use the `ng serve` command to start them again. This will repeat the build process for the project and should reflect the changes you have made.

All the building blocks created in the previous section work together to display the—admittedly simple—content, which shows how many products there are and how many categories they fit in to.

Figure 5-4. *Basic features in the SportsStore application*

Adding Store Features the Product Details

The nature of Angular development begins with a slow start as the foundation of the project is put in place and the basic building blocks are created. But once that's done, new features can be created relatively easily. In the sections that follow, I add features to the store so that the user can see the products on offer.

Displaying the Product Details

The obvious place to start is to display details for the products so that the customer can see what's on offer. Listing 5-20 adds HTML elements to the store component's template with data bindings that generate content for each product provided by the component.

Listing 5-20. Adding Elements in the store.component.html File in the src/app/store Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
    <div class="row text-white">
        <div class="col-3 bg-info p-2">
```

```
            {{categories.length}} Categories
        </div>
        <div class="col-9 p-2 text-dark">
            <div *ngFor="let product of products" class="card m-1 p-1 bg-light">
                <h4>
                    {{product.name}}
                    <span class="badge rounded-pill bg-primary" style="float:right">
                        {{ product.price | currency:"USD":"symbol":"2.2-2" }}
                    </span>
                </h4>
                <div class="card-text bg-white p-1">{{product.description}}</div>
            </div>
        </div>
    </div>
</div>
```

Most of the elements control the layout and appearance of the content. The most important change is the addition of an Angular data binding expression.

```
...
<div *ngFor="let product of products" class="card m-1 p-1 bg-light">
...
```

This is an example of a directive, which transforms the HTML element it is applied to. This specific directive is called ngFor, and it transforms the div element by duplicating it for each object returned by the component's products property. Angular includes a range of built-in directives that perform the most commonly required tasks, as described in Chapter 11.

As it duplicates the div element, the current object is assigned to a variable called product, which allows it to be referred to in other data bindings, such as this one, which inserts the value of the current product's name description property as the content of the div element:

```
...
<div class="card-text p-1 bg-white">{{product.description}}</div>
...
```

Not all data in an application's data model can be displayed directly to the user. Angular includes a feature called *pipes*, which are classes used to transform or prepare a data value for its use in a data binding. There are several built-in pipes included with Angular, including the currency pipe, which formats number values as currencies, like this:

```
...
{{ product.price | currency:"USD":"symbol":"2.2-2" }}
...
```

The syntax for applying pipes can be a little awkward, but the expression in this binding tells Angular to format the price property of the current product using the currency pipe, with the currency conventions from the United States. Save the changes to the template, and you will see a list of the products in the data model displayed as a long list, as illustrated in Figure 5-5.

Figure 5-5. *Displaying product information*

Adding Category Selection

Adding support for filtering the list of products by category requires preparing the store component so that it keeps track of which category the user wants to display and requires changing the way that data is retrieved to use that category, as shown in Listing 5-21.

Listing 5-21. Adding Category Filtering in the store.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";

@Component({
    selector: "store",
    templateUrl: "store.component.html"
})
export class StoreComponent {
    selectedCategory: string | undefined;

    constructor(private repository: ProductRepository) { }

    get products(): Product[] {
        return this.repository.getProducts(this.selectedCategory);
    }
```

```
    get categories(): string[] {
        return this.repository.getCategories();
    }

    changeCategory(newCategory?: string) {
        this.selectedCategory = newCategory;
    }
}
```

The changes are simple because they build on the foundation that took so long to create at the start of the chapter. The selectedCategory property is assigned the user's choice of category (where undefined means all categories) and is used in the updateData method as an argument to the getProducts method, delegating the filtering to the data source. The changeCategory method brings these two members together in a method that can be invoked when the user makes a category selection.

Listing 5-22 shows the corresponding changes to the component's template to provide the user with the set of buttons that change the selected category and show which category has been picked.

Listing 5-22. Adding Category Buttons in the store.component.html File in the src/app/store Folder

```html
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
    <div class="row text-white">
        <div class="col-3 p-2">
            <div class="d-grid gap-2">
                <button class="btn btn-outline-primary" (click)="changeCategory()">
                    Home
                </button>
                <button *ngFor="let cat of categories"
                        class="btn btn-outline-primary"
                        [class.active]="cat == selectedCategory"
                        (click)="changeCategory(cat)">
                    {{cat}}
                </button>
            </div>
        </div>
        <div class="col-9 p-2 text-dark">
            <div *ngFor="let product of products" class="card m-1 p-1 bg-light">
                <h4>
                    {{product.name}}
                    <span class="badge rounded-pill bg-primary" style="float:right">
                        {{ product.price | currency:"USD":"symbol":"2.2-2" }}
                    </span>
                </h4>
                <div class="card-text bg-white p-1">{{product.description}}</div>
            </div>
        </div>
    </div>
</div>
```

There are two new button elements in the template. The first is a Home button, and it has an event binding that invokes the component's changeCategory method when the button is clicked. No argument is provided to the method, which has the effect of setting the category to null and selecting all the products.

The ngFor binding has been applied to the other button element, with an expression that will repeat the element for each value in the array returned by the component's categories property. The button has a click event binding whose expression calls the changeCategory method to select the current category, which will filter the products displayed to the user. There is also a class binding, which adds the button element to the active class when the category associated with the button is the selected category. This provides the user with visual feedback when the categories are filtered, as shown in Figure 5-6.

Figure 5-6. *Selecting product categories*

Adding Product Pagination

Filtering the products by category has helped make the product list more manageable, but a more typical approach is to break the list into smaller sections and present each of them as a page, along with navigation buttons that move between the pages. Listing 5-23 enhances the store component so that it keeps track of the current page and the number of items on a page.

Listing 5-23. Adding Pagination Support in the store.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";

@Component({
    selector: "store",
    templateUrl: "store.component.html"
})
export class StoreComponent {
    selectedCategory: string | undefined;
    productsPerPage = 4;
    selectedPage = 1;
```

```
    constructor(private repository: ProductRepository) { }

    get products(): Product[] {
        let pageIndex = (this.selectedPage - 1) * this.productsPerPage
        return this.repository.getProducts(this.selectedCategory)
            .slice(pageIndex, pageIndex + this.productsPerPage);
    }

    get categories(): string[] {
        return this.repository.getCategories();
    }

    changeCategory(newCategory?: string) {
        this.selectedCategory = newCategory;
    }

    changePage(newPage: number) {
        this.selectedPage = newPage;
    }

    changePageSize(newSize: number) {
        this.productsPerPage = Number(newSize);
        this.changePage(1);
    }

    get pageNumbers(): number[] {
        return Array(Math.ceil(this.repository
            .getProducts(this.selectedCategory).length / this.productsPerPage))
                .fill(0).map((x, i) => i + 1);
    }
}
```

There are two new features in this listing. The first is the ability to get a page of products, and the second is to change the size of the pages, allowing the number of products that each page contains to be altered.

There is an oddity that the component has to work around. There is a limitation in the built-in ngFor directive that Angular provides, which can generate content only for the objects in an array or a collection, rather than using a counter. Since I need to generate numbered page navigation buttons, this means I need to create an array that contains the numbers I need, like this:

```
...
return Array(Math.ceil(this.repository.getProducts(this.selectedCategory).length
    / this.productsPerPage)).fill(0).map((x, i) => i + 1);
...
```

This statement creates a new array, fills it with the value 0, and then uses the map method to generate a new array with the number sequence. This works well enough to implement the pagination feature, but it feels awkward, and I demonstrate a better approach in the next section. Listing 5-24 shows the changes to the store component's template to implement the pagination feature.

Listing 5-24. Adding Pagination in the store.component.html File in the src/app/store Folder

```html
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
    <div class="row text-white">
        <div class="col-3 p-2">
            <div class="d-grid gap-2">
                <button class="btn btn-outline-primary" (click)="changeCategory()">
                    Home
                  </button>
                <button *ngFor="let cat of categories"
                        class="btn btn-outline-primary"
                        [class.active]="cat == selectedCategory"
                        (click)="changeCategory(cat)">
                  {{cat}}
                </button>
            </div>
        </div>
        <div class="col-9 p-2 text-dark">
            <div *ngFor="let product of products" class="card m-1 p-1 bg-light">
                <h4>
                    {{product.name}}
                    <span class="badge rounded-pill bg-primary" style="float:right">
                        {{ product.price | currency:"USD":"symbol":"2.2-2" }}
                    </span>
                </h4>
                <div class="card-text bg-white p-1">{{product.description}}</div>
            </div>
            <div class="form-inline float-start mr-1">
                <select class="form-control" [value]="productsPerPage"
                        (change)="changePageSize($any($event).target.value)">
                    <option value="3">3 per Page</option>
                    <option value="4">4 per Page</option>
                    <option value="6">6 per Page</option>
                    <option value="8">8 per Page</option>
                </select>
            </div>
            <div class="btn-group float-end">
                <button *ngFor="let page of pageNumbers" (click)="changePage(page)"
                        class="btn btn-outline-primary"
                        [class.active]="page == selectedPage">
                    {{page}}
                </button>
            </div>
        </div>
    </div>
</div>
```

The new elements add a `select` element that allows the size of the page to be changed and a set of buttons that navigate through the product pages. The new elements have data bindings to wire them up to the properties and methods provided by the component. The result is a more manageable set of products, as shown in Figure 5-7.

■ **Tip**   The `select` element in Listing 5-24 is populated with `option` elements that are statically defined, rather than created using data from the component. One impact of this is that when the selected value is passed to the `changePageSize` method, it will be a `string` value, which is why the argument is parsed to a `number` before being used to set the page size in Listing 5-23. Care must be taken when receiving data values from HTML elements to ensure they are of the expected type. TypeScript type annotations don't help in this situation because the data binding expression is evaluated at runtime, long after the TypeScript compiler has generated JavaScript code that doesn't contain the extra type information.

Figure 5-7. *Pagination for products*

Creating a Custom Directive

In this section, I am going to create a custom directive so that I don't have to generate an array full of numbers to create the page navigation buttons. Angular provides a good range of built-in directives, but it is a simple process to create your own directives to solve problems that are specific to your application or to

support features that the built-in directives don't have. I added a file called counter.directive.ts in the src/app/store folder and used it to define the class shown in Listing 5-25.

Listing 5-25. The Contents of the counter.directive.ts File in the src/app/store Folder

```
import {
    Directive, ViewContainerRef, TemplateRef, Input, SimpleChanges
} from "@angular/core";

@Directive({
    selector: "[counterOf]"
})
export class CounterDirective {

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>) {
    }

    @Input("counterOf")
    counter: number = 0;

    ngOnChanges(changes: SimpleChanges) {
        this.container.clear();
        for (let i = 0; i < this.counter; i++) {
            this.container.createEmbeddedView(this.template,
                new CounterDirectiveContext(i + 1));
        }
    }
}

class CounterDirectiveContext {
    constructor(public $implicit: any) { }
}
```

This is an example of a structural directive, which is described in detail in Chapter 14. This directive is applied to elements through a counter property and relies on special features that Angular provides for creating content repeatedly, just like the built-in ngFor directive. In this case, rather than yield each object in a collection, the custom directive yields a series of numbers that can be used to create the page navigation buttons.

■ **Tip** This directive deletes all the content it has created and starts again when the number of pages changes. This can be an expensive process in more complex directives, and I explain how to improve performance in Chapter 14.

To use the directive, it must be added to the declarations property of its feature module, as shown in Listing 5-26.

Listing 5-26. Registering the Custom Directive in the store.module.ts File in the src/app/store Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { StoreComponent } from "./store.component";
import { CounterDirective } from "./counter.directive";

@NgModule({
    imports: [ModelModule, BrowserModule, FormsModule],
    declarations: [StoreComponent, CounterDirective],
    exports: [StoreComponent]
})
export class StoreModule { }
```

Now that the directive has been registered, it can be used in the store component's template to replace the ngFor directive, as shown in Listing 5-27.

Listing 5-27. Replacing the Built-in Directive in the store.component.html File in the src/app/store Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
    <div class="row text-white">
        <div class="col-3 p-2">
            <div class="d-grid gap-2">
                <button class="btn btn-outline-primary" (click)="changeCategory()">
                    Home
                </button>
                <button *ngFor="let cat of categories"
                        class="btn btn-outline-primary"
                        [class.active]="cat == selectedCategory"
                        (click)="changeCategory(cat)">
                    {{cat}}
                </button>
            </div>
        </div>
        <div class="col-9 p-2 text-dark">
            <div *ngFor="let product of products" class="card m-1 p-1 bg-light">
                <h4>
                    {{product.name}}
                    <span class="badge rounded-pill bg-primary" style="float:right">
                        {{ product.price | currency:"USD":"symbol":"2.2-2" }}
                    </span>
                </h4>
                <div class="card-text bg-white p-1">{{product.description}}</div>
            </div>
```

```
            <div class="form-inline float-start mr-1">
                <select class="form-control" [value]="productsPerPage"
                        (change)="changePageSize($any($event).target.value)">
                    <option value="3">3 per Page</option>
                    <option value="4">4 per Page</option>
                    <option value="6">6 per Page</option>
                    <option value="8">8 per Page</option>
                </select>
            </div>
            <div class="btn-group float-end">
                <button *counter="let page of pageCount" (click)="changePage(page)"
                        class="btn btn-outline-primary"
                        [class.active]="page == selectedPage">
                    {{page}}
                </button>
            </div>
        </div>
    </div>
</div>
```

The new data binding relies on a property called pageCount to configure the custom directive.
In Listing 5-28, I have replaced the array of numbers with a simple number that provides the expression value.

Listing 5-28. Supporting the Custom Directive in the store.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";

@Component({
    selector: "store",
    templateUrl: "store.component.html"
})
export class StoreComponent {
    selectedCategory: string | undefined;
    productsPerPage = 4;
    selectedPage = 1;

    constructor(private repository: ProductRepository) { }

    get products(): Product[] {
        let pageIndex = (this.selectedPage - 1) * this.productsPerPage
        return this.repository.getProducts(this.selectedCategory)
            .slice(pageIndex, pageIndex + this.productsPerPage);
    }

    get categories(): string[] {
        return this.repository.getCategories();
    }
```

```
    changeCategory(newCategory?: string) {
        this.selectedCategory = newCategory;
    }

    changePage(newPage: number) {
        this.selectedPage = newPage;
    }

    changePageSize(newSize: number) {
        this.productsPerPage = Number(newSize);
        this.changePage(1);
    }

    // get pageNumbers(): number[] {
    //     return Array(Math.ceil(this.repository
    //         .getProducts(this.selectedCategory).length / this.productsPerPage))
    //             .fill(0).map((x, i) => i + 1);
    // }

    get pageCount(): number {
        return Math.ceil(this.repository
            .getProducts(this.selectedCategory).length / this.productsPerPage)
    }
}
```

There is no visual change to the SportsStore application, but this section has demonstrated that it is possible to supplement the built-in Angular functionality with custom code that is tailored to the needs of a specific project.

Summary

In this chapter, I started the SportsStore project. The early part of the chapter was spent creating the foundation for the project, including creating the root building blocks for the application and starting work on the feature modules. Once the foundation was in place, I was able to rapidly add features to display the dummy model data to the user, add pagination, and filter the products by category. I finished the chapter by creating a custom directive to demonstrate how the built-in features provided by Angular can be supplemented by custom code. In the next chapter, I continue to build the SportsStore application.

CHAPTER 6

■ ■ ■

SportsStore: Orders and Checkout

In this chapter, I continue adding features to the SportsStore application that I created in Chapter 5. I add support for a shopping cart and a checkout process and replace the dummy data with the data from the RESTful web service.

Preparing the Example Application

No preparation is required for this chapter, which continues using the SportsStore project from Chapter 5. To start the RESTful web service, open a command prompt and run the following command in the SportsStore folder:

```
npm run json
```

Open a second command prompt and run the following command in the SportsStore folder to start the development tools and HTTP server:

```
ng serve --open
```

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Creating the Cart

The user needs a cart into which products can be placed and used to start the checkout process. In the sections that follow, I'll add a cart to the application and integrate it into the store so that the user can select the products they want.

Creating the Cart Model

The starting point for the cart feature is a new model class that will be used to gather together the products that the user has selected. I added a file called `cart.model.ts` in the `src/app/model` folder and used it to define the class shown in Listing 6-1.

Listing 6-1. The Contents of the cart.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";

@Injectable()
export class Cart {
    public lines: CartLine[] = [];
    public itemCount: number = 0;
    public cartPrice: number = 0;

    addLine(product: Product, quantity: number = 1) {
        let line = this.lines.find(line => line.product.id == product.id);
        if (line != undefined) {
            line.quantity += quantity;
        } else {
            this.lines.push(new CartLine(product, quantity));
        }
        this.recalculate();
    }

    updateQuantity(product: Product, quantity: number) {
        let line = this.lines.find(line => line.product.id == product.id);
        if (line != undefined) {
            line.quantity = Number(quantity);
        }
        this.recalculate();
    }

    removeLine(id: number) {
        let index = this.lines.findIndex(line => line.product.id == id);
        this.lines.splice(index, 1);
        this.recalculate();
    }

    clear() {
        this.lines = [];
        this.itemCount = 0;
        this.cartPrice = 0;
    }

    private recalculate() {
        this.itemCount = 0;
        this.cartPrice = 0;
```

```
        this.lines.forEach(l => {
            this.itemCount += l.quantity;
            this.cartPrice += l.lineTotal;
        })
    }
}

export class CartLine {

    constructor(public product: Product,
        public quantity: number) {}

    get lineTotal() {
        return this.quantity * (this.product.price ?? 0);
    }
}
```

Individual product selections are represented as an array of CartLine objects, each of which contains a Product object and a quantity. The Cart class keeps track of the total number of items that have been selected and their total cost.

There should be a single Cart object used throughout the entire application, ensuring that any part of the application can access the user's product selections. To achieve this, I am going to make the Cart a service, which means that Angular will take responsibility for creating an instance of the Cart class and will use it when it needs to create a component that has a Cart constructor argument. This is another use of the Angular dependency injection feature, which can be used to share objects throughout an application and which is described in detail in Chapters 17 and 18. The @Injectable decorator, which has been applied to the Cart class in the listing, indicates that this class will be used as a service.

■ **Note**   Strictly speaking, the @Injectable decorator is required only when a class has its own constructor arguments to resolve, but it is a good idea to apply it anyway because it serves as a signal that the class is intended for use as a service.

Listing 6-2 registers the Cart class as a service in the providers property of the model feature module class.

Listing 6-2. Registering the Cart as a Service in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { ProductRepository } from "./product.repository";
import { StaticDataSource } from "./static.datasource";
import { Cart } from "./cart.model";

@NgModule({
    providers: [ProductRepository, StaticDataSource, Cart]
})
export class ModelModule { }
```

Creating the Cart Summary Components

Components are the essential building blocks for Angular applications because they allow discrete units of code and content to be easily created. The SportsStore application will show users a summary of their product selections in the title area of the page, which I am going to implement by creating a component. I added a file called `cartSummary.component.ts` in the `src/app/store` folder and used it to define the component shown in Listing 6-3.

Listing 6-3. The Contents of the cartSummary.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Cart } from "../model/cart.model";

@Component({
    selector: "cart-summary",
    templateUrl: "cartSummary.component.html"
})
export class CartSummaryComponent {

    constructor(public cart: Cart) { }
}
```

When Angular needs to create an instance of this component, it will have to provide a `Cart` object as a constructor argument, using the service that I configured in the previous section by adding the `Cart` class to the feature module's `providers` property. The default behavior for services means that a single `Cart` object will be created and shared throughout the application, although there are different service behaviors available (as described in Chapter 18).

To provide the component with a template, I created an HTML file called `cartSummary.component.html` in the same folder as the component class file and added the markup shown in Listing 6-4.

Listing 6-4. The Contents of the cartSummary.component.html File in the src/app/store Folder

```
<div class="float-end">
    <small class="fs-6">
        Your cart:
        <span *ngIf="cart.itemCount > 0">
            {{ cart.itemCount }} item(s)
            {{ cart.cartPrice | currency:"USD":"symbol":"2.2-2" }}
        </span>
        <span *ngIf="cart.itemCount == 0">
            (empty)
        </span>
    </small>
    <button class="btn btn-sm bg-dark text-white" [disabled]="cart.itemCount == 0">
        <i class="fa fa-shopping-cart"></i>
    </button>
</div>
```

This template uses the `Cart` object provided by its component to display the number of items in the cart and the total cost. There is also a button that will start the checkout process when I add it to the application later in the chapter.

■ **Tip** The button element in Listing 6-4 is styled using classes defined by Font Awesome, which is one of the packages in the package.json file from Chapter 5. This open-source package provides excellent support for icons in web applications, including the shopping cart I need for the SportsStore application. See http://fontawesome.io for details.

Listing 6-5 registers the new component with the store feature module, in preparation for using it in the next section.

Listing 6-5. Registering the Component in the store.module.ts File in the src/app/store Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { StoreComponent } from "./store.component";
import { CounterDirective } from "./counter.directive";
import { CartSummaryComponent } from "./cartSummary.component";

@NgModule({
    imports: [ModelModule, BrowserModule, FormsModule],
    declarations: [StoreComponent, CounterDirective, CartSummaryComponent],
    exports: [StoreComponent]
})
export class StoreModule { }
```

Integrating the Cart into the Store

The store component is the key to integrating the cart and the cart widget into the application. Listing 6-6 updates the store component so that its constructor has a Cart parameter and defines a method that will add a product to the cart.

Listing 6-6. Adding Cart Support in the store.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";
import { Cart } from "../model/cart.model";

@Component({
    selector: "store",
    templateUrl: "store.component.html"
})
export class StoreComponent {
    selectedCategory: string | undefined;
    productsPerPage = 4;
    selectedPage = 1;

    constructor(private repository: ProductRepository,
        private cart: Cart) { }
```

```
    get products(): Product[] {
        let pageIndex = (this.selectedPage - 1) * this.productsPerPage
        return this.repository.getProducts(this.selectedCategory)
            .slice(pageIndex, pageIndex + this.productsPerPage);
    }

    get categories(): string[] {
        return this.repository.getCategories();
    }

    changeCategory(newCategory?: string) {
        this.selectedCategory = newCategory;
    }

    changePage(newPage: number) {
        this.selectedPage = newPage;
    }

    changePageSize(newSize: number) {
        this.productsPerPage = Number(newSize);
        this.changePage(1);
    }

    get pageCount(): number {
        return Math.ceil(this.repository
            .getProducts(this.selectedCategory).length / this.productsPerPage)
    }

    addProductToCart(product: Product) {
        this.cart.addLine(product);
    }
}
```

To complete the integration of the cart into the store component, Listing 6-7 adds the element that will apply the cart summary component to the store component's template and adds a button to each product description with the event binding that calls the addProductToCart method.

Listing 6-7. Applying the Component in the store.component.html File in the src/app/store Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">
                SPORTS STORE
                <cart-summary></cart-summary>
            </span>
        </div>
    </div>
    <div class="row text-white">
        <div class="col-3 p-2">
            <div class="d-grid gap-2">
```

```
                <button class="btn btn-outline-primary" (click)="changeCategory()">
                    Home
                </button>
                <button *ngFor="let cat of categories"
                        class="btn btn-outline-primary"
                        [class.active]="cat == selectedCategory"
                        (click)="changeCategory(cat)">
                    {{cat}}
                </button>
            </div>
        </div>
        <div class="col-9 p-2 text-dark">
            <div *ngFor="let product of products" class="card m-1 p-1 bg-light">
                <h4>
                    {{product.name}}
                    <span class="badge rounded-pill bg-primary" style="float:right">
                        {{ product.price | currency:"USD":"symbol":"2.2-2" }}
                    </span>
                </h4>
                <div class="card-text bg-white p-1">
                    {{product.description}}
                    <button class="btn btn-success btn-sm float-end"
                            (click)="addProductToCart(product)">
                        Add To Cart
                    </button>
                </div>
            </div>
            <div class="form-inline float-start mr-1">
                <select class="form-control" [value]="productsPerPage"
                        (change)="changePageSize($any($event).target.value)">
                    <option value="3">3 per Page</option>
                    <option value="4">4 per Page</option>
                    <option value="6">6 per Page</option>
                    <option value="8">8 per Page</option>
                </select>
            </div>
            <div class="btn-group float-end">
                <button *counter="let page of pageCount" (click)="changePage(page)"
                        class="btn btn-outline-primary"
                        [class.active]="page == selectedPage">
                    {{page}}
                </button>
            </div>
        </div>
    </div>
</div>
</div>
```

The result is a button for each product that adds it to the cart, as shown in Figure 6-1. The full cart process isn't complete yet, but you can see the effect of each addition in the cart summary at the top of the page.

Figure 6-1. *Adding cart support to the SportsStore application*

Notice how clicking one of the Add To Cart buttons updates the summary component's content automatically. This happens because there is a single `Cart` object being shared between two components, and changes made by one component are reflected when Angular evaluates the data binding expressions in the other component.

Adding URL Routing

Most applications need to show different content to the user at different times. In the case of the SportsStore application, when the user clicks one of the Add To Cart buttons, they should be shown a detailed view of their selected products and given the chance to start the checkout process.

Angular supports a feature called *URL routing*, which uses the current URL displayed by the browser to select the components that are displayed to the user. This is an approach that makes it easy to create applications whose components are loosely coupled and easy to change without needing corresponding modifications elsewhere in the applications. URL routing also makes it easy to change the path that a user follows through an application.

For the SportsStore application, I am going to add support for three different URLs, which are described in Table 6-1. This is a simple configuration, but the routing system has a lot of features, which are described in detail in Chapters 24 to 26.

Table 6-1. *The URLs Supported by the SportsStore Application*

URL	Description
/store	This URL will display the list of products.
/cart	This URL will display the user's cart in detail.
/checkout	This URL will display the checkout process.

In the sections that follow, I create placeholder components for the SportsStore cart and order checkout stages and then integrate them into the application using URL routing. Once the URLs are implemented, I will return to the components and add more useful features.

Creating the Cart Detail and Checkout Components

Before adding URL routing to the application, I need to create the components that will be displayed by the /cart and /checkout URLs. I only need some basic placeholder content to get started, just to make it obvious which component is being displayed. I started by adding a file called `cartDetail.component.ts` in the `src/app/store` folder and defined the component shown in Listing 6-8.

Listing 6-8. The Contents of the cartDetail.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";

@Component({
    template: `<div><h3 class="bg-info p-1 text-white">Cart Detail Component</h3></div>`
})
export class CartDetailComponent {}
```

Next, I added a file called `checkout.component.ts` in the `src/app/store` folder and defined the component shown in Listing 6-9.

Listing 6-9. The Contents of the checkout.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";

@Component({
    template: `<div><h3 class="bg-info p-1 text-white">Checkout Component</h3></div>`
})
export class CheckoutComponent { }
```

This component follows the same pattern as the cart component and displays a placeholder message. Listing 6-10 registers the components in the store feature module and adds them to the `exports` property, which means they can be used elsewhere in the application.

Listing 6-10. Registering Components in the store.module.ts File in the src/app/store Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { StoreComponent } from "./store.component";
import { CounterDirective } from "./counter.directive";
import { CartSummaryComponent } from "./cartSummary.component";
import { CartDetailComponent } from "./cartDetail.component";
import { CheckoutComponent } from "./checkout.component";

@NgModule({
    imports: [ModelModule, BrowserModule, FormsModule],
    declarations: [StoreComponent, CounterDirective, CartSummaryComponent,
        CartDetailComponent, CheckoutComponent],
    exports: [StoreComponent, CartDetailComponent, CheckoutComponent]
})
export class StoreModule { }
```

Creating and Applying the Routing Configuration

Now that I have a range of components to display, the next step is to create the routing configuration that tells Angular how to map URLs into components. Each mapping of a URL to a component is known as a *URL route* or just a *route*. In Part 3, where I create more complex routing configurations, I define the routes in a separate file, but for this project, I am going to follow a simpler approach and define the routes within the @NgModule decorator of the application's root module, as shown in Listing 6-11.

■ **Tip** The Angular routing feature requires a base element in the HTML document, which provides the base URL against which routes are applied. This element was added to the index.html file by the ng new command when I created the SportsStore project in Chapter 5. If you omit the element, Angular will report an error and be unable to apply the routes.

Listing 6-11. Creating the Routing Configuration in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { StoreModule } from "./store/store.module";
import { StoreComponent } from "./store/store.component";
import { CheckoutComponent } from "./store/checkout.component";
import { CartDetailComponent } from "./store/cartDetail.component";
import { RouterModule } from "@angular/router";

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, StoreModule,
    RouterModule.forRoot([
        { path: "store", component: StoreComponent },
        { path: "cart", component: CartDetailComponent },
        { path: "checkout", component: CheckoutComponent },
        { path: "**", redirectTo: "/store" }
    ])],
  providers: [],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

The RouterModule.forRoot method is passed a set of routes, each of which maps a URL to a component. The first three routes in the listing match the URLs from Table 6-1. The final route is a wildcard that redirects any other URL to /store, which will display StoreComponent.

When the routing feature is used, Angular looks for the router-outlet element, which defines the location in which the component that corresponds to the current URL should be displayed. Listing 6-12 replaces the store element in the root component's template with the router-outlet element.

Listing 6-12. Defining the Routing Target in the app.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "app",
    template: "<router-outlet></router-outlet>"
})
export class AppComponent { }
```

Angular will apply the routing configuration when you save the changes and the browser reloads the HTML document. The content displayed in the browser window hasn't changed, but if you examine the browser's URL bar, you will be able to see that the routing configuration has been applied, as shown in Figure 6-2.

Figure 6-2. The effect of URL routing

Navigating Through the Application

With the routing configuration in place, it is time to add support for navigating between components by changing the browser's URL. The URL routing feature relies on a JavaScript API provided by the browser, which means the user can't simply type the target URL into the browser's URL bar. Instead, the navigation has to be performed by the application, either by using JavaScript code in a component or other building block or by adding attributes to HTML elements in the template.

When the user clicks one of the Add To Cart buttons, the cart detail component should be shown, which means that the application should navigate to the /cart URL. Listing 6-13 adds navigation to the component method that is invoked when the user clicks the button.

Listing 6-13. Navigating Using JavaScript in the store.component.ts File in the app/src/store Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";
import { Cart } from "../model/cart.model";
import { Router } from "@angular/router";

@Component({
    selector: "store",
    templateUrl: "store.component.html"
})
export class StoreComponent {
    selectedCategory: string | undefined;
    productsPerPage = 4;
    selectedPage = 1;

    constructor(private repository: ProductRepository,
        private cart: Cart,
        private router: Router) { }

    get products(): Product[] {
        let pageIndex = (this.selectedPage - 1) * this.productsPerPage
        return this.repository.getProducts(this.selectedCategory)
            .slice(pageIndex, pageIndex + this.productsPerPage);
    }

    get categories(): string[] {
        return this.repository.getCategories();
    }

    changeCategory(newCategory?: string) {
        this.selectedCategory = newCategory;
    }

    changePage(newPage: number) {
        this.selectedPage = newPage;
    }

    changePageSize(newSize: number) {
        this.productsPerPage = Number(newSize);
        this.changePage(1);
    }

    get pageCount(): number {
        return Math.ceil(this.repository
            .getProducts(this.selectedCategory).length / this.productsPerPage)
    }
```

```
    addProductToCart(product: Product) {
        this.cart.addLine(product);
        this.router.navigateByUrl("/cart");
    }
}
```

The constructor has a `Router` parameter, which is provided by Angular through the dependency injection feature when a new instance of the component is created. In the `addProductToCart` method, the `Router.navigateByUrl` method is used to navigate to the `/cart` URL.

Navigation can also be done by adding the `routerLink` attribute to elements in the template. In Listing 6-14, the `routerLink` attribute has been applied to the cart button in the cart summary component's template.

Listing 6-14. Adding Navigation in the cartSummary.component.html File in the src/app/store Folder

```
<div class="float-end">
    <small class="fs-6">
        Your cart:
        <span *ngIf="cart.itemCount > 0">
            {{ cart.itemCount }} item(s)
            {{ cart.cartPrice | currency:"USD":"symbol":"2.2-2" }}
        </span>
        <span *ngIf="cart.itemCount == 0">
            (empty)
        </span>
    </small>
    <button class="btn btn-sm bg-dark text-white"
            [disabled]="cart.itemCount == 0" routerLink="/cart">
        <i class="fa fa-shopping-cart"></i>
    </button>
</div>
```

The value specified by the `routerLink` attribute is the URL that the application will navigate to when the `button` is clicked. This particular button is disabled when the cart is empty, so it will perform the navigation only when the user has added a product to the cart.

To add support for the `routerLink` attribute, the `RouterModule` module must be imported into the feature module, as shown in Listing 6-15.

Listing 6-15. Importing the Router Module in the store.module.ts File in the src/app/store Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { StoreComponent } from "./store.component";
import { CounterDirective } from "./counter.directive";
import { CartSummaryComponent } from "./cartSummary.component";
import { CartDetailComponent } from "./cartDetail.component";
import { CheckoutComponent } from "./checkout.component";
import { RouterModule } from "@angular/router";
```

```
@NgModule({
    imports: [ModelModule, BrowserModule, FormsModule, RouterModule],
    declarations: [StoreComponent, CounterDirective, CartSummaryComponent,
        CartDetailComponent, CheckoutComponent],
    exports: [StoreComponent, CartDetailComponent, CheckoutComponent]
})
export class StoreModule { }
```

To see the effect of the navigation, save the changes of the files, and once the browser has reloaded the HTML document, click one of the Add To Cart buttons. The browser will navigate to the /cart URL, as shown in Figure 6-3.

Figure 6-3. *Using URL routing*

Guarding the Routes

Remember that navigation can be performed only by the application. If you change the URL directly in the browser's URL bar, the browser will request the URL you enter from the web server. The Angular development server that is responding to HTTP requests will respond to any URL that doesn't correspond to a file by returning the contents of index.html. This is generally a useful behavior because it means you won't receive an HTTP error when the browser's reload button is clicked. But it can cause problems if the application expects the user to navigate through the application following a specific path.

As an example, if you click one of the Add To Cart buttons and then click the browser's reload button, the HTTP server will return the contents of the index.html file, and Angular will immediately jump to the cart detail component, skipping over the part of the application that allows the user to select products.

For some applications, being able to start using different URLs makes sense, but if that's not the case, then Angular supports *route guards*, which are used to govern the routing system.

To prevent the application from starting with the /cart or /order URL, I added a file called storeFirst.guard.ts in the SportsStore/src/app folder and defined the class shown in Listing 6-16.

Listing 6-16. The Contents of the storeFirst.guard.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";
import {
    ActivatedRouteSnapshot, RouterStateSnapshot,
    Router
} from "@angular/router";
import { StoreComponent } from "./store/store.component";

@Injectable()
export class StoreFirstGuard {
    private firstNavigation = true;

    constructor(private router: Router) { }

    canActivate(route: ActivatedRouteSnapshot,
        state: RouterStateSnapshot): boolean {
        if (this.firstNavigation) {
            this.firstNavigation = false;
            if (route.component != StoreComponent) {
                this.router.navigateByUrl("/");
                return false;
            }
        }
        return true;
    }
}
```

There are different ways to guard routes, as described in Chapter 26, and this is an example of a guard that prevents a route from being activated, which is implemented as a class that defines a canActivate method. The implementation of this method uses the context objects that Angular provides that describe the route that is about to be navigated to and checks to see whether the target component is a StoreComponent. If this is the first time that the canActivate method has been called and a different component is about to be used, then the Router.navigateByUrl method is used to navigate to the root URL.

The @Injectable decorator has been applied in the listing because route guards are services. Listing 6-17 registers the guard as a service using the root module's providers property and guards each route using the canActivate property.

Listing 6-17. Guarding Routes in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { StoreModule } from "./store/store.module";

import { StoreComponent } from "./store/store.component";
import { CheckoutComponent } from "./store/checkout.component";
import { CartDetailComponent } from "./store/cartDetail.component";
import { RouterModule } from "@angular/router";
import { StoreFirstGuard } from "./storeFirst.guard";
```

```
@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, StoreModule,
    RouterModule.forRoot([
        {
            path: "store", component: StoreComponent,
            canActivate: [StoreFirstGuard]
        },
        {
            path: "cart", component: CartDetailComponent,
            canActivate: [StoreFirstGuard]
        },
        {
            path: "checkout", component: CheckoutComponent,
            canActivate: [StoreFirstGuard]
        },
        { path: "**", redirectTo: "/store" }
    ])],
  providers: [StoreFirstGuard],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

If you reload the browser after clicking one of the Add To Cart buttons now, then you will see the browser is automatically directed back to safety, as shown in Figure 6-4.

Figure 6-4. *Guarding routes*

Completing the Cart Detail Feature

Now that the application has navigation support, it is time to complete the view that details the contents of the user's cart. Listing 6-18 removes the inline template from the cart detail component, specifies an external template in the same directory, and adds a Cart parameter to the constructor, which will be accessible in the template through a property called cart.

Listing 6-18. Changing the Template in the cartDetail.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Cart } from "../model/cart.model";

@Component({
    templateUrl: "cartDetail.component.html"
})
export class CartDetailComponent {

    constructor(public cart: Cart) { }
}
```

To complete the cart detail feature, I created an HTML file called cartDetail.component.html in the src/app/store folder and added the content shown in Listing 6-19.

Listing 6-19. The Contents of the cartDetail.component.html File in the src/app/store Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
    <div class="row">
        <div class="col mt-2">
            <h2 class="text-center">Your Cart</h2>
            <table class="table table-bordered table-striped p-2">
                <thead>
                    <tr>
                        <th>Quantity</th>
                        <th>Product</th>
                        <th class="text-end">Price</th>
                        <th class="text-end">Subtotal</th>
                    </tr>
                </thead>
                <tbody>
                    <tr *ngIf="cart.lines.length == 0">
                        <td colspan="4" class="text-center">
                            Your cart is empty
                        </td>
                    </tr>
                    <tr *ngFor="let line of cart.lines">
                        <td>
                            <input type="number" class="form-control-sm"
                                style="width:5em" [value]="line.quantity"
                                (change)="cart.updateQuantity(line.product,
                                  $any($event).target.value)" />
                        </td>
```

143

```
                    <td>{{line.product.name}}</td>
                    <td class="text-end">
                        {{line.product.price | currency:"USD":"symbol":"2.2-2"}}
                    </td>
                    <td class="text-end">
                        {{(line.lineTotal) | currency:"USD":"symbol":"2.2-2" }}
                    </td>
                    <td class="text-center">
                        <button class="btn btn-sm btn-danger"
                                (click)="cart.removeLine(line.product.id ?? 0)">
                            Remove
                        </button>
                    </td>
                </tr>
            </tbody>
            <tfoot>
                <tr>
                    <td colspan="3" class="text-end">Total:</td>
                    <td class="text-end">
                        {{cart.cartPrice | currency:"USD":"symbol":"2.2-2"}}
                    </td>
                </tr>
            </tfoot>
        </table>
    </div>
</div>
<div class="row">
    <div class="col">
        <div class="text-center">
            <button class="btn btn-primary m-1" routerLink="/store">
                Continue Shopping
            </button>
            <button class="btn btn-secondary m-1" routerLink="/checkout"
                    [disabled]="cart.lines.length == 0">
                Checkout
            </button>
        </div>
    </div>
</div>
</div>
```

This template displays a table showing the user's product selections. For each product, there is an `input` element that can be used to change the quantity, and there is a Remove button that deletes it from the cart. There are also two navigation buttons that allow the user to return to the list of products or continue to the checkout process, as shown in Figure 6-5. The combination of the Angular data bindings and the shared `Cart` object means that any changes made to the cart take immediate effect, recalculating the prices; and if you click the Continue Shopping button, the changes are reflected in the cart summary component shown above the list of products.

■ **Tip** If you receive an error after you have saved the template, then stop and restart the `ng serve` command.

Figure 6-5. *Completing the cart detail feature*

Processing Orders

Being able to receive orders from customers is the most important aspect of an online store. In the sections that follow, I build on the application to add support for receiving the final details from the user and checking them out. To keep the process simple, I am going to avoid dealing with payment and fulfillment platforms, which are generally back-end services that are not specific to Angular applications.

Extending the Model

To describe orders placed by users, I added a file called `order.model.ts` in the `src/app/model` folder and defined the code shown in Listing 6-20.

Listing 6-20. The Contents of the order.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Cart } from "./cart.model";

@Injectable()
export class Order {
    public id?: number;
    public name?: string;
    public address?: string;
    public city?: string;
    public state?: string;
    public zip?: string;
    public country?: string;
    public shipped: boolean = false;

    constructor(public cart: Cart) { }

    clear() {
        this.id = undefined;
        this.name = this.address = this.city = undefined;
        this.state = this.zip = this.country = undefined;
        this.shipped = false;
        this.cart.clear();
    }
}
```

The `Order` class will be another service, which means there will be one instance shared throughout the application. When Angular creates the `Order` object, it will detect the `Cart` constructor parameter and provide the same `Cart` object that is used elsewhere in the application.

Updating the Repository and Data Source

To handle orders in the application, I need to extend the repository and the data source so they can receive `Order` objects. Listing 6-21 adds a method to the data source that receives an order. Since this is still the dummy data source, the method simply produces a JSON string from the order and writes it to the JavaScript console. I'll do something more useful with the objects in the next section when I create a data source that uses HTTP requests to communicate with the RESTful web service.

Listing 6-21. Handling Orders in the static.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { Observable, from } from "rxjs";
import { Order } from "./order.model";

@Injectable()
export class StaticDataSource {
    private products: Product[] = [
        new Product(1, "Product 1", "Category 1", "Product 1 (Category 1)", 100),
        new Product(2, "Product 2", "Category 1", "Product 2 (Category 1)", 100),
```

```
        new Product(3, "Product 3", "Category 1", "Product 3 (Category 1)", 100),
        new Product(4, "Product 4", "Category 1", "Product 4 (Category 1)", 100),
        new Product(5, "Product 5", "Category 1", "Product 5 (Category 1)", 100),
        new Product(6, "Product 6", "Category 2", "Product 6 (Category 2)", 100),
        new Product(7, "Product 7", "Category 2", "Product 7 (Category 2)", 100),
        new Product(8, "Product 8", "Category 2", "Product 8 (Category 2)", 100),
        new Product(9, "Product 9", "Category 2", "Product 9 (Category 2)", 100),
        new Product(10, "Product 10", "Category 2", "Product 10 (Category 2)", 100),
        new Product(11, "Product 11", "Category 3", "Product 11 (Category 3)", 100),
        new Product(12, "Product 12", "Category 3", "Product 12 (Category 3)", 100),
        new Product(13, "Product 13", "Category 3", "Product 13 (Category 3)", 100),
        new Product(14, "Product 14", "Category 3", "Product 14 (Category 3)", 100),
        new Product(15, "Product 15", "Category 3", "Product 15 (Category 3)", 100),
    ];

    getProducts(): Observable<Product[]> {
        return from([this.products]);
    }

    saveOrder(order: Order): Observable<Order> {
        console.log(JSON.stringify(order));
        return from([order]);
    }
}
```

To manage orders, I added a file called order.repository.ts to the src/app/model folder and used it to define the class shown in Listing 6-22. There is only one method in the order repository at the moment, but I will add more functionality in Chapter 7 when I create the administration features.

■ **Tip** You don't have to use different repositories for each model type in the application, but I often do so because a single class responsible for multiple model types can become complex and difficult to maintain.

Listing 6-22. The Contents of the order.repository.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Observable } from "rxjs";
import { Order } from "./order.model";
import { StaticDataSource } from "./static.datasource";

@Injectable()
export class OrderRepository {
    private orders: Order[] = [];

    constructor(private dataSource: StaticDataSource) {}

    getOrders(): Order[] {
        return this.orders;
    }
```

```
    saveOrder(order: Order): Observable<Order> {
        return this.dataSource.saveOrder(order);
    }
}
```

Updating the Feature Module

Listing 6-23 registers the Order class and the new repository as services using the providers property of the model feature module.

Listing 6-23. Registering Services in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { ProductRepository } from "./product.repository";
import { StaticDataSource } from "./static.datasource";
import { Cart } from "./cart.model";
import { Order } from "./order.model";
import { OrderRepository } from "./order.repository";

@NgModule({
    providers: [ProductRepository, StaticDataSource, Cart, Order, OrderRepository]
})
export class ModelModule { }
```

Collecting the Order Details

The next step is to gather the details from the user required to complete the order. Angular includes built-in directives for working with HTML forms and validating their contents. Listing 6-24 prepares the checkout component, switching to an external template, receiving the Order object as a constructor parameter, and providing some additional support to help the template.

Listing 6-24. Preparing for a Form in the checkout.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { NgForm } from "@angular/forms";
import { OrderRepository } from "../model/order.repository";
import { Order } from "../model/order.model";

@Component({
    templateUrl: "checkout.component.html",
    styleUrls: ["checkout.component.css"]
})
export class CheckoutComponent {
    orderSent: boolean = false;
    submitted: boolean = false;

    constructor(public repository: OrderRepository,
                public order: Order) {}
```

```
    submitOrder(form: NgForm) {
        this.submitted = true;
        if (form.valid) {
            this.repository.saveOrder(this.order).subscribe(order => {
                this.order.clear();
                this.orderSent = true;
                this.submitted = false;
            });
        }
    }
}
```

The submitOrder method will be invoked when the user submits a form, which is represented by an NgForm object. If the data that the form contains is valid, then the Order object will be passed to the repository's saveOrder method, and the data in the cart and the order will be reset.

The @Component decorator's styleUrls property is used to specify one or more CSS stylesheets that should be applied to the content in the component's template. To provide validation feedback for the values that the user enters into the HTML form elements, I created a file called checkout.component.css in the src/app/store folder and defined the styles shown in Listing 6-25.

Listing 6-25. The Contents of the checkout.component.css File in the src/app/store Folder

```
input.ng-dirty.ng-invalid { border: 2px solid #ff0000 }
input.ng-dirty.ng-valid { border: 2px solid #6bc502 }
```

Angular adds elements to the ng-dirty, ng-valid, and ng-valid classes to indicate their validation status. The full set of validation classes is described in Chapter 12, but the effect of the styles in Listing 6-25 is to add a green border around input elements that are valid and a red border around those that are invalid.

The final piece of the puzzle is the template for the component, which presents the user with the form fields required to populate the properties of an Order object, as shown in Listing 6-26.

Listing 6-26. The Contents of the checkout.component.html File in the src/app/store Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="bg-dark text-white p-2">
            <span class="navbar-brand ml-2">SPORTS STORE</span>
        </div>
    </div>
</div>

<div *ngIf="orderSent" class="m-2 text-center">
    <h2>Thanks!</h2>
    <p>Thanks for placing your order.</p>
    <p>We'll ship your goods as soon as possible.</p>
    <button class="btn btn-primary" routerLink="/store">Return to Store</button>
</div>
<form *ngIf="!orderSent" #form="ngForm" novalidate
        (ngSubmit)="submitOrder(form)" class="m-2">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control" #name="ngModel" name="name"
```

```
            [(ngModel)]="order.name" required />
        <span *ngIf="submitted && name.invalid" class="text-danger">
            Please enter your name
        </span>
    </div>
    <div class="form-group">
        <label>Address</label>
        <input class="form-control" #address="ngModel" name="address"
            [(ngModel)]="order.address" required />
        <span *ngIf="submitted && address.invalid" class="text-danger">
            Please enter your address
        </span>
    </div>
    <div class="form-group">
        <label>City</label>
        <input class="form-control" #city="ngModel" name="city"
            [(ngModel)]="order.city" required />
        <span *ngIf="submitted && city.invalid" class="text-danger">
            Please enter your city
        </span>
    </div>
    <div class="form-group">
        <label>State</label>
        <input class="form-control" #state="ngModel" name="state"
            [(ngModel)]="order.state" required />
        <span *ngIf="submitted && state.invalid" class="text-danger">
            Please enter your state
        </span>
    </div>
    <div class="form-group">
        <label>Zip/Postal Code</label>
        <input class="form-control" #zip="ngModel" name="zip"
            [(ngModel)]="order.zip" required />
        <span *ngIf="submitted && zip.invalid" class="text-danger">
            Please enter your zip/postal code
        </span>
    </div>
    <div class="form-group">
        <label>Country</label>
        <input class="form-control" #country="ngModel" name="country"
            [(ngModel)]="order.country" required />
        <span *ngIf="submitted && country.invalid" class="text-danger">
            Please enter your country
        </span>
    </div>
    <div class="text-center">
        <button class="btn btn-secondary m-1" routerLink="/cart">Back</button>
        <button class="btn btn-primary m-1" type="submit">Complete Order</button>
    </div>
</form>
```

The `form` and `input` elements in this template use Angular features to ensure that the user provides values for each field, and they provide visual feedback if the user clicks the Complete Order button without completing the form. Part of this feedback comes from applying the styles that were defined in Listing 6-25, and part comes from `span` elements that remain hidden until the user tries to submit an invalid form.

■ **Tip** Requiring values is only one of the ways that Angular can validate form fields, and as I explained in Chapter 12, you can easily add your own custom validation as well.

To see the process, start with the list of products and click one of the Add To Cart buttons to add a product to the cart. Click the Checkout button, and you will see the HTML form shown in Figure 6-6. Click the Complete Order button without entering text into any of the `input` elements, and you will see the validation feedback messages. Fill out the form and click the Complete Order button; you will see the confirmation message shown in the figure.

■ **Tip** Restart the `ng serve` command if you see an error after saving the template.

Figure 6-6. *Completing an order*

If you look at the browser's JavaScript console, you will see a JSON representation of the order like this:

```
{"cart":
    {"lines":[
        {"product":{"id":1,"name":"Product 1","category":"Category 1",
         "description":"Product 1 (Category 1)","price":100},"quantity":1}],
         "itemCount":1,"cartPrice":100},
    "shipped":false,
    "name":"Joe Smith","address":"123 Main Street",
    "city":"Smallville","state":"NY","zip":"10036","country":"USA"
}
```

Using the RESTful Web Service

Now that the basic SportsStore functionality is in place, it is time to replace the dummy data source with one that gets its data from the RESTful web service that was created during the project setup in Chapter 5.

To create the data source, I added a file called rest.datasource.ts in the src/app/model folder and added the code shown in Listing 6-27.

Listing 6-27. The Contents of the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";
import { Order } from "./order.model";

const PROTOCOL = "http";
const PORT = 3500;

@Injectable()
export class RestDataSource {
    baseUrl: string;

    constructor(private http: HttpClient) {
        this.baseUrl = `${PROTOCOL}://${location.hostname}:${PORT}/`;
    }

    getProducts(): Observable<Product[]> {
        return this.http.get<Product[]>(this.baseUrl + "products");
    }

    saveOrder(order: Order): Observable<Order> {
        return this.http.post<Order>(this.baseUrl + "orders", order);
    }
}
```

Angular provides a built-in service called HttpClient that is used to make HTTP requests. The RestDataSource constructor receives the HttpClient service and uses the global location object provided by the browser to determine the URL that the requests will be sent to, which is port 3500 on the same host that the application has been loaded from.

The methods defined by the RestDataSource class correspond to the ones defined by the static data source but are implemented using the HttpClient service, described in Chapter 23.

■ **Tip**   When obtaining data via HTTP, it is possible that network congestion or server load will delay the request and leave the user looking at an application that has no data. In Chapter 26, I explain how to configure the routing system to prevent this problem.

Applying the Data Source

To complete this chapter, I am going to apply the RESTful data source by reconfiguring the application so that the switch from the dummy data to the REST data is done with changes to a single file. Listing 6-28 changes the behavior of the data source service in the model feature module.

Listing 6-28. Changing the Service Configuration in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { ProductRepository } from "./product.repository";
import { StaticDataSource } from "./static.datasource";
import { Cart } from "./cart.model";
import { Order } from "./order.model";
import { OrderRepository } from "./order.repository";
import { RestDataSource } from "./rest.datasource";
import { HttpClientModule } from "@angular/common/http";

@NgModule({
    imports: [HttpClientModule],
    providers: [ProductRepository, StaticDataSource, Cart, Order, OrderRepository,
        { provide: StaticDataSource, useClass: RestDataSource }]
})
export class ModelModule { }
```

The imports property is used to declare a dependency on the HttpClientModule feature module, which provides the HttpClient service used in Listing 6-27. The change to the providers property tells Angular that when it needs to create an instance of a class with a StaticDataSource constructor parameter, it should use a RestDataSource instead. Since both objects define the same methods, the dynamic JavaScript type system means that the substitution is seamless. When all the changes have been saved and the browser reloads the application, you will see the dummy data has been replaced with the data obtained via HTTP, as shown in Figure 6-7.

Figure 6-7. *Using the RESTful web service*

If you go through the process of selecting products and checking out, you can see that the data source has written the order to the web service by navigating to this URL:

```
http://localhost:3500/db
```

This will display the full contents of the database, including the collection of orders. You won't be able to request the /orders URL because it requires authentication, which I set up in the next chapter.

■ **Tip**   Remember that the data provided by the RESTful web service is reset when you stop the server and start it again using the npm run json command.

Summary

In this chapter, I continued adding features to the SportsStore application, adding support for a shopping cart into which the user can place products and a checkout process that completes the shopping process. To complete the chapter, I replaced the dummy data source with one that sends HTTP requests to the RESTful web service. In the next chapter, I create administration features that allow the SportsStore data to be managed.

CHAPTER 7

■ ■ ■

SportsStore: Administration

In this chapter, I continue building the SportsStore application by adding administration features. Relatively few users will need to access the administration features, so it would be wasteful to force all users to download the administration code and content when it is unlikely to be used. Instead, I am going to put the administration features in a separate module that will be loaded only when it is required.

Preparing the Example Application

No preparation is required for this chapter, which continues using the SportsStore project from Chapter 6. To start the RESTful web service, open a command prompt and run the following command in the SportsStore folder:

```
npm run json
```

Open a second command prompt and run the following command in the SportsStore folder to start the development tools and HTTP server:

```
ng serve --open
```

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book— from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Creating the Module

The process for creating the feature module follows the same pattern you have seen in earlier chapters. The key difference is that it is important that no other part of the application has dependencies on the module or the classes it contains, which would undermine the dynamic loading of the module and cause the JavaScript module to load the administration code, even if it is not used.

The starting point for the administration features will be authentication, which will ensure that only authorized users can administer the application. I created a file called `auth.component.ts` in the `src/app/admin` folder and used it to define the component shown in Listing 7-1.

Listing 7-1. The Content of the auth.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";
import { NgForm } from "@angular/forms";
import { Router } from "@angular/router";

@Component({
    templateUrl: "auth.component.html"
})
export class AuthComponent {
    username?: string;
    password?: string;
    errorMessage?: string;

    constructor(private router: Router) {}

    authenticate(form: NgForm) {
        if (form.valid) {
            // perform authentication
            this.router.navigateByUrl("/admin/main");
        } else {
            this.errorMessage = "Form Data Invalid";
        }
    }
}
```

The component defines properties for the username and password that will be used to authenticate the user, an `errorMessage` property that will be used to display messages when there are problems, and an `authenticate` method that will perform the authentication process (but that does nothing at the moment).

To provide the component with a template, I created a file called `auth.component.html` in the `src/app/admin` folder and added the content shown in Listing 7-2.

Listing 7-2. The Content of the auth.component.html File in the src/app/admin Folder

```
<div class="bg-info p-2 text-center text-white">
    <h3>SportsStore Admin</h3>
</div>
<div class="bg-danger mt-2 p-2 text-center text-white" *ngIf="errorMessage != null">
    {{errorMessage}}
</div>
<div class="p-2">
    <form novalidate #form="ngForm" (ngSubmit)="authenticate(form)">
        <div class="form-group">
            <label>Name</label>
            <input class="form-control" name="username"
                [(ngModel)]="username" required />
        </div>
```

```
        <div class="form-group">
            <label>Password</label>
            <input class="form-control" type="password" name="password"
                [(ngModel)]="password" required />
        </div>
        <div class="text-center p-2">
            <button class="btn btn-secondary m-1" routerLink="/">Go back</button>
            <button class="btn btn-primary m-1" type="submit">Log In</button>
        </div>
    </form>
</div>
```

The template contains an HTML form that uses two-way data binding expressions for the component's properties. There is a button that will submit the form, a button that navigates back to the root URL, and a div element that is visible only when there is an error message to display.

To create a placeholder for the administration features, I added a file called admin.component.ts in the src/app/admin folder and defined the component shown in Listing 7-3.

Listing 7-3. The Contents of the admin.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";

@Component({
    templateUrl: "admin.component.html"
})
export class AdminComponent {}
```

The component doesn't contain any functionality at the moment. To provide a template for the component, I added a file called admin.component.html to the src/app/admin folder and the placeholder content shown in Listing 7-4.

Listing 7-4. The Contents of the admin.component.html File in the src/app/admin Folder

```
<div class="bg-info p-2 text-white">
  <h3>Placeholder for Admin Features</h3>
</div>
```

To define the feature module, I added a file called admin.module.ts in the src/app/admin folder and added the code shown in Listing 7-5.

Listing 7-5. The Contents of the admin.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { FormsModule } from "@angular/forms";
import { RouterModule } from "@angular/router";
import { AuthComponent } from "./auth.component";
import { AdminComponent } from "./admin.component";
```

```
let routing = RouterModule.forChild([
    { path: "auth", component: AuthComponent },
    { path: "main", component: AdminComponent },
    { path: "**", redirectTo: "auth" }
]);

@NgModule({
    imports: [CommonModule, FormsModule, routing],
    declarations: [AuthComponent, AdminComponent]
})
export class AdminModule { }
```

The `RouterModule.forChild` method is used to define the routing configuration for the feature module, which is then included in the module's `imports` property.

A dynamically loaded module must be self-contained and include all the information that Angular requires, including the routing URLs that are supported and the components they display. If any other part of the application depends on the module, then it will be included in the JavaScript bundle with the rest of the application code, which means that all users will have to download code and resources for features they won't use.

However, a dynamically loaded module is allowed to declare dependencies on the main part of the application. This module relies on the functionality in the data model module, which has been added to the module's `imports` so that components can access the model classes and the repositories.

Configuring the URL Routing System

Dynamically loaded modules are managed through the routing configuration, which triggers the loading process when the application navigates to a specific URL. Listing 7-6 extends the routing configuration of the application so that the /admin URL will load the administration feature module.

Listing 7-6. Configuring a Dynamically Loaded Module in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { StoreModule } from "./store/store.module";
import { StoreComponent } from "./store/store.component";
import { CheckoutComponent } from "./store/checkout.component";
import { CartDetailComponent } from "./store/cartDetail.component";
import { RouterModule } from "@angular/router";
import { StoreFirstGuard } from "./storeFirst.guard";

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, StoreModule,
    RouterModule.forRoot([
        {
            path: "store", component: StoreComponent,
            canActivate: [StoreFirstGuard]
        },
```

```
        {
            path: "cart", component: CartDetailComponent,
            canActivate: [StoreFirstGuard]
        },
        {
            path: "checkout", component: CheckoutComponent,
            canActivate: [StoreFirstGuard]
        },
        {
            path: "admin",
            loadChildren: () => import("./admin/admin.module")
                .then(m => m.AdminModule),
            canActivate: [StoreFirstGuard]
        },
        { path: "**", redirectTo: "/store" }
    ])],
    providers: [StoreFirstGuard],
    bootstrap: [AppComponent]
})
export class AppModule { }
```

The new route tells Angular that when the application navigates to the /admin URL, it should load a
feature module defined by a class called AdminModule from the admin/admin.module.ts file, whose path is
specified relative to the app.module.ts file. When Angular processes the admin module, it will incorporate
the routing information it contains into the overall set of routes and complete the navigation.

Navigating to the Administration URL

The final preparatory step is to provide the user with the ability to navigate to the /admin URL so that the
administration feature module will be loaded and its component displayed to the user. Listing 7-7 adds a
button to the store component's template that will perform the navigation.

Listing 7-7. Adding a Navigation Button in the store.component.html File in the src/app/store Folder

```
...
<div class="d-grid gap-2">
    <button class="btn btn-outline-primary" (click)="changeCategory()">
        Home
        </button>
        <button *ngFor="let cat of categories"
                class="btn btn-outline-primary"
                [class.active]="cat == selectedCategory"
                (click)="changeCategory(cat)">
            {{cat}}
        </button>
        <button class="btn btn-danger mt-5" routerLink="/admin">
            Admin
        </button>
</div>
...
```

To reflect the changes, stop the development tools and restart them by running the following command in the SportsStore folder:

```
ng serve
```

Use the browser to navigate to http://localhost:4200 and use the browser's F12 developer tools to see the network requests made by the browser as the application is loaded. The files for the administration module will not be loaded until you click the Admin button, at which point Angular will request the files and display the login page shown in Figure 7-1.

Figure 7-1. *Using a dynamically loaded module*

Enter any name and password into the form fields and click the Log In button to see the placeholder content, as shown in Figure 7-2. If you leave either of the form fields empty, a warning message will be displayed.

Figure 7-2. *The placeholder administration features*

Implementing Authentication

The RESTful web service has been configured so that it requires authentication for the requests that the administration feature will require. In the sections that follow, I add support for authenticating the user by sending an HTTP request to the RESTful web service.

Understanding the Authentication System

When the RESTful web service authenticates a user, it will return a JSON Web Token (JWT) that the application must include in subsequent HTTP requests to show that authentication has been successfully performed. You can read the JWT specification at `https://tools.ietf.org/html/rfc7519`, but for the SportsStore application, it is enough to know that the Angular application can authenticate the user by sending a POST request to the `/login` URL, including a JSON-formatted object in the request body that contains name and password properties. There is only one set of valid credentials in the authentication code I added to the application in Chapter 5, which is shown in Table 7-1.

Table 7-1. *The Authentication Credentials Supported by the RESTful Web Service*

Username	Password
admin	secret

As I noted in Chapter 5, you should not hard-code credentials in real projects, but this is the username and password that you will need for the SportsStore application.

If the correct credentials are sent to the /login URL, then the response from the RESTful web service will contain a JSON object like this:

```json
{
  "success": true,
   "token":"eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.eyJkYXRhIjoiYWRtaW4iLCJleHBpcmVz
            SW4iOiIxaCIsImlhdCI6MTQ3ODk1NjI1Mn0.lJaDDrSu-bHBtdWrzO312p_DG5tKypGv6cA
            NgOyzlg8"
}
```

The success property describes the outcome of the authentication operation, and the token property contains the JWT, which should be included in subsequent requests using the Authorization HTTP header in this format:

```
Authorization: Bearer<eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.eyJkYXRhIjoiYWRtaW4iLC
    JleHBpcmVzSW4iOiIxaCIsImlhdCI6MTQ3ODk1NjI1Mn0.lJaDDrSu-
    bHBtdWrzO312p_DG5tKypGv6cANgOyzlg8>
```

I configured the JWT tokens returned by the server so they expire after one hour. If the wrong credentials are sent to the server, then the JSON object returned in the response will just contain a success property set to false, like this:

```json
{
  "success": false
}
```

Extending the Data Source

The RESTful data source will do most of the work because it is responsible for sending the authentication request to the /login URL and including the JWT in subsequent requests. Listing 7-8 adds authentication to the RestDataSource class and defines a variable that will store the JWT once it has been obtained.

Listing 7-8. Adding Authentication in the rest.datasource.ts File in the src/app/model Folder

```typescript
import { Injectable } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { map, Observable } from "rxjs";
import { Product } from "./product.model";
import { Order } from "./order.model";

const PROTOCOL = "http";
const PORT = 3500;

@Injectable()
export class RestDataSource {
    baseUrl: string;
    auth_token?: string;
```

```
    constructor(private http: HttpClient) {
        this.baseUrl = `${PROTOCOL}://${location.hostname}:${PORT}/`;
    }

    getProducts(): Observable<Product[]> {
        return this.http.get<Product[]>(this.baseUrl + "products");
    }

    saveOrder(order: Order): Observable<Order> {
        return this.http.post<Order>(this.baseUrl + "orders", order);
    }

    authenticate(user: string, pass: string): Observable<boolean> {
        return this.http.post<any>(this.baseUrl + "login", {
            name: user, password: pass
        }).pipe(map(response => {
            this.auth_token = response.success ? response.token : null;
            return response.success;
        }));
    }
}
```

The `pipe` method and `map` function are provided by the RxJS package, and they allow the response event from the server, which is presented through an `Observable<any>` to be transformed into an event in the `Observable<bool>` that is the result of the `authenticate` method.

Creating the Authentication Service

Rather than expose the data source directly to the rest of the application, I am going to create a service that can be used to perform authentication and determine whether the application has been authenticated. I added a file called `auth.service.ts` in the `src/app/model` folder and added the code shown in Listing 7-9.

Listing 7-9. The Contents of the auth.service.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Observable } from "rxjs";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class AuthService {

    constructor(private datasource: RestDataSource) {}

    authenticate(username: string, password: string): Observable<boolean> {
        return this.datasource.authenticate(username, password);
    }

    get authenticated(): boolean {
        return this.datasource.auth_token != null;
    }
```

```
    clear() {
        this.datasource.auth_token = undefined;
    }
}
```

The `authenticate` method receives the user's credentials and passes them on to the data source `authenticate` method, returning an `Observable` that will yield `true` if the authentication process has succeeded and `false` otherwise. The `authenticated` property is a getter-only property that returns `true` if the data source has obtained an authentication token. The `clear` method removes the token from the data source.

Listing 7-10 registers the new service with the model feature module. It also adds a `providers` entry for the `RestDataSource` class, which has been used only as a substitute for the `StaticDataSource` class in earlier chapters. Since the `AuthService` class has a `RestDataSource` constructor parameter, it needs its own entry in the module.

Listing 7-10. Configuring the Services in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { ProductRepository } from "./product.repository";
import { StaticDataSource } from "./static.datasource";
import { Cart } from "./cart.model";
import { Order } from "./order.model";
import { OrderRepository } from "./order.repository";
import { RestDataSource } from "./rest.datasource";
import { HttpClientModule } from "@angular/common/http";
import { AuthService } from "./auth.service";

@NgModule({
    imports: [HttpClientModule],
    providers: [ProductRepository, StaticDataSource, Cart, Order, OrderRepository,
        { provide: StaticDataSource, useClass: RestDataSource },
        RestDataSource, AuthService]
})
export class ModelModule { }
```

Enabling Authentication

The next step is to wire up the component that obtains the credentials from the user so that it will perform authentication through the new service, as shown in Listing 7-11.

Listing 7-11. Enabling Authentication in the auth.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";
import { NgForm } from "@angular/forms";
import { Router } from "@angular/router";
import { AuthService } from "../model/auth.service";

@Component({
    templateUrl: "auth.component.html"
})
```

```
export class AuthComponent {
    username?: string;
    password?: string;
    errorMessage?: string;

    constructor(private router: Router,
        private auth: AuthService) { }

    authenticate(form: NgForm) {
        if (form.valid) {
            this.auth.authenticate(this.username ?? "", this.password ?? "")
                .subscribe(response => {
                    if (response) {
                        this.router.navigateByUrl("/admin/main");
                    }
                    this.errorMessage = "Authentication Failed";
                })
        } else {
            this.errorMessage = "Form Data Invalid";
        }
    }
}
```

To prevent the application from navigating directly to the administration features, which will lead to HTTP requests being sent without a token, I added a file called auth.guard.ts in the src/app/admin folder and defined the route guard shown in Listing 7-12.

Listing 7-12. The Contents of the auth.guard.ts File in the src/app/admin Folder

```
import { Injectable } from "@angular/core";
import { ActivatedRouteSnapshot, RouterStateSnapshot,
         Router } from "@angular/router";
import { AuthService } from "../model/auth.service";

@Injectable()
export class AuthGuard {

    constructor(private router: Router,
                private auth: AuthService) { }

    canActivate(route: ActivatedRouteSnapshot,
        state: RouterStateSnapshot): boolean {

        if (!this.auth.authenticated) {
            this.router.navigateByUrl("/admin/auth");
            return false;
        }
        return true;
    }
}
```

Listing 7-13 applies the route guard to one of the routes defined by the administration feature module.

Listing 7-13. Guarding a Route in the admin.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { FormsModule } from "@angular/forms";
import { RouterModule } from "@angular/router";
import { AuthComponent } from "./auth.component";
import { AdminComponent } from "./admin.component";
import { AuthGuard } from "./auth.guard";

let routing = RouterModule.forChild([
    { path: "auth", component: AuthComponent },
    { path: "main", component: AdminComponent },
    { path: "main", component: AdminComponent, canActivate: [AuthGuard] },
    { path: "**", redirectTo: "auth" }
]);

@NgModule({
    imports: [CommonModule, FormsModule, routing],
    declarations: [AuthComponent, AdminComponent],
    providers: [AuthGuard]
})
export class AdminModule { }
```

To test the authentication system, click the Admin button, enter some credentials, and click the Log In button. If the credentials are the ones from Table 7-1, then you will see the placeholder for the administration features. If you enter other credentials, you will see an error message. Figure 7-3 illustrates both outcomes.

■ **Tip**   The token isn't stored persistently, so if you can, reload the application in the browser to start again and try a different set of credentials.

Figure 7-3. *Testing the authentication feature*

Extending the Data Source and Repositories

With the authentication system in place, the next step is to extend the data source so that it can send authenticated requests and to expose those features through the order and product repository classes. Listing 7-14 adds methods to the data source that include the authentication token.

Listing 7-14. Adding New Operations in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { map, Observable } from "rxjs";
import { Product } from "./product.model";
import { Order } from "./order.model";
import { HttpHeaders } from '@angular/common/http';

const PROTOCOL = "http";
const PORT = 3500;

@Injectable()
export class RestDataSource {
    baseUrl: string;
    auth_token?: string;

    constructor(private http: HttpClient) {
        this.baseUrl = `${PROTOCOL}://${location.hostname}:${PORT}/`;
    }

    getProducts(): Observable<Product[]> {
        return this.http.get<Product[]>(this.baseUrl + "products");
    }

    saveOrder(order: Order): Observable<Order> {
        return this.http.post<Order>(this.baseUrl + "orders", order);
    }

    authenticate(user: string, pass: string): Observable<boolean> {
        return this.http.post<any>(this.baseUrl + "login", {
            name: user, password: pass
        }).pipe(map(response => {
            this.auth_token = response.success ? response.token : null;
            return response.success;
        }));
    }

    saveProduct(product: Product): Observable<Product> {
        return this.http.post<Product>(this.baseUrl + "products",
            product, this.getOptions());
    }
```

167

```
    updateProduct(product: Product): Observable<Product> {
        return this.http.put<Product>(`${this.baseUrl}products/${product.id}`,
            product, this.getOptions());
    }

    deleteProduct(id: number): Observable<Product> {
        return this.http.delete<Product>(`${this.baseUrl}products/${id}`,
            this.getOptions());
    }

    getOrders(): Observable<Order[]> {
        return this.http.get<Order[]>(this.baseUrl + "orders", this.getOptions());
    }

    deleteOrder(id: number): Observable<Order> {
        return this.http.delete<Order>(`${this.baseUrl}orders/${id}`,
            this.getOptions());
    }

    updateOrder(order: Order): Observable<Order> {
        return this.http.put<Order>(`${this.baseUrl}orders/${order.id}`,
            order, this.getOptions());
    }

    private getOptions() {
        return {
            headers: new HttpHeaders({
                "Authorization": `Bearer<${this.auth_token}>`
            })
        }
    }
}
```

Listing 7-15 adds new methods to the product repository class that allow products to be created, updated, or deleted. The saveProduct method is responsible for creating and updating products, which is an approach that works well when using a single object managed by a component, which you will see demonstrated later in this chapter. The listing also changes the type of the constructor argument to RestDataSource.

Listing 7-15. Adding New Operations in the product.repository.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
//import { StaticDataSource } from "./static.datasource";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class ProductRepository {
    private products: Product[] = [];
    private categories: string[] = [];
```

```
    constructor(private dataSource: RestDataSource) {
        dataSource.getProducts().subscribe(data => {
            this.products = data;
            this.categories = data.map(p => p.category ?? "(None)")
                .filter((c, index, array) => array.indexOf(c) == index).sort();
        });
    }

    getProducts(category?: string): Product[] {
        return this.products
            .filter(p => category == undefined || category == p.category);
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => p.id == id);
    }

    getCategories(): string[] {
        return this.categories;
    }

    saveProduct(product: Product) {
        if (product.id == null || product.id == 0) {
            this.dataSource.saveProduct(product)
                .subscribe(p => this.products.push(p));
        } else {
            this.dataSource.updateProduct(product)
                .subscribe(p => {
                    this.products.splice(this.products.
                        findIndex(p => p.id == product.id), 1, product);
                });
        }
    }

    deleteProduct(id: number) {
        this.dataSource.deleteProduct(id).subscribe(p => {
            this.products.splice(this.products.
                findIndex(p => p.id == id), 1);
        })
    }
}
```

Listing 7-16 makes the corresponding changes to the order repository, adding methods that allow orders to be modified and deleted.

Listing 7-16. Adding New Operations in the order.repository.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Observable } from "rxjs";
import { Order } from "./order.model";
//import { StaticDataSource } from "./static.datasource";
import { RestDataSource } from "./rest.datasource";
```

```
@Injectable()
export class OrderRepository {
    private orders: Order[] = [];
    private loaded: boolean = false;

    constructor(private dataSource: RestDataSource) { }

    loadOrders() {
        this.loaded = true;
        this.dataSource.getOrders()
            .subscribe(orders => this.orders = orders);
    }

    getOrders(): Order[] {
        if (!this.loaded) {
            this.loadOrders();
        }
        return this.orders;
    }

    saveOrder(order: Order): Observable<Order> {
        this.loaded = false;
        return this.dataSource.saveOrder(order);
    }

    updateOrder(order: Order) {
        this.dataSource.updateOrder(order).subscribe(order => {
            this.orders.splice(this.orders.
                findIndex(o => o.id == order.id), 1, order);
        });
    }

    deleteOrder(id: number) {
        this.dataSource.deleteOrder(id).subscribe(order => {
            this.orders.splice(this.orders.findIndex(o => id == o.id), 1);
        });
    }
}
```

The order repository defines a loadOrders method that gets the orders from the repository and that ensures the request isn't sent to the RESTful web service until authentication has been performed.

Installing the Component Library

All the features presented to the user so far have been written using the Angular API and styled using the features provided by the Bootstrap CSS package. An alternative approach is to use a component library that contains commonly required features, such as tables and layouts, which lets you focus on the features that are unique to your project. The advantage of using a component library is that you can get a project up and running quickly, but the drawbacks are that you must fit your data and code into the model expected by the component library and that it can be difficult to perform customizations.

In this chapter, I am going to use the Angular Material component library. There are other good packages available for Angular, but Angular Material is the most popular package and has features that suit most projects. To add Angular Material to the project, stop the ng serve command and run the command shown in Listing 7-17 in the SportsStore folder.

Listing 7-17. Installing the Component Library Package

```
ng add @angular/material@13.0.2
```

The installation process asks several questions. The first question is just a request to confirm that you want to install the package:

```
Using package manager: npm
Package information loaded.
The package @angular/material@13.0.2 will be installed and executed.
Would you like to proceed? (Y/n)
```

The rest of the questions are specific to Angular Material and allow the theme to be selected and configure typography and animation options:

```
? Choose a prebuilt theme name, or "custom" for a custom theme: (Use arrow keys)
> Indigo/Pink        [ Preview: https://material.angular.io?theme=indigo-pink ]
  Deep Purple/Amber  [ Preview: https://material.angular.io?theme=deeppurple-amber ]
  Pink/Blue Grey     [ Preview: https://material.angular.io?theme=pink-bluegrey ]
  Purple/Green       [ Preview: https://material.angular.io?theme=purple-green ]
  Custom
? Set up global Angular Material typography styles? (y/N)
? Set up browser animations for Angular Material? (Y/n)
```

For the SportsStore project, select the default options.

Each feature provided by Angular Material is defined in its own module, and the simplest way to deal with this is to define a separate module that is used just to select the Angular Material features that are required by a project. Add a file named material.module.ts to the src/app/admin folder with the content shown in Listing 7-18.

Listing 7-18. The Contents of the material.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";

const features: any[] = [];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

No Angular Material features are selected at present, but I'll add to this file as I work through the administration features. In Listing 7-19, I have incorporated the module into the application.

Listing 7-19. Using Material Features in the admin.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { FormsModule } from "@angular/forms";
import { RouterModule } from "@angular/router";
import { AuthComponent } from "./auth.component";
import { AdminComponent } from "./admin.component";
import { AuthGuard } from "./auth.guard";
import { MaterialFeatures } from "./material.module";

let routing = RouterModule.forChild([
    { path: "auth", component: AuthComponent },
    { path: "main", component: AdminComponent },
    { path: "main", component: AdminComponent, canActivate: [AuthGuard] },
    { path: "**", redirectTo: "auth" }
]);

@NgModule({
    imports: [CommonModule, FormsModule, routing, MaterialFeatures],
    declarations: [AuthComponent, AdminComponent],
    providers: [AuthGuard]
})
export class AdminModule { }
```

Save the changes and run the ng serve command in the SportsStore folder to start the Angular development tools again.

Creating the Administration Feature Structure

Now that the authentication system is in place and the repositories provide the full range of operations, I can create the structure that will display the administration features, which I create by building on the existing URL routing configuration. Table 7-2 lists the URLs that I am going to support and the functionality that each will present to the user.

Table 7-2. *The URLs for Administration Features*

Name	Description
/admin/main/ products	Navigating to this URL will display all the products in a table, along with buttons that allow an existing product to be edited or deleted and a new product to be created.
/admin/main/ products/create	Navigating to this URL will present the user with an empty editor for creating a new product.
/admin/main/ products/edit/1	Navigating to this URL will present the user with a populated editor for editing an existing product.
/admin/main/ orders	Navigating to this URL will present the user with all the orders in a table, along with buttons to mark an order shipped and to cancel an order by deleting it.

Creating the Placeholder Components

I find the easiest way to add features to an Angular project is to define components that have placeholder content and build the structure of the application around them. Once the structure is in place, then I return to the components and implement the features in detail. For the administration features, I started by adding a file called `productTable.component.ts` to the `src/app/admin` folder and defined the component shown in Listing 7-20. This component will be responsible for showing a list of products, along with buttons required to edit and delete them or to create a new product.

Listing 7-20. The Contents of the productTable.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";

@Component({
    template: `
        <h3 style="padding-top: 10px">
            Product Table Placeholder
        </h3>
    `
})
export class ProductTableComponent {}
```

I added a file called `productEditor.component.ts` in the `src/app/admin` folder and used it to define the component shown in Listing 7-21, which will be used to allow the user to enter the details required to create or edit a component.

Listing 7-21. The Contents of the productEditor.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";

@Component({
    template: `<h3 style="padding-top: 10px">
                Product Editor Placeholder
               </h3>`
})
export class ProductEditorComponent { }
```

To create the component that will be responsible for managing customer orders, I added a file called `orderTable.component.ts` to the `src/app/admin` folder and added the code shown in Listing 7-22.

Listing 7-22. The Contents of the orderTable.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";

@Component({
    template: `<h3 style="padding-top: 10px">
                Order Table Placeholder
               </h3>`
})
export class OrderTableComponent { }
```

Preparing the Common Content and the Feature Module

The components created in the previous section will be responsible for specific features. To bring those features together and allow the user to navigate between them, I need to modify the template of the placeholder component that I have been using to demonstrate the result of a successful authentication attempt. I replaced the placeholder content with the elements shown in Listing 7-23.

Listing 7-23. Replacing the Content in the admin.component.html File in the src/app/admin Folder

```html
<mat-toolbar color="primary">
    <button mat-icon-button *ngIf="sidenav.mode === 'over'"
            (click)="sidenav.toggle()">
        <mat-icon *ngIf="!sidenav.opened">menu</mat-icon>
        <mat-icon *ngIf="sidenav.opened">close</mat-icon>
    </button>
    <span></span>
    SportsStore Administration
    <span></span>
</mat-toolbar>

<mat-sidenav-container>
    <mat-sidenav #sidenav="matSidenav" class="mat-elevation-z8">

        <button mat-button class="menu-button"
                routerLink="/admin/main/products"
                routerLinkActive="mat-accent"
                (click)="sidenav.close()">
            <mat-icon>shopping_cart</mat-icon>
            <span>Products</span>
        </button>

        <button mat-button class="menu-button"
                routerLink="/admin/main/orders"
                routerLinkActive="mat-accent"
                (click)="sidenav.close()">
            <mat-icon>local_shipping</mat-icon>
            <span>Orders</span>
        </button>

        <mat-divider></mat-divider>

        <button mat-button class="menu-button logout" (click)="logout()">
            <mat-icon>logout</mat-icon>
            <span>Logout</span>
        </button>

    </mat-sidenav>
    <mat-sidenav-content>
        <div class="content">
            <router-outlet></router-outlet>
        </div>
    </mat-sidenav-content>
</mat-sidenav-container>
```

When you first start working with a component library, it can take a while to make sense of how the components are applied. This template relies on the Angular Material toolbar, applied using the `mat-toolbar` element, and the sidenav component, which is applied through the `mat-sidenav-container`, `mat-sidenav`, and `mat-sidenav-content` elements. A sidenav is a collapsible panel that contains navigation content that will allow the user to select different administration features.

This template also contains a `router-outlet` element that will be used to display the components from the previous section. The sidenav panel contains buttons to which the `mat-button` directive has been applied, which formats the buttons to match the rest of the Angular Material theme. These buttons are configured with `routerLink` attributes that target the `router-outlet` element and are styled with the `routerLinkAttribute` attribute to indicate which feature has been selected.

Listing 7-24 adds dependencies on the Angular Material features used in this template.

Listing 7-24. Adding Features in the material.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { MatToolbarModule } from "@angular/material/toolbar";
import { MatSidenavModule } from "@angular/material/sidenav";
import { MatIconModule } from '@angular/material/icon';
import { MatDividerModule } from '@angular/material/divider';
import { MatButtonModule } from "@angular/material/button";

const features: any[] = [MatToolbarModule,MatSidenavModule,MatIconModule,
    MatDividerModule, MatButtonModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

One drawback of the Angular Material package is that it requires CSS styles to be applied to fine-tune the component layout. Listing 7-25 defines the styles required to lay out the components used in Listing 7-23.

Listing 7-25. Defining Styles in the styles.css File in the src Folder

```
html, body  { height: 100%}
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

mat-toolbar span { flex: 1 1 auto; }

.menu-button { width: 100%; font-size: 1rem; }
.menu-button .mat-icon {  margin-right: 10px; }
.menu-button span {  flex: 1 1 auto; }

mat-sidenav { margin: 16px; width: 175px; border-right: none;
    border-radius: 4px; padding: 4px;
}
mat-sidenav .mat-divider { margin-top: 20px; margin-bottom: 5px; }
mat-sidenav-container { height: calc(100vh - 60px); }
mat-sidenav .mat-button-wrapper {
```

```
    display: flex; width: 100%; justify-content: baseline; align-content: center;
}
mat-sidenav .mat-button-wrapper  mat-icon { margin-top: 5px; }
mat-sidenav .mat-button-wrapper span { text-align: start; }
```

These styles can be awkward to determine, and I find the most useful approach is to use the browser's F12 developer tools to work out how to select the elements I am interested in and determine how they are styled.

The sidenav panel defined in Listing 7-23 contains a Logout button that has an event binding that targets a method called logout. Listing 7-26 adds this method to the component, which uses the authentication service to remove the bearer token and navigates the application to the default URL.

Listing 7-26. Implementing the Logout Method in the admin.component.ts File in the src/app/ admin Folder

```
import { Component } from "@angular/core";
import { Router } from "@angular/router";
import { AuthService } from "../model/auth.service";

@Component({
    templateUrl: "admin.component.html"
})
export class AdminComponent {

    constructor(private auth: AuthService,
                private router: Router) { }

    logout() {
        this.auth.clear();
        this.router.navigateByUrl("/");
    }
}
```

Listing 7-27 enables the placeholder components that will be used for each administration feature and extends the URL routing configuration to implement the URLs from Table 7-2.

Listing 7-27. Configuring the Feature Module in the admin.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { FormsModule } from "@angular/forms";
import { RouterModule } from "@angular/router";
import { AuthComponent } from "./auth.component";
import { AdminComponent } from "./admin.component";
import { AuthGuard } from "./auth.guard";
import { MaterialFeatures } from "./material.module";
import { ProductTableComponent } from "./productTable.component";
import { ProductEditorComponent } from "./productEditor.component";
import { OrderTableComponent } from "./orderTable.component";

let routing = RouterModule.forChild([
    { path: "auth", component: AuthComponent },
    // { path: "main", component: AdminComponent },
```

```
    // { path: "main", component: AdminComponent, canActivate: [AuthGuard] },
    {
        path: "main", component: AdminComponent, canActivate: [AuthGuard],
        children: [
            { path: "products/:mode/:id", component: ProductEditorComponent },
            { path: "products/:mode", component: ProductEditorComponent },
            { path: "products", component: ProductTableComponent },
            { path: "orders", component: OrderTableComponent },
            { path: "**", redirectTo: "products" }
        ]
    },
    { path: "**", redirectTo: "auth" }
]);

@NgModule({
    imports: [CommonModule, FormsModule, routing, MaterialFeatures],
    declarations: [AuthComponent, AdminComponent, ProductTableComponent,
        ProductEditorComponent, OrderTableComponent],
    providers: [AuthGuard]
})
export class AdminModule { }
```

Individual routes can be extended using the children property, which is used to define routes that will target a nested router-outlet element, which I describe in Chapter 24. As you will see, components can get details of the active route from Angular so they can adapt their behavior. Routes can include route parameters, such as :mode or :id, that match any URL segment and that can be used to provide information to components that can be used to change their behavior.

When all the changes have been saved, click the Admin button and authenticate as admin with the password secret. You will see the new layout, as shown in Figure 7-4. Click the button on the left side of the toolbar to display the navigation panel, and click the Orders button to change the selected component, or the Logout button to exit the administration area.

Figure 7-4. *The administration layout structure*

Implementing the Product Table Feature

The initial administration feature presented to the user will be a table of products, with the ability to create a new product and delete or edit an existing one. Listing 7-28 adds the Angular Material table component to the application.

Listing 7-28. Adding Features in the material.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { MatToolbarModule } from "@angular/material/toolbar";
import { MatSidenavModule } from "@angular/material/sidenav";
import { MatIconModule } from '@angular/material/icon';
import { MatDividerModule } from '@angular/material/divider';
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";

const features: any[] = [MatToolbarModule,MatSidenavModule,MatIconModule,
    MatDividerModule, MatButtonModule, MatTableModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

To provide the template that defines the table, I added a file called `productTable.component.html` in the `src/app/admin` folder and added the markup shown in Listing 7-29.

Listing 7-29. The Contents of the productTable.component.html File in the src/app/admin Folder

```
<table mat-table [dataSource]="dataSource">

    <mat-text-column name="id"></mat-text-column>
    <mat-text-column name="name"></mat-text-column>
    <mat-text-column name="category"></mat-text-column>

    <ng-container matColumnDef="price">
      <th mat-header-cell *matHeaderCellDef>Price</th>
      <td mat-cell *matCellDef="let item"> {{item.price | currency:"USD"}} </td>
    </ng-container>

    <ng-container matColumnDef="buttons">
      <th mat-header-cell *matHeaderCellDef></th>
      <td mat-cell *matCellDef="let p">
          <button mat-flat-button color="accent"
                (click)="deleteProduct(p.id)">
            Delete
          </button>
          <button mat-flat-button color="warn"
                [routerLink]="['/admin/main/products/edit', p.id]">
            Edit
          </button>
      </td>
    </ng-container>
```

```
    <tr mat-header-row *matHeaderRowDef="colsAndRows"></tr>
    <tr mat-row *matRowDef="let row; columns: colsAndRows"></tr>
</table>

<button mat-flat-button color="primary" routerLink="/admin/main/products/create">
    Create New Product
</button>
```

The table relies on the features provided by the Angular Material table component, which has an unusual approach to defining the table contents, but one that provides a good foundation for extra features, as I demonstrate shortly. The table defines columns that display the details of products, and each row contains a Delete button that invokes a component method named delete method, and an Edit button that navigates to a URL that targets the editor component. The editor component is also the target of the Create New Product button, although a different URL is used.

Once again, custom CSS styles are required to fine-tune the layout of the table, as shown in Listing 7-30.

Listing 7-30. Defining Styles in the styles.css File in the src Folder

```
html, body  { height: 100%}
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

mat-toolbar span { flex: 1 1 auto; }

.menu-button { width: 100%; font-size: 1rem; }
.menu-button .mat-icon {  margin-right: 10px; }
.menu-button span {  flex: 1 1 auto; }

mat-sidenav { margin: 16px; width: 175px; border-right: none;
    border-radius: 4px; padding: 4px;
}
mat-sidenav .mat-divider { margin-top: 20px; margin-bottom: 5px; }
mat-sidenav-container { height: calc(100vh - 60px); }
mat-sidenav .mat-button-wrapper {
    display: flex; width: 100%; justify-content: baseline; align-content: center;
}
mat-sidenav .mat-button-wrapper  mat-icon { margin-top: 5px; }
mat-sidenav .mat-button-wrapper span { text-align: start; }

table[mat-table] { width: 100%; table-layout: auto; }
table[mat-table] button { margin-left: 5px;}
table[mat-table] th.mat-header-cell { font-size: large; font-weight: bold;}
table[mat-table] .mat-column-name { width: 25%; }
table[mat-table] .mat-column-buttons { width: 30%; }
table[mat-table] + button[mat-flat-button] { margin-top: 10px;}
```

As I explained when I installed the Angular Material package, using a component library means that you have to adapt your application or data to the expectations of the package. Taking full advantage of the Angular Material table requires the use of a data source class, which can require work when the data displayed in the table is obtained via an HTTP request. In Part 3, I demonstrate how to avoid this issue using observables, including with the Angular Material table in Chapter 28. For this chapter, I am going

to demonstrate a different approach, which is to use the features that Angular provides for detecting and processing updates. Listing 7-31 removes the placeholder content from the product table component and adds the logic required to implement this feature.

Listing 7-31. Adding Features in the productTable.component.ts File in the src/app/admin Folder

```
import { Component, IterableDiffer, IterableDiffers } from "@angular/core";
import { MatTableDataSource } from "@angular/material/table";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";

@Component({
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {
    colsAndRows: string[] = ['id', 'name', 'category', 'price', 'buttons'];
    dataSource = new MatTableDataSource<Product>(this.repository.getProducts());
    differ: IterableDiffer<Product>;

    constructor(private repository: ProductRepository, differs: IterableDiffers) {
        this.differ = differs.find(this.repository.getProducts()).create();
    }

    ngDoCheck() {
        let changes = this.differ?.diff(this.repository.getProducts());
        if (changes != null) {
            this.dataSource.data = this.repository.getProducts();
        }
    }

    deleteProduct(id: number) {
        this.repository.deleteProduct(id);
    }
}
```

The colsAndRows property is used to specify the columns that are displayed in the table. I have selected all of the columns that were defined, but this feature can be used to programmatically alter the structure of the table.

The MatTableDataSource<Product> class connects the data in the application with the table. The data source object is created with the data in the repository, but this isn't helpful if the component is displayed before the application receives the data from the server. Angular has an efficient change-detection system, which it uses to ensure that updates are processed with the minimum of work, and the ngDoCheck method allows me to hook into that system and check to see if the data in the repository has been changed, using features that are described in context in Chapter 13. If there is a change in the data, then I refresh the data source, which has the effect of updating the table.

Save the changes and log into the administration features, and you will see the table shown in Figure 7-5.

Figure 7-5. *Displaying the product table*

Using the Table Component Features

Getting a library component working can require effort, but once the initial work is done, it becomes relatively simple to take advantage of the additional features that are provided. In the case of the Angular Material table, these features include filtering, sorting, and paginating data. I demonstrate the filtering support when implementing the orders feature, but in this section, I am going to use the pagination feature. The first step is to add the pagination feature to the application, as shown in Listing 7-32.

Listing 7-32. Adding a Feature in the material.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { MatToolbarModule } from "@angular/material/toolbar";
import { MatSidenavModule } from "@angular/material/sidenav";
import { MatIconModule } from '@angular/material/icon';
import { MatDividerModule } from '@angular/material/divider';
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";
import { MatPaginatorModule } from "@angular/material/paginator";

const features: any[] = [MatToolbarModule,MatSidenavModule,MatIconModule,
    MatDividerModule, MatButtonModule, MatTableModule, MatPaginatorModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

The next step is to add a paginator to the component that displays the table, as shown in Listing 7-33.

Listing 7-33. Adding Pagination in the productTable.component.html File in the src/app/admin Folder

```
<table mat-table [dataSource]="dataSource">

    <mat-text-column name="id"></mat-text-column>
    <mat-text-column name="name"></mat-text-column>
    <mat-text-column name="category"></mat-text-column>

    <ng-container matColumnDef="price">
      <th mat-header-cell *matHeaderCellDef>Price</th>
      <td mat-cell *matCellDef="let item"> {{item.price | currency:"USD"}} </td>
    </ng-container>

    <ng-container matColumnDef="buttons">
      <th mat-header-cell *matHeaderCellDef></th>
      <td mat-cell *matCellDef="let p">
          <button mat-flat-button color="accent"
                (click)="deleteProduct(p.id)">
            Delete
          </button>
          <button mat-flat-button color="warn"
                [routerLink]="['/admin/main/products/edit', p.id]">
            Edit
          </button>
    </ng-container>

    <tr mat-header-row *matHeaderRowDef="colsAndRows"></tr>
    <tr mat-row *matRowDef="let row; columns: colsAndRows"></tr>
</table>
```

```
<div class="bottom-box">
    <button mat-flat-button color="primary" routerLink="/admin/main/products/create">
        Create New Product
    </button>
    <mat-paginator [pageSize]="5" [pageSizeOptions]="[3, 5, 10]">
    </mat-paginator>
</div>
```

The paginator must be associated with the data source that is used by the table, which is done in the component, as shown in Listing 7-34.

Listing 7-34. Connecting the Paginator in the productTable.component.ts File in the src/app/admin Folder

```
import { Component, IterableDiffer, IterableDiffers, ViewChild } from "@angular/core";
import { MatTableDataSource } from "@angular/material/table";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";
import { MatPaginator } from "@angular/material/paginator";

@Component({
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {
    colsAndRows: string[] = ['id', 'name', 'category', 'price', 'buttons'];

    dataSource = new MatTableDataSource<Product>(this.repository.getProducts());
    differ: IterableDiffer<Product>;

    @ViewChild(MatPaginator)
    paginator? : MatPaginator

    constructor(private repository: ProductRepository, differs: IterableDiffers) {
        this.differ = differs.find(this.repository.getProducts()).create();
    }

    ngDoCheck() {
        let changes = this.differ?.diff(this.repository.getProducts());
        if (changes != null) {
            this.dataSource.data = this.repository.getProducts();
        }
    }

    ngAfterViewInit() {
        if (this.paginator) {
            this.dataSource.paginator = this.paginator;
        }
    }

    deleteProduct(id: number) {
        this.repository.deleteProduct(id);
    }
}
```

The ViewChild decorator is used to query the component's template content, as described in Chapter 15, and is used here to find the paginator component. The ngAfterViewInit method is called after Angular has finished processing the template, as described in Chapter 13, by which time the paginator component will have been created and can be associated with the data source.

And, of course, some additional CSS styles are required to manage the layout, as shown in Listing 7-35.

Listing 7-35. Defining Styles in the styles.css File in the src Folder

```
html, body  { height: 100%}
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

mat-toolbar span { flex: 1 1 auto; }

.menu-button { width: 100%; font-size: 1rem; }
.menu-button .mat-icon {  margin-right: 10px; }
.menu-button span {  flex: 1 1 auto; }

mat-sidenav { margin: 16px; width: 175px; border-right: none;
    border-radius: 4px; padding: 4px;
}
mat-sidenav .mat-divider { margin-top: 20px; margin-bottom: 5px; }
mat-sidenav-container { height: calc(100vh - 60px); }
mat-sidenav .mat-button-wrapper {
    display: flex; width: 100%; justify-content: baseline; align-content: center;
}
mat-sidenav .mat-button-wrapper  mat-icon { margin-top: 5px; }
mat-sidenav .mat-button-wrapper span { text-align: start; }

table[mat-table] { width: 100%; table-layout: auto; }
table[mat-table] button { margin-left: 5px;}
table[mat-table] th.mat-header-cell { font-size: large; font-weight: bold;}
table[mat-table] .mat-column-name { width: 25%; }
table[mat-table] .mat-column-buttons { width: 30%; }
/* table[mat-table] +  button[mat-flat-button] { margin-top: 10px;} */

.bottom-box { background-color: white; padding-bottom: 20px;}
.bottom-box  >  button[mat-flat-button] { margin-top: 10px;}
.bottom-box mat-paginator { float: right; font-size: 14px; }
```

Save the changes, and you will see that the initial work adapting the application to work in the model expected by Angular Material has paid off, and I am able to use the built-in support for pagination, as shown in Figure 7-6.

Figure 7-6. *Using the Angular Material table paginator*

Implementing the Product Editor

Components can receive information about the current routing URL and adapt their behavior accordingly. The editor component needs to use this feature to differentiate between requests to create a new component and edit an existing one.

Listing 7-36 adds the functionality to the editor component required to create or edit products.

Listing 7-36. Adding Functionality in the productEditor.component.ts File in the src/app/admin Folder

```
import { Component } from "@angular/core";
import { Router, ActivatedRoute } from "@angular/router";
import { Product } from "../model/product.model";
import { ProductRepository } from "../model/product.repository";

@Component({
    templateUrl: "productEditor.component.html"
})
export class ProductEditorComponent {
    editing: boolean = false;
    product: Product = new Product();
```

185

```
    constructor(private repository: ProductRepository,
                private router: Router,
                activeRoute: ActivatedRoute) {

        this.editing = activeRoute.snapshot.params["mode"] == "edit";
        if (this.editing) {
            Object.assign(this.product,
                repository.getProduct(activeRoute.snapshot.params["id"]));
        }
    }

    save() {
        this.repository.saveProduct(this.product);
        this.router.navigateByUrl("/admin/main/products");
    }
}
```

Angular will provide an ActivatedRoute object as a constructor argument when it creates a new instance of the component class, and this object can be used to inspect the activated route. In this case, the component works out whether it should be editing or creating a product and, if editing, retrieves the current details from the repository. There is also a save method, which uses the repository to save changes that the user has made.

An HTML form will be used to allow the user to edit products. The Angular Material package provides support for form fields; Listing 7-37 adds those features to the SportsStore application.

Listing 7-37. Adding a Feature in the material.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { MatToolbarModule } from "@angular/material/toolbar";
import { MatSidenavModule } from "@angular/material/sidenav";
import { MatIconModule } from '@angular/material/icon';
import { MatDividerModule } from '@angular/material/divider';
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";
import { MatPaginatorModule } from "@angular/material/paginator";
import { MatFormFieldModule } from '@angular/material/form-field';
import { MatInputModule } from '@angular/material/input';

const features: any[] = [MatToolbarModule,MatSidenavModule,MatIconModule,
    MatDividerModule, MatButtonModule, MatTableModule, MatPaginatorModule,
    MatFormFieldModule, MatInputModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

To define the template with the form, add a file called productEditor.component.html in the src/app/admin folder and add the markup shown in Listing 7-38.

Listing 7-38. The Contents of the productEditor.component.html File in the src/app/admin Folder

```html
<h3 class="heading">{{editing  ? "Edit" : "Create"}} Product</h3>

<form (ngSubmit)="save()">

    <mat-form-field *ngIf="editing">
        <mat-label>ID</mat-label>
        <input matInput name="id" [(ngModel)]="product.id" disabled />
    </mat-form-field>

    <mat-form-field>
        <mat-label>Name</mat-label>
        <input matInput name="name" [(ngModel)]="product.name" />
    </mat-form-field>

    <mat-form-field>
        <mat-label>Category</mat-label>
        <input matInput name="category" [(ngModel)]="product.category" />
    </mat-form-field>

    <mat-form-field>
        <mat-label>Description</mat-label>
        <input name="description"  matInput [(ngModel)]="product.description"/>
    </mat-form-field>

    <mat-form-field>
        <mat-label>Price</mat-label>
        <input matInput name="price" [(ngModel)]="product.price" />
    </mat-form-field>

    <button type="submit" mat-flat-button color="primary">
        {{editing ? "Save" : "Create"}}
    </button>
    <button type="reset" mat-stroked-button  routerLink="/admin/main/products">
        Cancel
    </button>
</form>
```

The template contains a form with fields for the properties defined by the Product model class. The field for the id property is shown only when editing an existing product and is disabled because the value cannot be changed. Listing 7-39 defines the styles that are required to lay out the form.

Listing 7-39. Defining Styles in the styles.css File in the src Folder

```css
html, body  { height: 100%}
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

mat-toolbar span { flex: 1 1 auto; }

.menu-button { width: 100%; font-size: 1rem; }
.menu-button .mat-icon {  margin-right: 10px; }
.menu-button span {  flex: 1 1 auto; }
```

```
mat-sidenav { margin: 16px; width: 175px; border-right: none;
    border-radius: 4px; padding: 4px;
}
mat-sidenav .mat-divider { margin-top: 20px; margin-bottom: 5px; }
mat-sidenav-container { height: calc(100vh - 60px); }
mat-sidenav .mat-button-wrapper {
    display: flex; width: 100%; justify-content: baseline; align-content: center;
}
mat-sidenav .mat-button-wrapper  mat-icon { margin-top: 5px; }
mat-sidenav .mat-button-wrapper span { text-align: start; }

table[mat-table] { width: 100%; table-layout: auto; }
table[mat-table] button { margin-left: 5px;}
table[mat-table] th.mat-header-cell { font-size: large; font-weight: bold;}
table[mat-table] .mat-column-name { width: 25%; }
table[mat-table] .mat-column-buttons { width: 30%; }
/* table[mat-table] +  button[mat-flat-button] { margin-top: 10px;} */

.bottom-box { background-color: white; padding-bottom: 20px;}
.bottom-box  >  button[mat-flat-button] { margin-top: 10px;}
.bottom-box mat-paginator { float: right; font-size: 14px; }

mat-form-field { width: 100%;}
mat-form-field:first-child { margin-top: 20px;}
form button[mat-flat-button] { margin-top: 10px; margin-right: 10px;}
h3.heading {  margin-top: 20px; }
```

To see how the component works, authenticate to access the Admin features and click the Create New Product button that appears under the table of products. Fill out the form, click the Create button, and the new product will be sent to the RESTful web service where it will be assigned an ID property and displayed in the product table, as shown in Figure 7-7.

■ **Tip** Restart the ng serve command if you see an error after saving these changes.

Figure 7-7. *Creating a new product*

The editing process works in a similar way. Click one of the Edit buttons to see the current details, edit them using the form fields, and click the Save button to save the changes, as shown in Figure 7-8.

Figure 7-8. *Editing an existing product*

189

Implementing the Order Table Feature

The order management feature is nice and simple. It requires a table that lists the set of orders, along with buttons that will set the shipped property or delete an order entirely. The table will be displayed with a checkbox that will include shipped orders in the table. Listing 7-40 adds the Angular Material checkbox feature to the SportsStore project.

Listing 7-40. Adding a Feature in the material.module.ts File in the src/app/admin Folder

```
import { NgModule } from "@angular/core";
import { MatToolbarModule } from "@angular/material/toolbar";
import { MatSidenavModule } from "@angular/material/sidenav";
import { MatIconModule } from '@angular/material/icon';
import { MatDividerModule } from '@angular/material/divider';
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";
import { MatPaginatorModule } from "@angular/material/paginator";
import { MatFormFieldModule } from '@angular/material/form-field';
import { MatInputModule } from '@angular/material/input';
import { MatCheckboxModule } from '@angular/material/checkbox';

const features: any[] = [MatToolbarModule,MatSidenavModule,MatIconModule,
    MatDividerModule, MatButtonModule, MatTableModule, MatPaginatorModule,
    MatFormFieldModule, MatInputModule, MatCheckboxModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

To create the template, I added a file called orderTable.component.html to the src/app/admin folder with the content shown in Listing 7-41.

Listing 7-41. The Contents of the orderTable.component.html File in the src/app/admin Folder

```
<mat-checkbox [(ngModel)]="includeShipped">Display Shipped Orders</mat-checkbox>

<table class="orders" mat-table [dataSource]="dataSource">

    <mat-text-column name="name"></mat-text-column>
    <mat-text-column name="zip"></mat-text-column>

    <ng-container matColumnDef="cart_p">
        <th mat-header-cell *matHeaderCellDef></th>
        <td mat-cell *matCellDef="let order">
            <table mat-table [dataSource]="order.cart.lines">
                <ng-container matColumnDef="p">
                    <th mat-header-cell *matHeaderCellDef>Product</th>
                    <td mat-cell *matCellDef="let line">{{ line.product.name }}</td>
                </ng-container>
```

```
                <tr mat-header-row *matHeaderRowDef="['p']"></tr>
                <tr mat-row *matRowDef="let row; columns: ['p']"></tr>
            </table>
        </td>
    </ng-container>

    <ng-container matColumnDef="cart_q">
        <th mat-header-cell *matHeaderCellDef></th>
        <td mat-cell *matCellDef="let order">
            <table mat-table [dataSource]="order.cart.lines">
                <ng-container matColumnDef="q">
                    <th mat-header-cell *matHeaderCellDef>Quantity</th>
                    <td mat-cell *matCellDef="let line">{{ line.quantity }}</td>
                </ng-container>
                <tr mat-header-row *matHeaderRowDef="['q']"></tr>
                <tr mat-row *matRowDef="let row; columns: ['q']"></tr>
            </table>
        </td>
    </ng-container>

    <ng-container matColumnDef="buttons">
      <th mat-header-cell *matHeaderCellDef>Actions</th>
      <td mat-cell *matCellDef="let o">
          <button mat-flat-button color="primary" (click)="toggleShipped(o)">
              {{ o.shipped ? "Unship" : "Ship" }}
          </button>
          <button mat-flat-button color="warn" (click)="delete(o.id)">
              Delete
          </button>
      </td>
    </ng-container>

    <tr mat-header-row *matHeaderRowDef="colsAndRows"></tr>
    <tr mat-row *matRowDef="let row; columns: colsAndRows"></tr>

    <tr class="mat-row" *matNoDataRow>
        <td class="mat-cell no-data" colspan="4">No orders to display</td>
    </tr>
</table>
```

This template contains tables within a table, which allows me to produce a variable number of rows for each order, reflecting the customer's product selections. There is also a checkbox that sets a property named includeShipped, which is defined in Listing 7-42, along with the rest of the features required to support the template.

Listing 7-42. Adding Features in the orderTable.component.ts File in the src/app/admin Folder

```
import { Component, IterableDiffer, IterableDiffers } from "@angular/core";
import { MatTableDataSource } from "@angular/material/table";
import { Order } from "../model/order.model";
import { OrderRepository } from "../model/order.repository";
```

```
@Component({
    templateUrl: "orderTable.component.html"
})
export class OrderTableComponent {
    colsAndRows: string[] = ['name', 'zip','cart_p','cart_q', 'buttons'];

    dataSource = new MatTableDataSource<Order>(this.repository.getOrders());
    differ: IterableDiffer<Order>;

    constructor(private repository: OrderRepository, differs: IterableDiffers) {
        this.differ = differs.find(this.repository.getOrders()).create();
        this.dataSource.filter = "true";
        this.dataSource.filterPredicate = (order, include) => {
            return !order.shipped || include.toString() == "true"
        };
    }

    get includeShipped(): boolean {
        return this.dataSource.filter == "true";
    }

    set includeShipped(include: boolean) {
        this.dataSource.filter = include.toString()
    }

    toggleShipped(order: Order) {
        order.shipped = !order.shipped;
        this.repository.updateOrder(order);
    }

    delete(id: number) {
        this.repository.deleteOrder(id);
    }

    ngDoCheck() {
        let changes = this.differ?.diff(this.repository.getOrders());
        if (changes != null) {
            this.dataSource.data = this.repository.getOrders();
        }
    }
}
```

The way that data is filtered in this example is a good example of adapting to the way the component library works. The support for filtering data provided by the Angular Material table is intended to search for strings in the table and to update the filtered data only when a new search string is specified. I have replaced the function used to filter rows and ensure that filtering is applied by binding changes from the checkbox so that the search string is altered each time.

The final step is to define yet more CSS to control the layout of the table and its contents, as shown in Listing 7-43.

Listing 7-43. Defining Styles in the styles.css File in the src Folder

```
html, body  { height: 100%}
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

mat-toolbar span { flex: 1 1 auto; }

.menu-button { width: 100%; font-size: 1rem; }
.menu-button .mat-icon {  margin-right: 10px; }
.menu-button span {  flex: 1 1 auto; }

mat-sidenav { margin: 16px; width: 175px; border-right: none;
    border-radius: 4px; padding: 4px;
}
mat-sidenav .mat-divider { margin-top: 20px; margin-bottom: 5px; }
mat-sidenav-container { height: calc(100vh - 60px); }
mat-sidenav .mat-button-wrapper {
    display: flex; width: 100%; justify-content: baseline; align-content: center;
}
mat-sidenav .mat-button-wrapper  mat-icon { margin-top: 5px; }
mat-sidenav .mat-button-wrapper span { text-align: start; }

table[mat-table] { width: 100%; table-layout: auto; }
table[mat-table] button { margin-left: 5px;}
table[mat-table] th.mat-header-cell { font-size: large; font-weight: bold;}
table[mat-table] .mat-column-name { width: 25%; }
table[mat-table] .mat-column-buttons { width: 30%; }
/* table[mat-table] +  button[mat-flat-button] { margin-top: 10px;} */

.bottom-box { background-color: white; padding-bottom: 20px;}
.bottom-box  >  button[mat-flat-button] { margin-top: 10px;}
.bottom-box mat-paginator { float: right; font-size: 14px; }

mat-form-field { width: 100%;}
mat-form-field:first-child { margin-top: 20px;}
form button[mat-flat-button] { margin-top: 10px; margin-right: 10px;}
h3.heading {  margin-top: 20px; }

mat-checkbox { margin: 10px; font-size: large;}
td.no-data { font-size: large;}
table.orders tbody, table.orders thead { vertical-align: top }
table.orders td { padding-top: 10px;}
table.orders table th:first-of-type, table.orders table td:first-of-type {
    margin: 0; padding: 0;
}
```

Remember that the data presented by the RESTful web service is reset each time the process is started, which means you will have to use the shopping cart and check out to create orders. Once that's done, you can inspect and manage them using the Orders section of the administration tool, as shown in Figure 7-9.

Figure 7-9. *Managing orders*

Summary

In this chapter, I created a dynamically loaded Angular feature module that contains the administration tools required to manage the catalog of products and process orders. In the next chapter, I finish the SportsStore application and prepare it for deployment into production.

CHAPTER 8

■ ■ ■

SportsStore: Progressive Features and Deployment

In this chapter, I prepare the SportsStore application for deployment by adding progressive features that will allow it to work while offline and show you how to prepare and deploy the application into a Docker container, which can be used on most hosting platforms.

Preparing the Example Application

No preparation is required for this chapter, which continues using the SportsStore project from Chapter 7.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from `https://github.com/Apress/pro-angular-5ed`. See Chapter 1 for how to get help if you have problems running the examples.

Adding Progressive Features

A *progressive web application* (PWA) behaves more like a native application, which means it can continue working when there is no network connectivity, its code and content are cached so it can start immediately, and it can use features such as notifications. Progressive web application features are not specific to Angular, but in the sections that follow, I add progressive features to the SportsStore application to show you how it is done.

■ **Tip**   The process for developing and testing a PWA can be laborious because it can be done only when the application is built for production, which means that the automatic build tools cannot be used.

Installing the PWA Package

The Angular team provides an NPM package that can be used to bring PWA features to Angular projects. Run the command shown in Listing 8-1 in the `SportsStore` folder to download and install the PWA package.

■ **Tip**   Notice that this command is ng add, rather than the npm install command that I use elsewhere for adding packages. The ng add command is used specifically to install packages, such as @angular/pwa, that have been designed to enhance or reconfigure an Angular project.

Listing 8-1. Installing a Package

```
ng add @angular/pwa
```

Caching the Data URLs

The @angular/pwa package configures the application so that HTML, JavaScript, and CSS files are cached, which will allow the application to be started even when there is no network available. I also want the product catalog to be cached so that the application has data to present to the user. In Listing 8-2, I added a new section to the ngsw-config.json file, which is used to configure the PWA features for an Angular application and is added to the project by the @angular/pwa package.

Listing 8-2. Caching the Data URLs in the ngsw-config.json File in the SportsStore Folder

```
{
  "$schema": "./node_modules/@angular/service-worker/config/schema.json",
  "index": "/index.html",
  "assetGroups": [
    {
      "name": "app",
      "installMode": "prefetch",
      "resources": {
        "files": [
          "/favicon.ico",
          "/index.html",
          "/manifest.webmanifest",
          "/*.css",
          "/*.js"
        ]
      }
    },
    {
      "name": "assets",
      "installMode": "lazy",
      "updateMode": "prefetch",
      "resources": {
        "files": [
          "/assets/**",
          "/*.(svg|cur|jpg|jpeg|png|apng|webp|avif|gif|otf|ttf|woff|woff2)"
        ]
      }
    }
  ],
```

```
    "dataGroups": [
      {
          "name": "api-product",
          "urls": ["/api/products"],
          "cacheConfig" : {
              "maxSize": 100,
              "maxAge": "5d"
          }
    }],
    "navigationUrls": ["/**"]
}
```

The PWA's code and content required to run the application are cached and updated when new versions are available, ensuring that updates are applied consistently when they are available, using the configuration in the assetGroups section of the configuration file.

The application's data is cached using the dataGroups section of the configuration file, which allows data to be managed using its own cache settings. In this listing, I configured the cache so that it will contain data from 100 requests, and that data will be valid for five days. The final configuration section is navigationUrls, which specifies the range of URLs that will be directed to the index.html file. In this example, I used a wildcard to match all URLs.

■ **Note** I am just touching the surface of the cache features that you can use in a PWA. There are lots of choices available, including the ability to try to connect to the network and then fall back to cached data if there is no connection. See https://angular.io/guide/service-worker-intro for details.

Responding to Connectivity Changes

The SportsStore application isn't an ideal candidate for progressive features because connectivity is required to place an order. To avoid user confusion when the application is running without connectivity, I am going to disable the checkout process. The APIs that are used to add progressive features provide information about the state of connectivity and send events when the application goes offline and online. To provide the application with details of its connectivity, I added a file called connection.service.ts to the src/app/model folder and used it to define the service shown in Listing 8-3.

Listing 8-3. The Contents of the connection.service.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Observable, Subject } from "rxjs";

@Injectable()
export class ConnectionService {
    private connEvents: Subject<boolean>;

    constructor() {
        this.connEvents = new Subject<boolean>();
        window.addEventListener("online",
            (e) => this.handleConnectionChange(e));
```

```
        window.addEventListener("offline",
            (e) => this.handleConnectionChange(e));
    }

    private handleConnectionChange(event: any) {
        this.connEvents.next(this.connected);
    }

    get connected() : boolean {
        return window.navigator.onLine;
    }

    get Changes(): Observable<boolean> {
        return this.connEvents;
    }
}
```

This service presets the connection status to the rest of the application, obtaining the status through the browser's `navigator.onLine` property and responding to the `online` and `offline` events, which are triggered when the connection state changes and which are accessed through the `addEventListener` method provided by the browser. In Listing 8-4, I added the new service to the module for the data model.

Listing 8-4. Adding a Service in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { ProductRepository } from "./product.repository";
import { StaticDataSource } from "./static.datasource";
import { Cart } from "./cart.model";
import { Order } from "./order.model";
import { OrderRepository } from "./order.repository";
import { RestDataSource } from "./rest.datasource";
import { HttpClientModule } from "@angular/common/http";
import { AuthService } from "./auth.service";
import { ConnectionService } from "./connection.service";

@NgModule({
    imports: [HttpClientModule],
    providers: [ProductRepository, StaticDataSource, Cart, Order, OrderRepository,
        { provide: StaticDataSource, useClass: RestDataSource },
        RestDataSource, AuthService, ConnectionService]
})
export class ModelModule { }
```

To prevent the user from checking out when there is no connection, I updated the cart detail component so that it receives the connection service in its constructor, as shown in Listing 8-5.

Listing 8-5. Receiving a Service in the cartDetail.component.ts File in the src/app/store Folder

```
import { Component } from "@angular/core";
import { Cart } from "../model/cart.model";
import { ConnectionService } from "../model/connection.service";
```

```
@Component({
    templateUrl: "cartDetail.component.html"
})
export class CartDetailComponent {
    public connected: boolean = true;

    constructor(public cart: Cart, private connection: ConnectionService) {
        this.connected = this.connection.connected;
        connection.Changes.subscribe((state) => this.connected = state);
    }
}
```

The component defines a connected property that is set from the service and then updated when changes are received. To complete this feature, I changed the checkout button so that it is disabled when there is no connectivity, as shown in Listing 8-6.

Listing 8-6. Reflecting Connectivity in the cartDetail.component.html File in the src/app/store Folder

```
...
<div class="row">
  <div class="col">
  <div class="text-center">
    <button class="btn btn-primary m-1" routerLink="/store">
        Continue Shopping
    </button>
    <button class="btn btn-secondary m-1" routerLink="/checkout"
            [disabled]="cart.lines.length == 0 || !connected">
      {{ connected ?  'Checkout' : 'Offline' }}
    </button>
  </div>
</div>
...
```

Preparing the Application for Deployment

In the sections that follow, I prepare the SportsStore application so that it can be deployed.

Creating the Data File

When I created the RESTful web service, I provided the json-server package with a JavaScript file, which is executed each time the server starts and ensures that the same data is always used. That isn't helpful in production, so I added a file called serverdata.json to the SportsStore folder with the contents shown in Listing 8-7. When the json-server package is configured to use a JSON file, any changes that are made by the application will be persisted.

Listing 8-7. The Contents of the serverdata.json File in the SportsStore Folder

```
{
    "products": [
        { "id": 1, "name": "Kayak", "category": "Watersports",
            "description": "A boat for one person", "price": 275 },
```

```
        { "id": 2, "name": "Lifejacket", "category": "Watersports",
            "description": "Protective and fashionable", "price": 48.95 },
        { "id": 3, "name": "Soccer Ball", "category": "Soccer",
            "description": "FIFA-approved size and weight", "price": 19.50 },
        { "id": 4, "name": "Corner Flags", "category": "Soccer",
            "description": "Give your playing field a professional touch",
            "price": 34.95 },
        { "id": 5, "name": "Stadium", "category": "Soccer",
            "description": "Flat-packed 35,000-seat stadium", "price": 79500 },
        { "id": 6, "name": "Thinking Cap", "category": "Chess",
            "description": "Improve brain efficiency by 75%", "price": 16 },
        { "id": 7, "name": "Unsteady Chair", "category": "Chess",
            "description": "Secretly give your opponent a disadvantage",
            "price": 29.95 },
        { "id": 8, "name": "Human Chess Board", "category": "Chess",
            "description": "A fun game for the family", "price": 75 },
        { "id": 9, "name": "Bling Bling King", "category": "Chess",
            "description": "Gold-plated, diamond-studded King", "price": 1200 }
    ],
    "orders": []
}
```

Creating the Server

When the application is deployed, I am going to use a single HTTP port to handle the requests for the application and its data, rather than the two ports that I have been using in development. Using separate ports is simpler in development because it means that I can use the Angular development HTTP server without having to integrate the RESTful web service. Angular doesn't provide an HTTP server for deployment, and since I have to provide one, I am going to configure it so that it will handle both types of request and include support for HTTP and HTTPS connections, as explained in the sidebar.

USING SECURE CONNECTIONS FOR PROGRESSIVE WEB APPLICATIONS

When you add progressive features to an application, you must deploy it so that it can be accessed over secure HTTP connections. If you do not, the progressive features will not work because the underlying technology—called *service workers*—won't be allowed by the browser over regular HTTP connections.

You can test progressive features using localhost, as I demonstrate shortly, but an SSL/TLS certificate is required when you deploy the application. If you do not have a certificate, then a good place to start is https://letsencrypt.org, where you can get one for free, although you should note that you also need to own the domain or hostname that you intend to deploy to generate a certificate. For this book, I deployed the SportsStore application with its progressive features to sportsstore.adam-freeman. com, which is a domain that I use for development testing and receiving emails. This is not a domain that provides public HTTP services, and you won't be able to access the SportsStore application through this domain.

Run the commands shown in Listing 8-8 in the SportsStore folder to install the packages that are required to create the HTTP/HTTPS server.

Listing 8-8. Installing Additional Packages

```
npm install --save-dev express@4.17.3
npm install --save-dev connect-history-api-fallback@1.6.0
npm install --save-dev https@1.0.0
```

I added a file called server.js to the SportsStore with the content shown in Listing 8-9, which uses the newly added packages to create an HTTP and HTTPS server that includes the json-server functionality that will provide the RESTful web service. (The json-server package is specifically designed to be integrated into other applications.)

Listing 8-9. The Contents of the server.js File in the SportsStore Folder

```
const express = require("express");
const https = require("https");
const fs = require("fs");
const history = require("connect-history-api-fallback");
const jsonServer = require("json-server");
const bodyParser = require('body-parser');
const auth = require("./authMiddleware");
const router = jsonServer.router("serverdata.json");

const enableHttps = false;

const ssloptions = {}

if (enableHttps) {
    ssloptions.cert =  fs.readFileSync("./ssl/sportsstore.crt");
    ssloptions.key = fs.readFileSync("./ssl/sportsstore.pem");
}

const app = express();

app.use(bodyParser.json());
app.use(auth);
app.use("/api", router);
app.use(history());
app.use("/", express.static("./dist/SportsStore"));

app.listen(80,
    () => console.log("HTTP Server running on port 80"));

if (enableHttps) {
    https.createServer(ssloptions, app).listen(443,
        () => console.log("HTTPS Server running on port 443"));
} else {
    console.log("HTTPS disabled")
}
```

The server can read the details of the SSL/TLS certificate from files in the `ssl` folder, which is where you should place the files for your certificate. If you do not have a certificate, then you can disable HTTPS by setting the `enableHttps` value to `false`. You will still be able to test the application using the local server, but you won't be able to use the progressive features in deployment.

Changing the Web Service URL in the Repository Class

Now that the RESTful data and the application's JavaScript and HTML content will be delivered by the same server, I need to change the URL that the application uses to get its data, as shown in Listing 8-10.

Listing 8-10. Changing the URL in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";
import { Cart } from "./cart.model";
import { Order } from "./order.model";
import { map } from "rxjs/operators";
import { HttpHeaders } from '@angular/common/http';

const PROTOCOL = "http";
const PORT = 3500;

@Injectable()
export class RestDataSource {
    baseUrl: string;
    auth_token: string;

    constructor(private http: HttpClient) {
        //this.baseUrl = `${PROTOCOL}://${location.hostname}:${PORT}/`;
        this.baseUrl = "/api/"
    }

    // ...methods omitted for brevity...
}
```

FIXING THE BROWSER VERSION ISSUE

At the time of writing, there is a bug that prevents the build process from parsing the output from one of the tools it depends on. Add these entries shown to the `.browserslistrc` file in the SportsStore folder:

```
# This file is used by the build system to adjust CSS and JS output to
support the specified browsers below.
# For additional information regarding the format and rule options,
please see:
# https://github.com/browserslist/browserslist#queries
```

```
# For the full list of supported browsers by the Angular framework,
please see:
# https://angular.io/guide/browser-support

# You can see what browsers were selected by your queries by running:
#   npx browserslist

last 1 Chrome version
last 1 Firefox version
last 2 Edge major versions
last 2 Safari major versions
last 2 iOS major versions
Firefox ESR

not ios_saf 15.2-15.3
not safari 15.2-15.3
```

This issue may have been resolved by the time you read this book, but the changes allow the build process to complete.

Building and Testing the Application

To build the application for production, run the command shown in Listing 8-11 in the SportsStore folder.

Listing 8-11. Building the Application for Production

```
ng build
```

This command builds an optimized version of the application without the additions that support the development tools. The output from the build process is placed in the dist/SportsStore folder. In addition to the JavaScript files, there is an index.html file that has been copied from the SportsStore/src folder and modified to use the newly built files.

■ **Note** Angular provides support for server-side rendering, where the application is run in the server, rather than the browser. This is a technique that can improve the perception of the application's startup time and can improve indexing by search engines. This is a feature that should be used with caution because it has serious limitations and can undermine the user experience. For these reasons, I have not covered server-side rendering in this book. You can learn more about this feature at https://angular.io/guide/universal.

The build process can take a few minutes to complete. Once the build is ready, run the command shown in Listing 8-12 in the SportsStore folder to start the HTTP server. If you have not configured the server to use a valid SSL/TLS certificate, you should change the value of the enableHttps constant in the server.js file and then run the command in Listing 8-12.

Listing 8-12. Starting the Production HTTP Server

```
node server.js
```

Once the server has started, open a new browser window and navigate to `http://localhost`, and you will see the familiar content shown in Figure 8-1.

Figure 8-1. *Testing the application*

Testing the Progressive Features

Open the F12 development tools, navigate to the Network tab, click the arrow to the right of Online, and select Offline, as shown in Figure 8-2. This simulates a device without connectivity, but since SportsStore is a progressive web application, it has been cached by the browser, along with its data.

Figure 8-2. *Going offline*

Once the application is offline, the application will be loaded from the browser's cache. If you click an Add To Cart button, you will see that the Checkout button is disabled, as shown in Figure 8-3. Uncheck the Offline checkbox, and the button's text will change so that the user can place an order.

Figure 8-3. *Reflecting the connection status in the application*

Containerizing the SportsStore Application

To complete this chapter, I am going to create a container for the SportsStore application so that it can be deployed into production. At the time of writing, Docker is the most popular way to create containers, which is a pared-down version of Linux with just enough functionality to run the application. Most cloud platforms or hosting engines have support for Docker, and its tools run on the most popular operating systems.

Installing Docker

The first step is to download and install the Docker tools on your development machine, which are available from `www.docker.com/products`. There are versions for macOS, Windows, and Linux, and there are some specialized versions to work with the Amazon and Microsoft cloud platforms. The free Community edition of Docker Desktop is sufficient for this chapter.

Preparing the Application

The first step is to create a configuration file for NPM that will be used to download the additional packages required by the application for use in the container. I created a file called `deploy-package.json` in the `SportsStore` folder with the content shown in Listing 8-13.

Listing 8-13. The Contents of the deploy-package.json File in the SportsStore Folder

```
{
  "dependencies": {
    "@fortawesome/fontawesome-free": "6.0.0",
    "bootstrap": "5.1.3"
  },

  "devDependencies": {
    "json-server": "0.17.0",
    "jsonwebtoken": "8.5.1",
    "express": "4.17.3",
    "https": "1.0.0",
    "connect-history-api-fallback": "1.6.0"
  },

  "scripts": {
    "start":  "node server.js"
  }
}
```

The `dependencies` section omits Angular and all of the other runtime packages that were added to the `package.json` file when the project was created because the build process incorporates all of the JavaScript code required by the application into the files in the `dist/SportsStore` folder. The `devDependencies` section includes the tools required by the production HTTP/HTTPS server.

The `scripts` section of the `deploy-package.json` file is set up so that the `npm start` command will start the production server, which will provide access to the application and its data.

Creating the Docker Container

To define the container, I added a file called Dockerfile (with no extension) to the SportsStore folder and added the content shown in Listing 8-14.

Listing 8-14. The Contents of the Dockerfile File in the SportsStore Folder

```
FROM node:16.3.0

RUN mkdir -p /usr/src/sportsstore

COPY dist/SportsStore /usr/src/sportsstore/dist/SportsStore
COPY ssl /usr/src/sportsstore/ssl

COPY authMiddleware.js /usr/src/sportsstore/
COPY serverdata.json /usr/src/sportsstore/
COPY server.js /usr/src/sportsstore/server.js
COPY deploy-package.json /usr/src/sportsstore/package.json

WORKDIR /usr/src/sportsstore

RUN npm install

EXPOSE 80

CMD ["node", "server.js"]
```

The contents of the Dockerfile use a base image that has been configured with Node.js and copies the files required to run the application, including the bundle file containing the application and the package.json file that will be used to install the packages required to run the application in deployment.

To speed up the containerization process, I created a file called .dockerignore in the SportsStore folder with the content shown in Listing 8-15. This tells Docker to ignore the node_modules folder, which is not required in the container and takes a long time to process.

Listing 8-15. The Contents of the .dockerignore File in the SportsStore Folder

```
node_modules
```

Run the command shown in Listing 8-16 in the SportsStore folder to create an image that will contain the SportsStore application, along with all of the tools and packages it requires.

■ **Tip** The SportsStore project must contain an ssl directory, even if you have not installed a certificate. This is because there is no way to check to see whether a file exists when using the COPY command in the Dockerfile.

Listing 8-16. Building the Docker Image

```
docker build . -t sportsstore  -f  Dockerfile
```

An image is a template for containers. As Docker processes the instructions in the Dockerfile, the NPM packages will be downloaded and installed, and the configuration and code files will be copied into the image.

Running the Application

Once the image has been created, create and start a new container using the command shown in Listing 8-17.

■ **Tip**   Make sure you stop the test server you started in Listing 8-12 before starting the Docker container since both use the same ports to listen for requests.

Listing 8-17.   Starting the Docker Container

```
docker run -p 80:80 -p 443:443 sportsstore
```

You can test the application by opening http://localhost in the browser, which will display the response provided by the web server running in the container, as shown in Figure 8-4.

Figure 8-4.   *Running the containerized SportsStore application*

To stop the container, run the command shown in Listing 8-18.

Listing 8-18. Listing the Containers

```
docker ps
```

You will see a list of running containers, like this (I have omitted some fields for brevity):

```
CONTAINER ID        IMAGE           COMMAND                 CREATED
ecc84f7245d6        sportsstore     "docker-entrypoint.s..."  33 seconds ago
```

Using the value in the Container ID column, run the command shown in Listing 8-19.

Listing 8-19. Stopping the Container

```
docker stop ecc84f7245d6
```

The application is ready to deploy to any platform that supports Docker, although the progressive features will work only if you have configured an SSL/TLS certificate for the domain to which the application is deployed.

Summary

This chapter completes the SportsStore application, showing how an Angular application can be prepared for deployment and how easy it is to put an Angular application into a container such as Docker. That's the end of this part of the book. In Part 2, I begin the process of digging into the details and show you how the features I used to create the SportsStore application work in depth.

Understanding Angular Projects and Tools

In this chapter, I explain the structure of an Angular project and the tools that are used for development. By the end of the chapter, you will understand how the parts of a project fit together and have a foundation on which to apply the more advanced features that are described in the chapters that follow.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from `https://github.com/Apress/pro-angular-5ed`. See Chapter 1 for how to get help if you have problems running the examples.

Creating a New Angular Project

The `angular-cli` package you installed in Chapter 1 contains all the functionality required to create a new Angular project that contains some placeholder content to jump-start development, and it contains a set of tightly integrated tools that are used to build, test, and prepare Angular applications for deployment.

To create a new Angular project, open a command prompt, navigate to a convenient location, and run the command shown in Listing 9-1.

Listing 9-1. Creating a Project

```
ng new example --routing false --style css --skip-git --skip-tests
```

The `ng new` command creates new projects, and the argument is the project name, which is `example` in this case. The `ng new` command has a set of arguments that shape the project that is created; Table 9-1 describes the most useful.

Table 9-1. *Useful ng new Options*

Argument	Description
--directory	This option is used to specify the name of the directory for the project. It defaults to the project name.
--force	When true, this option overwrites any existing files.
--minimal	This option creates a project without adding support for testing frameworks.
--package-manager	This option is used to specify the package manager that will be used to download and install the packages required by Angular. If omitted, NPM will be used. Other options are yarn, pnpm, and cnpm. The default package manager is suitable for most projects.
--prefix	This option applies a prefix to all of the component selectors, as described in the "Understanding How an Angular Application Works" section.
--routing	This option is used to create a routing module in the project. I explain how the routing feature works in detail in Chapters 24–26.
--skip-git	Using this option prevents a Git repository from being created in the project. You must install the Git tools if you create a project without this option.
--skip-install	This option prevents the initial operation that downloads and installs the packages required by Angular applications and the project's development tools.
--skip-tests	This option prevents the addition of the initial configuration for testing tools.
--style	This option specifies how stylesheets are handled. I use the css option throughout this book, but popular CSS preprocessors such as SCSS, SASS, and LESS also are supported. Chapter 28 contains an advanced example that uses SCSS.

The project initialization process performed by the ng new command can take some time to complete because there are a large number of packages required by the project, both to run the Angular application and for the development and testing tools that I describe in this chapter.

Understanding the Project Structure

Use your preferred code editor to open the example folder, and you will see the files and folder structure shown in Figure 9-1. The figure shows the way that Visual Studio Code presents the project; other editors may present the project contents differently.

Figure 9-1. *The contents of a new Angular project*

Table 9-2 describes the files and folders that are added to a new project by the ng new command and that provide the starting point for most Angular development.

Table 9-2. *The Files and Folders in a New Angular Project*

Name	Description
node_modules	This folder contains the NPM packages that are required for the application and for the Angular development tools, as described in the "Understanding the Packages Folder" section.
src	This folder contains the application's source code, resources, and configuration files, as described in the "Understanding the Source Code Folder" section.
.browserslistrc	This file is used to specify the browsers that the application will support, which can alter the way that code is compiled and prepared for distribution. The default settings are suitable for most projects, but you can find details of how to change the target browsers at https://github.com/browserslist/browserslist.
.editorconfig	This file contains settings that configure text editors. Not all editors respond to this file, but it may override the preferences you have defined. You can learn more about the editor settings that can be set in this file at http://editorconfig.org.
.gitignore	This file contains a list of files and folders that are excluded from version control when using Git.
angular.json	This file contains the configuration for the Angular development tools.
karma.conf.js	This file configures the Karma test runner. See Chapter 29 for details of unit testing in Angular projects.
package.json	This file contains details of the NPM packages required by the application and the development tools and defines the commands that run the development tools, as described in the "Understanding the Packages Folder" section.
package-lock.json	This file contains version information for all the packages that are installed in the node_modules folder, as described in the "Understanding the Packages Folder" section.
README.md	This is a readme file that contains the list of commands for the development tools, which are described in the "Using the Development Tools" section.
tsconfig.json	This file contains the configuration settings for the TypeScript compiler. You don't need to change the compiler configuration in most Angular projects.
tsconfig.app.json	This file contains additional configuration options for the TypeScript compiler related to the locations of source files, type definition files, and where compiled output will be written.
tsconfig.spec.json	This file contains additional configuration options for the TypeScript compiler related to the locations of source files for unit tests.

You won't need all these files in every project, and you can remove the ones you don't require. I tend to remove the README.md, .editorconfig, and .gitignore files, for example, because I am already familiar with the tool commands, I prefer not to override my editor settings, and I don't use Git for version control.

Understanding the Source Code Folder

The src folder contains the application's files, including the source code and static assets, such as images. This folder is the focus of most development activities, and Figure 9-2 shows the contents of the src folder created using the ng new command.

Figure 9-2. *The contents of the src folder*

The app folder is where you will add the custom code and content for your application, and its structure becomes more complex as you add features. The other files support the development process, as described in Table 9-3.

Table 9-3. *The Files and Folders in the src Folder*

Name	Description
app	This folder contains an application's source code and content. The contents of this folder are the topic of the "Understanding How an Angular Application Works" section and other chapters in this part of the book.
assets	This folder is used for the static resources required by the application, such as images.
environments	This folder contains configuration files that define settings for different environments. By default, the only configuration setting is the production flag, which is set to true when the application is built for deployment, as explained in the "Understanding the Application Bootstrap" section.
favicon.ico	This file contains an icon that browsers will display in the tab for the application. The default image is the Angular logo.
index.html	This is the HTML file that is sent to the browser during development, as explained in the "Understanding the HTML Document" section.
main.ts	This file contains the TypeScript statements that start the application when they are executed, as described in the "Understanding the Application Bootstrap" section.
polyfills.ts	This file is used to include polyfills in the project to provide support for features that are not available natively in some browsers.
styles.css	This file is used to define CSS styles that are applied throughout the application.
tests.ts	This is the configuration file for the Karma test package, which I describe in Chapter 29.

Understanding the Packages Folder

The world of JavaScript application development depends on a rich ecosystem of packages, some of which contain the Angular framework that will be sent to the browser through small packages that are used behind the scenes during development. A lot of packages are required for an Angular project; the example project created at the start of this chapter, for example, requires more than 850 packages.

Many of these packages are just a few lines of code, but there is a complex hierarchy of dependencies between them that is too large to manage manually, so a package manager is used. The package manager is given an initial list of packages required for the project. Each of these packages is then inspected for its dependencies, and the process continues until the complete set of packages has been created. All the required packages are downloaded and installed in the node_modules folder.

The initial set of packages is defined in the package.json file using the dependencies and devDependencies properties. The dependencies property is used to list the packages that the application will require to run. Here are the dependencies packages from the package.json file in the example application, although you may see different version numbers in your project:

```
...
"dependencies": {
    "@angular/animations": "~13.0.0",
    "@angular/common": "~13.0.0",
    "@angular/compiler": "~13.0.0",
    "@angular/core": "~13.0.0",
    "@angular/forms": "~13.0.0",
```

```
    "@angular/platform-browser": "~13.0.0",
    "@angular/platform-browser-dynamic": "~13.0.0",
    "@angular/router": "~13.0.0",
    "rxjs": "~7.4.0",
    "tslib": "^2.3.0",
    "zone.js": "~0.11.4"
},
...
```

Most of the packages provide Angular functionality, with a handful of supporting packages that are used behind the scenes. For each package, the package.json file includes details of the version numbers that are acceptable, using the format described in Table 9-4.

Table 9-4. The Package Version Numbering System

Format	Description
13.0.0	Expressing a version number directly will accept only the package with the exact matching version number, e.g., 13.0.0.
*	Using an asterisk accepts any version of the package to be installed.
>13.0.0 >=13.0.0	Prefixing a version number with > or >= accepts any version of the package that is greater than or greater than or equal to a given version.
<13.0.0 <=13.0.0	Prefixing a version number with < or <= accepts any version of the package that is less than or less than or equal to a given version.
~13.0.0	Prefixing a version number with a tilde (the ~ character) accepts versions to be installed even if the patch level number (the last of the three version numbers) doesn't match. For example, specifying ~13.0.0 means you will accept version 13.0.1 or 13.0.2 (which would contain patches to version 13.0.0) but not version 13.1.0 (which would be a new minor release).
^13.0.0	Prefixing a version number with a caret (the ^ character) will accept versions even if the minor release number (the second of the three version numbers) or the patch number doesn't match. For example, specifying ^13.0.0 means you will accept versions 13.1.0, and 13.2.0, for example, but not version 14.0.0.

The version numbers specified in the dependencies section of the package.json file will accept minor updates and patches. Version flexibility is more important when it comes to the devDependencies section of the file, which contains a list of the packages that are required for development but which will not be part of the finished application. There are 19 packages listed in the devDependencies section of the package.json file in the example application, each of which has a range of acceptable versions.

```
...
"devDependencies": {
    "@angular-devkit/build-angular": "~13.0.3",
    "@angular/cli": "~13.0.3",
    "@angular/compiler-cli": "~13.0.0",
    "@types/jasmine": "~3.10.0",
    "@types/node": "^12.11.1",
    "jasmine-core": "~3.10.0",
    "karma": "~6.3.0",
    "karma-chrome-launcher": "~3.1.0",
```

```
    "karma-coverage": "~2.0.3",
    "karma-jasmine": "~4.0.0",
    "karma-jasmine-html-reporter": "~1.7.0",
    "typescript": "~4.4.3"
}
...
```

Once again, you may see different details, but the key point is that the management of dependencies between packages is too complex to do manually and is delegated to a package manager. The most widely used package manager is NPM, which is installed alongside Node.js and was part of the preparations for this book in Chapter 2.

The packages required for basic development are automatically downloaded and installed into the node_modules folder when you create a project, but Table 9-5 lists some commands that you may find useful during development. All these commands should be run inside the project folder, which is the one that contains the package.json file.

UNDERSTANDING GLOBAL AND LOCAL PACKAGES

NPM can install packages so they are specific to a single project (known as a *local install*) or so they can be accessed from anywhere (known as a *global install*). Few packages require global installs, but one exception is the @angular/cli package installed in Chapter 2 as part of the preparations for this book. The @angular-cli package requires a global install because it is used to create new projects. The individual packages required for the project are installed locally, into the node_modules folder.

Table 9-5. *Useful NPM Commands*

Command	Description
npm install	This command performs a local install of the packages specified in the package.json file.
npm install package@version	This command performs a local install of a specific version of a package and updates the package.json file to add the package to the dependencies section.
npm install package@version --save-dev	This command performs a local install of a specific version of a package and updates the package.json file to add the package to the devDependencies section.
npm install --global package@version	This command performs a global install of a specific version of a package.
npm list	This command lists all of the local packages and their dependencies.
npm run <script name>	This command executes one of the scripts defined in the package.json file, as described next.
npx package@version	This command downloads and executes a package.

The last two commands described in Table 9-5 are oddities, but package managers have traditionally included support for running commands that are defined in the scripts section of the package.json file. In an Angular project, this feature is used to provide access to the tools that are used during development and that prepare the application for deployment. Here is the scripts section of the package.json file in the example project:

```
...
"scripts": {
    "ng": "ng",
    "start": "ng serve",
    "build": "ng build",
    "watch": "ng build --watch --configuration development",
    "test": "ng test"
},
...
```

Table 9-6 summarizes these commands, and I demonstrate their use in later sections of this chapter or in later chapters in this part of the book.

Table 9-6. *The Commands in the scripts Section of the package.json File*

Name	Description
ng	This command runs the ng command, which provides access to the Angular development tools.
start	This command starts the development tools and is equivalent to the ng serve command.
build	This command performs the production build process.
test	This command starts the unit testing tools, which are described in Chapter 29, and is equivalent to the ng test command.

These commands are run by using npm run followed by the name of the command that you require, and this must be done in the folder that contains the package.json file. So, if you want to run the test command in the example project, navigate to the example folder and type npm run test. You can get the same result by using the command ng test.

The npx command is useful for downloading and executing a package in a single command, which I use in the "Running the Production Build" section later in the chapter. Not all packages are set up for use with npx, which is a recent feature.

Adding Packages with Schematics to an Angular Project

As noted in Table 9-5, the npm install command can be used to add a JavaScript package to the project. Packages installed with this command are added to the node_modules folder and then typically require some manual integration to make them part of the Angular application. You can see an example of this in the "Understanding the Styles Bundle" section, where I install the popular Bootstrap CSS framework and configure Angular to include its CSS stylesheet in the content sent to the browser.

Some JavaScript packages take advantage of the *schematics API* provided by the @angular/cli package to automate the integration process. Typically, this is because the package provides Angular-specific functionality, such as the Angular Material package, but some package authors provide schematics because Angular is so widely used. The npm install command doesn't understand the schematics API, so the ng add command is used to download these packages and perform the integration. Run the command shown in Listing 9-2 in the example folder to install the Angular Material package.

Listing 9-2. Installing the Angular Material Package

```
ng add @angular/material@13.0.2
```

The schematics API allows package authors to ask the user questions and use the responses during the integration process. As you go through the setup for Angular Material, you will be asked four questions, and you can press the Enter key to select the default answer for each one.

The first question is just a request to confirm that you want to install the package:

```
Using package manager: npm
Package information loaded.
The package @angular/material@13.0.2 will be installed and executed.
Would you like to proceed? (Y/n)
```

The ng add command uses the package manager selected when the Angular project was created to download the package. The example project was created to use the npm package manager, but, as noted earlier, other package managers can be selected, and these will be used automatically by the ng add command.

The remaining questions are specific to Angular Material and allow the theme to be selected and typography and animation options to be configured:

```
? Choose a prebuilt theme name, or "custom" for a custom theme: (Use arrow keys)
> Indigo/Pink         [ Preview: https://material.angular.io?theme=indigo-pink ]
  Deep Purple/Amber   [ Preview: https://material.angular.io?theme=deeppurple-amber ]
  Pink/Blue Grey      [ Preview: https://material.angular.io?theme=pink-bluegrey ]
  Purple/Green        [ Preview: https://material.angular.io?theme=purple-green ]
  Custom
? Set up global Angular Material typography styles? (y/N)
? Set up browser animations for Angular Material? (Y/n)
```

Each package that uses the schematics API will ask questions, and once you have made your choices, the package will be integrated into the Angular project, and the list of files that are changed is shown:

```
UPDATE src/app/app.module.ts (423 bytes)
UPDATE angular.json (3770 bytes)
UPDATE src/index.html (552 bytes)
UPDATE src/styles.css (181 bytes)
```

I describe all of these files in later sections, and you will see the additions that the Angular Material package has made to each of them.

■ **Note** You don't need to understand the schematics API to add packages to an Angular project. But if you are interested in publishing a package for use by Angular developers, then you can learn about the features available at https://angular.io/guide/schematics-authoring.

Using the Development Tools

Projects created using the `ng new` command include a complete set of development tools that monitor the application's files and build the project when a change is detected. Run the command shown in Listing 9-3 in the `example` folder to start the development tools.

Listing 9-3. Starting the Development Tools

```
ng serve
```

The command starts the build process, which produces messages like these at the command prompt:

```
...
Generating browser application bundles (phase: building)...
...
```

At the end of the process, you will see a summary of the bundles that have been created, like this:

```
...
Browser application bundle generation complete.

Initial Chunk Files   | Names         |      Size
vendor.js             | vendor        |   1.89 MB
polyfills.js          | polyfills     | 339.12 kB
styles.css, styles.js | styles        | 289.27 kB
main.js               | main          |  51.79 kB
runtime.js            | runtime       |   6.85 kB

                      | Initial Total |   2.57 MB

Build at: 2021-12-05T07:51:57.541Z - Hash: 5762f0ed7a6c45f4 - Time: 10531ms

** Angular Live Development Server is listening on localhost:4200, open your browser on
http://localhost:4200/ **

Compiled successfully.
...
```

Understanding the Development HTTP Server

To simplify the development process, the project incorporates an HTTP server that is tightly integrated with the build process. After the initial build process, the HTTP server is started, and a message is displayed that tells you which port is being used to listen for requests, like this:

```
...
** Angular Live Development Server is listening on localhost:4200, open your browser on
http://localhost:4200/ **
...
```

223

The default is port 4200, but you may see a different message if you are already using port 4200. Open a new browser window and request `http://localhost:4200`; you will see the placeholder content added to the project by the `ng new` command, as shown in Figure 9-3.

Figure 9-3. *Using the HTTP development server*

Understanding the Build Process

When you run `ng serve`, the project is built so that it can be used by the browser. This is a process that requires three important tools: the TypeScript compiler, the Angular compiler, and a package named *webpack*.

Angular applications are created using TypeScript files and HTML templates containing expressions, neither of which can be understood by browsers. The TypeScript compiler is responsible for compiling the TypeScript files into JavaScript, and the Angular compiler is responsible for transforming templates into JavaScript statements that use the browser APIs to create the HTML elements in the template file and evaluate the expressions they contain.

The build process is managed through webpack, which is a module bundler, meaning that it takes the compiled output and consolidates it into a module that can be sent to the browser. This process is known as *bundling*, which is a bland description for an important function, and it is one of the key tools that you will rely on while developing an Angular application, albeit one that you won't deal with directly since it is managed for you by the Angular development tools.

When you run the `ng serve` command, you will see a series of messages as webpack processes the application. Webpack starts with the code in the `main.ts` file, which is the entry point for the application and follows the `import` statements it contains to discover its dependencies, repeating this process for each file on which there is a dependency. Webpack works its way through the `import` statements, compiling each TypeScript and template file on which a dependency is declared to produce JavaScript code for the entire application.

■ **Note** This section describes the development build process. See the "Understanding the Production Build Process" section for details of the process used to prepare an application for deployment.

The output from the main.ts compilation process is combined into a single file, known as a *bundle*. During the bundling process, webpack generates multiple bundles, each of which contains resources required by the application. At the end of the process, you will see a summary of the bundles that have been created, like this:

```
...
Initial Chunk Files   | Names         |      Size
vendor.js             | vendor        |   1.89 MB
polyfills.js          | polyfills     | 339.12 kB
styles.css, styles.js | styles        | 289.27 kB
main.js               | main          |  51.79 kB
runtime.js            | runtime       |   6.85 kB
                      | Initial Total |   2.57 MB
...
```

The initial build process can take a while to complete because five bundles are produced, as described in Table 9-7.

Table 9-7. *The Bundles Produced by the Angular Build Process*

Name	Description
main.js	This file contains the compiled output produced from the src/app folder.
polyfills.js	This file contains JavaScript polyfills required for features used by the application that are not supported by the target browsers.
runtime.js	This file contains the code that loads the other modules.
styles.js	This file contains JavaScript code that adds the application's global CSS stylesheets.
vendor.js	This file contains the third-party packages the application depends on, including the Angular packages.

Understanding the Application Bundle

The full build process is performed only when the ng serve command is first run. Thereafter, bundles are rebuilt if the files they are composed of change. You can see this by replacing the contents of the app.component.html file with the elements shown in Listing 9-4.

Listing 9-4. Replacing the Contents of the app.component.html File in the src/app Folder

```
<div>
    Hello, World
</div>
```

When you save the changes, only the affected bundles will be rebuilt, and you will see messages at the command prompt like this:

```
Initial Chunk Files | Names   |   Size
runtime.js          | runtime | 6.85 kB
main.js             | main    | 5.96 kB
3 unchanged chunks
Build at: 2021-12-05T08:34:49.753Z - Hash: 387bffb37bb32d06 - Time: 243ms
Compiled successfully.
```

Selectively compiling files and preparing bundles ensures that the effect of changes during development can be seen quickly. Figure 9-4 shows the effect of the change in Listing 9-4.

Figure 9-4. *Changing a file used in the main.js bundle*

UNDERSTANDING HOT RELOADING

During development, the Angular development tools add support for a feature called *hot reloading*. This is the feature that meant you saw the effect of the change in Listing 9-4 automatically. The JavaScript code added to the bundle opens a connection back to the Angular development HTTP server. When a change triggers a build, the server sends a signal over the HTTP connection, which causes the browser to reload the application automatically.

Understanding the Polyfills Bundle

The Angular build process targets the most recent versions of browsers by default, which can be a problem if you need to provide support for older browsers (something that commonly arises in corporate applications where old browsers are often). The polyfills.js bundle is used to provide implementations of JavaScript features to older versions that do not have native support. The content of the polyfills.js file is determined by the polyfills.ts file, which can be found in the src folder. Only one polyfill is enabled by default, which enables the Zone.js library, which is used by Angular to perform change detection in browsers. You can add your own polyfills to the bundle by adding import statements to the polyfills.ts file.

Understanding the Styles Bundle

The `styles.js` bundle is used to add CSS stylesheets to the application. The bundle file contains JavaScript code that uses the browser API to define styles, along with the contents of the CSS stylesheets the application requires. (It may seem counterintuitive to use JavaScript to distribute a CSS file, but it works well and has the advantage of making the application self-contained so that it can be deployed as a series of JavaScript files that do not rely on additional assets to be set up on the deployment web servers.)

CSS stylesheets are added to the application using the `styles` section of the `angular.json` file. Run the command shown in Listing 9-5 in the `example` folder to see the current set of stylesheets included in the styles bundle.

Listing 9-5. Displaying the Configured Stylesheets

```
ng config "projects.example.architect.build.options.styles"
```

The `ng config` command is used to get and change configuration settings in the `angular.json` file. The argument to the `ng config` command in Listing 9-5 selects the `projects.example.architect.build. options.styles` setting, which defines the stylesheets that are included in the styles bundle and produces the following results:

```
[
  "./node_modules/@angular/material/prebuilt-themes/indigo-pink.css",
  "src/styles.css"
]
```

The `indigo-pink.css` file was added to the list when the Angular Material package was installed. The `styles.css` file was added to the list as part of the initial configuration when the project was created.

The structure of the `angular.json` file and the effect of the settings it contains are described at https://angular.io/guide/workspace-config. Using this description, I was able to determine the configuration option for the CSS stylesheets.

Many projects require no direct changes to the `angular.json` file and can rely on the default settings. One exception is when manual integration is required for packages that don't use the schematics API. Run the command shown in Listing 9-6 in the `example` folder to install the popular Bootstrap CSS framework.

Listing 9-6. Adding a Package to the Project

```
npm install bootstrap@5.1.3
```

The Bootstrap package isn't specific to Angular development and doesn't use the schematics API, which means that a manual change must be made to the `angular.config` file to include the Bootstrap CSS stylesheet in the styles bundle, which is done by running the command shown in Listing 9-7 in the `example` folder. Take care to enter the command exactly as shown and do not introduce additional spaces or quotes.

Listing 9-7. Changing the Application Configuration

```
ng config projects.example.architect.build.options.styles \
'["./node_modules/@angular/material/prebuilt-themes/indigo-pink.css",'\
'"src/styles.css",'\
'"node_modules/bootstrap/dist/css/bootstrap.min.css"]'
```

If you are using Windows, then use a PowerShell prompt to run the command shown in Listing 9-8 in the example folder.

Listing 9-8. Changing the Application Configuration Using PowerShell

```
ng config projects.example.architect.build.options.styles `
'[""./node_modules/@angular/material/prebuilt-themes/indigo-pink.css"",
""src/styles.css"",
""node_modules/bootstrap/dist/css/bootstrap.min.css""]'
```

Check that the stylesheet has been added to the configuration by running the command in Listing 9-5 again, which should produce the following result:

```
[
  "./node_modules/@angular/material/prebuilt-themes/indigo-pink.css",
  "src/styles.css",
  "node_modules/bootstrap/dist/css/bootstrap.min.css"
]
```

EDITING THE CONFIGURATION FILE DIRECTLY

The commands to edit the configuration can be difficult to enter correctly, and it is easy to mistype the character escape sequences required to ensure that the command prompt passes the setting to the ng config command in the format it expects.

An alternative approach is to edit the angular.json file directly and add the stylesheet to the styles section, like this:

```
...
"architect": {
"build": {
    "builder": "@angular-devkit/build-angular:browser",
    "options": {
    "outputPath": "dist/example",
    "index": "src/index.html",
    "main": "src/main.ts",
    "polyfills": "src/polyfills.ts",
    "tsConfig": "tsconfig.app.json",
    "assets": [
```

```
        "src/favicon.ico",
        "src/assets"
    ],
    "styles": [
        "./node_modules/@angular/material/prebuilt-themes/indigo-pink.css",
        "src/styles.css",
        "node_modules/bootstrap/dist/css/bootstrap.min.css"
    ],
    "scripts": []
    },
...
```

There are two `styles` sections in the `angular.json` file, and you must make sure to add the filename to the one closest to the top of the file. Save the changes to the file and run the command shown in Listing 9-5 to check that you have edited the correct `styles` section. If you don't see the new stylesheet in the output, then you have edited the wrong part of the file.

Add the classes shown in Listing 9-9 to the `div` element in the `app.component.html` file. These classes apply styles defined by the Bootstrap CSS framework.

Listing 9-9. Adding Classes in the app.component.html File in the src/app Folder

```
<div class="bg-primary text-white text-center">
    Hello, World
</div>
```

The development tools do not detect changes to the `angular.json` file, so stop them by typing Control+C and run the command shown in Listing 9-10 in the `example` folder to start them again.

Listing 9-10. Starting the Angular Development Tools

```
ng serve
```

A new `styles.js` bundle will be created during the initial startup. Reload the browser window if the browser doesn't reconnect to the development HTTP server, and you will see the effect of the new styles, as shown in Figure 9-5. (These styles were applied by the classes I added to the `div` element in Listing 9-9.)

Figure 9-5. *Adding a stylesheet*

The original bundle contained just the `styles.css` file in the `src` folder, which is empty by default (but which was modified by the Angular Material installation), and the stylesheet from the Angular Material package. Now that the bundle contains the Bootstrap stylesheet, the bundle is larger, as shown by the build message:

```
...
styles.css, styles.js | styles        | 450.86 kB
...
```

This may seem like a large file just for some styles, but it is this size only during development, as I explain in the "Understanding the Production Build Process" section.

Using the Linter

A linter is a tool that inspects source code to ensure that it conforms to a set of coding conventions and rules. Run the command shown in Listing 9-11 in the `example` folder, which installs the popular ESLint linter package and uses the schematics API to configure the project.

Listing 9-11. Adding the Linter Package

```
ng add @angular-eslint/schematics@13.0.1
```

As part of the integration process, the linter package creates a configuration file named `.eslintrc.json` in the `example` folder. Two changes are required to configure the linter, as shown in Listing 9-12.

Listing 9-12. Configuring the Linter in the .eslintrc.json File in the example Folder

```
{
  "root": true,
  "ignorePatterns": [
    "projects/**/*",
    "src/test.ts"
  ],
  "overrides": [
    {
      "files": [
        "*.ts"
      ],
      "parserOptions": {
        "project": [
          "tsconfig.json"
        ],
        "createDefaultProgram": true
      },
      "extends": [
        "plugin:@angular-eslint/ng-cli-compat",
        "plugin:@angular-eslint/recommended",
```

```
        "plugin:@angular-eslint/template/process-inline-templates"
      ],
      "rules": {
        "@angular-eslint/directive-selector": [
          "error",
          {
            "type": "attribute",
            "prefix": "app",
            "style": "camelCase"
          }
        ],
        "@angular-eslint/component-selector": [
          "error",
          {
            "type": "element",
            "prefix": "app",
            "style": "kebab-case"
          }
        ]
      }
    },
    {
      "files": [
        "*.html"
      ],
      "extends": [
        "plugin:@angular-eslint/template/recommended"
      ],
      "rules": {}
    }
  ]
}
```

The first change excludes the test.ts file from linting. This file is created by the ng new command to support unit tests, and its contents will produce linting warnings. The second change expands the set of rules applied by the linter.

Additional JavaScript packages are required to support the expanded set of linting rules. Install these packages by running the command shown in Listing 9-13 in the example folder.

Listing 9-13. Installing Additional Packages

```
npm install eslint-plugin-import eslint-plugin-jsdoc eslint-plugin-prefer-arrow
```

To demonstrate how the linter works, I made two changes to a TypeScript file, as shown in Listing 9-14.

Listing 9-14. Making Changes in the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';

debugger

@Component({
  selector: 'approot',
  templateUrl: './app.component.html',
  styleUrls: ['./app.component.css']
})
export class AppComponent {
  title = 'example';
}
```

I added a `debugger` statement and changed the value of the selector property in the `Component` decorator. These changes illustrate the range of issues that can be detected by the linter. The `debugger` statement can cause problems when the application is deployed because it can halt code execution.

The change to the `selector` value breaks the style convention for Angular applications, where the selector should be specified in kebab-case, meaning that each word is separated by a hyphen. This is only a convention, however, and it doesn't prevent the application from working. (However, since I have changed only the `app.component.ts` file and not made a corresponding change in the HTML file, the application will build but not run as expected. I explain the relationship between the selector property and the HTML file in the next section of this chapter.)

Run the command shown in Listing 9-15 in the `example` folder to run the linter.

Listing 9-15. Running the Linter

```
ng lint
```

The linter inspects the files in the project and reports any problems that it encounters. The changes in Listing 9-14 result in the following messages:

```
...

Linting "example"...

C:\example\src\app\app.component.ts
  3:1    error  Unexpected 'debugger' statement no-debugger
  6:13   error  The selector should be kebab-case
    (https://angular.io/guide/styleguide#style-05-02)
    @angular-eslint/component-selector

2 problems (2 errors, 0 warnings)
Lint errors found in the listed files.
...
```

Linting isn't integrated into the regular build process and is performed manually. The most common use for linting is to check for potential problems before committing changes to a version control system, although some project teams make broader use of the linting facility by integrating it into other processes.

You may find that there are individual statements that cause the linter to report an error but that you are not able to change. Rather than disable the rule entirely, you can add a comment to the code that tells the linter to ignore the next line, like this:

```
...
// eslint-disable-next-line
...
```

If you have a file that is full of problems but you cannot make changes—often because there are constraints applied from some other part of the application—then you can disable linting for the entire file by adding this comment at the top of the page:

```
...
/* eslint-disable */
...
```

These comments allow you to ignore code that doesn't conform to the rules but that cannot be changed, while still linting the rest of the project.

You can also disable rules for the entire project in the `.eslintrc` file. Each rule has a name, which is included in the linter's error report. The name of the rule that checks for the debugger statement, for example, is `no-debugger`:

```
...
3:1    error   Unexpected 'debugger' statement  no-debugger
...
```

The rules section of the `.eslintrc` file can be used to disable rules, as shown in Listing 9-16.

UNDERSTANDING THE LINTER RULES

The linter rules that are provided by the ESLint package are described at https://eslint.org/docs/rules, and each description includes examples of code that will pass and fail the rule. Rules whose names begin with @angular are defined by the @angular-eslint package and are described at https://github.com/angular-eslint/angular-eslint/tree/master/packages/eslint-plugin/docs/rules.

Listing 9-16. Disabling a Rule in the .eslintrc File in the example Folder

```
...
"rules": {
"@angular-eslint/directive-selector": [
    "error",
    {
    "type": "attribute", "prefix": "app", "style": "camelCase"
    }
],
"@angular-eslint/component-selector": [
    "error",
    {
    "type": "element", "prefix": "app", "style": "kebab-case"
    }
```

233

```
],
"no-debugger": "off"
}
...
```

Save the configuration file and run the ng lint command in the example folder. The new configuration disables the no-debugger rule, so the only warning is for the selector naming convention:

```
Linting "example"...
C:\example\src\app\app.component.ts
  6:13  error  The selector should be kebab-case (https://angular.io/guide/
styleguide#style-05-02)  @angular-eslint/component-selector
1 problem (1 error, 0 warnings)
Lint errors found in the listed files.
```

To address the remaining linter warning, I have changed the selector property back to its original value, as shown in Listing 9-17. I have also commented out the debugger statement, even though it will no longer be detected by the linter.

Listing 9-17. Changing a Property in the app.component.ts File in the src/app Folder

```
import { Component } from '@angular/core';

//debugger

@Component({
  selector: 'app-root',
  templateUrl: './app.component.html',
  styleUrls: ['./app.component.css']
})
export class AppComponent {
  title = 'example';
}
```

THE JOY AND MISERY OF LINTING

Linters can be a powerful tool for good, especially in a development team with mixed levels of skill and experience. Linters can detect common problems and subtle errors that lead to unexpected behavior or long-term maintenance issues. A good example is the difference between the JavaScript == and === operators, where a linter can warn when the wrong type of comparison has been performed. I like this kind of linting, and I like to run my code through the linting process after I have completed a major application feature or before I commit my code into version control.

But linters can also be a tool of division and strife. In addition to detecting coding errors, linters can be used to enforce rules about indentation, brace placement, the use of semicolons and spaces, and dozens of other style issues. Most developers have style preferences—I certainly do: I like four spaces for indentation, and I like opening braces to be on the same line and the expression they relate to. I know that some programmers have different preferences, just as I know those people are plain wrong and will one day see the light and start formatting their code correctly.

Linters allow people with strong views about formatting to enforce them on others, generally under the banner of being "opinionated," which can tend toward "obnoxious." The logic is that developers waste time arguing about different coding styles and everyone is better off being forced to write in the same way, which is typically the way preferred by the person with the strong views and ignores the fact that developers will just argue about something else because arguing is fun.

I especially dislike linting of formatting, which I see as divisive and unnecessary. I often help readers when they can't get book examples working (my email address is adam@adam-freeman.com if you need help), and I see all sorts of coding style every week. But rather than forcing readers to code my way, I just get my code editor to reformat the code to the format that I prefer, which is a feature that every capable editor provides.

My advice is to use linting sparingly and focus on the issues that will cause real problems. Leave formatting decisions to the individuals and rely on code editor reformatting when you need to read code written by a team member who has different preferences.

Understanding How an Angular Application Works

Angular can seem like magic when you first start using it, and it is easy to become wary of making changes to the project files for fear of breaking something. Although there are lots of files in an Angular application, they all have a specific purpose, and they work together to do something far from magic: display HTML content to the user. In this section, I explain how the example Angular application works and how each part works toward the end result.

If you stopped the Angular development tools to run the linter in the previous section, run the command shown in Listing 9-18 in the example folder to start them again.

Listing 9-18. Starting the Angular Development Tools

```
ng serve
```

Once the initial build is complete, use a browser to request http://localhost:4200, and you will see the content shown in Figure 9-6.

Figure 9-6. *Running the example application*

In the sections that follow, I explain how the files in the project are combined to produce the response shown in the figure.

Understanding the HTML Document

The starting point for running the application is the index.html file, which is found in the src folder. When the browser sent the request to the development HTTP server, it received this file, which contains the following elements:

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Example</title>
  <base href="/">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <link rel="icon" type="image/x-icon" href="favicon.ico">
  <link rel="preconnect" href="https://fonts.gstatic.com">
  <link href="https://fonts.googleapis.com/css2?family=Roboto:wght@300;400;500&display=swap"
  rel="stylesheet">
  <link href="https://fonts.googleapis.com/icon?family=Material+Icons" rel="stylesheet">
</head>
<body>
  <app-root></app-root>
</body>
</html>
```

The header contains link elements for font files, which are required by the Angular Material package. The most important part of the file is the app-root element in the document body, whose purpose will become clear shortly.

The contents of the index.html file are modified as they are sent to the browser to include script elements for JavaScript files, like this:

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Example</title>
  <base href="/">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <link rel="icon" type="image/x-icon" href="favicon.ico">
  <link rel="preconnect" href="https://fonts.gstatic.com">
  <link href="https://fonts.googleapis.com/css2?
      family=Roboto:wght@300;400;500&display=swap" rel="stylesheet">
  <link href="https://fonts.googleapis.com/icon?family=Material+Icons" rel="stylesheet">
<link rel="stylesheet" href="styles.css"></head>
<body>
  <app-root></app-root>
  <script src="runtime.js" type="module"></script>
  <script src="polyfills.js" type="module"></script>
  <script src="styles.js" defer></script>
  <script src="vendor.js" type="module"></script>
  <script src="main.js" type="module"></script>
</body>
</html>
```

236

Understanding the Application Bootstrap

Browsers execute JavaScript files in the order in which their `script` elements appear, starting with the `runtime.js` file, which contains the code that processes the contents of the other JavaScript files.

Next comes the `polyfills.js` file, which contains code that provides implementations of features that the browser doesn't support, and then the `styles.js` file, which contains the CSS styles the application needs. The `vendor.js` file contains the third-party code the application requires, including the Angular framework. This file can be large during development because it contains all the Angular features, even if they are not required by the application. An optimization process is used to prepare an application for deployment, as described later in this chapter.

The final file is the `main.js` bundle, which contains the custom application code. The name of the bundle is taken from the entry point for the application, which is the `main.ts` file in the `src` folder. Once the other bundle files have been processed, the statements in the `main.ts` file are executed to initialize Angular and run the application. Here is the content of the `main.ts` file as it is created by the `ng new` command:

```
import { enableProdMode } from '@angular/core';
import { platformBrowserDynamic } from '@angular/platform-browser-dynamic';

import { AppModule } from './app/app.module';
import { environment } from './environments/environment';

if (environment.production) {
  enableProdMode();
}

platformBrowserDynamic().bootstrapModule(AppModule)
  .catch(err => console.error(err));
```

The `import` statements declare dependencies on other JavaScript modules, providing access to Angular features (the dependencies on `@angular` modules, which are included in the `vendor.js` file) and the custom code in the application (the `AppModule` dependency). The final import is for environment settings, which are used to create different configuration settings for development, test, and production platforms, such as this code:

```
...
if (environment.production) {
  enableProdMode();
}
...
```

Angular has a production mode that disables some useful checks that are performed during development and that are described in later chapters. Production mode is enabled by calling the `enableProdMode` function, which is imported from the `@angular/core` module.

To work out whether production mode should be enabled, a check is performed to see whether `environment.production` is `true`. This check corresponds to the contents of the `environment.prod.ts` file in the `src/environments` folder, which sets this value and is applied when the application is built in preparation for deployment. The result is that production mode will be enabled if the application has been built for production but disabled the rest of the time.

The remaining statement in the `main.ts` file is responsible for starting the application.

```
...
platformBrowserDynamic().bootstrapModule(AppModule).catch(err => console.error(err));
...
```

The `platformBrowserDynamic` function initializes the Angular platform for use in a web browser and is imported from the `@angular/platform-browser-dynamic` module. Angular has been designed to run in a range of different environments, and calling the `platformBrowserDynamic` function is the first step in starting an application in a browser.

The next step is to call the `bootstrapModule` method, which accepts the Angular root module for the application, which is AppModule by default; AppModule is imported from the `app.module.ts` file in the `src/app` folder and described in the next section. The `bootstrapModule` method provides Angular with the entry point into the application and represents the bridge between the functionality provided by the `@angular` modules and the custom code and content in the project. The final part of this statement uses the `catch` keyword to handle any bootstrapping errors by writing them to the browser's JavaScript console.

Understanding the Root Angular Module

The term *module* does double duty in an Angular application and refers to both a JavaScript module and an Angular module. JavaScript modules are used to track dependencies in the application and ensure that the browser receives only the code it requires. Angular modules are used to configure a part of the Angular application.

Every application has a *root* Angular module, which is responsible for describing the application to Angular. For applications created with the `ng new` command, the root module is called AppModule, and it is defined in the `app.module.ts` file in the `src/app` folder, which contains the following code:

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

@NgModule({
  declarations: [
    AppComponent
  ],
  imports: [
    BrowserModule,
    BrowserAnimationsModule
  ],
  providers: [],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

The `AppModule` class doesn't define any members, but it provides Angular with essential information through the configuration properties of its `@NgModule` decorator. I describe the different properties that are used to configure an Angular module in later chapters, but the one that is of interest now is the

bootstrap property, which tells Angular that it should load a component called AppComponent as part of the application startup process. Components are the main building block in Angular applications, and the content provided by the component called AppComponent will be displayed to the user.

Understanding the Angular Component

The component called AppComponent, which is selected by the root Angular module, is defined in the app.component.ts file in the src/app folder. Here are the contents of the app.component.ts file, which I edited earlier in the chapter to demonstrate linting:

```
import { Component } from '@angular/core';

//debugger

@Component({
  selector: 'app-root',
  templateUrl: './app.component.html',
  styleUrls: ['./app.component.css']
})
export class AppComponent {
  title = 'example';
}
```

The properties for the @Component decorator configure its behavior. The selector property tells Angular that this component will be used to replace an HTML element called app-root. The templateUrl and styleUrls properties tell Angular that the HTML content that the component wants to present to the user can be found in a file called app.component.html and that the CSS styles to apply to the HTML content are defined in a file called app.component.css (although the CSS file is empty in new projects).

Here is the content of the app.component.html file, which I edited earlier in the chapter to demonstrate hot reloading and the use of CSS styles:

```
<div class="bg-primary text-white text-center">
    Hello, World
</div>
```

This file contains regular HTML elements, but, as you will learn, Angular features are applied by using custom HTML elements or by adding attributes to regular HTML elements.

Understanding Content Display

When the application starts, Angular processes the index.html file, locates the element that matches the root component's selector property, and replaces it with the contents of the files specified by the root component's templateUrl and styleUrls properties. This is done using the Domain Object Model (DOM) API provided by the browser for JavaScript applications, and the changes can be seen only by right-clicking in the browser window and selecting Inspect from the pop-up menu, producing the following result:

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
```

```
    <title>Example</title>
    <base href="/">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <link rel="icon" type="image/x-icon" href="favicon.ico">
    <link rel="preconnect" href="https://fonts.gstatic.com">
    <link href="https://fonts.googleapis.com/css2?
        family=Roboto:wght@300;400;500&display=swap" rel="stylesheet">
    <link href="https://fonts.googleapis.com/icon?family=Material+Icons"
        rel="stylesheet">
    <link rel="stylesheet" href="styles.css">
    <style>
        /*# sourceMappingURL=data:application/json;
      base64,eyJ2ZXJzaW9uIjozLCJzb3VyY2VzIjpbXSwibmFtZXMiOltdLCJtY
     XBwaW5ncyI6IiIsImZpbGGUiOiJhcHAuY29tcG9uZW50LmNzcyJ9 */
    </style>
</head>
<body>
    <app-root _nghost-ogl-c11="" ng-version="13.0.3">
        <div _ngcontent-ogl-c11="" class="bg-primary text-white text-center">
            Hello, World
        </div>
    </app-root>
    <script src="runtime.js" type="module"></script>
    <script src="polyfills.js" type="module"></script>
    <script src="styles.js" defer=""></script>
    <script src="vendor.js" type="module"></script>
    <script src="main.js" type="module"></script>
</body>
```

The app-root element contains the div element from the component's template, and the attributes are added by Angular during the initialization process.

The style elements represent the contents of the styles.css file in the app folder, the app.component. css file in the src/app folder, and the Angular Material and Bootstrap stylesheets added using the angular. json file.

The combination of the dynamically generated div element and the class attributes I specified in the template produces the result shown in Figure 9-7.

Figure 9-7. Displaying a component's content

Understanding the Production Build Process

During development, the emphasis is on fast compilation so that the results can be displayed as quickly as possible in the browser, leading to a good iterative development process. During development with the `ng serve` command, the compilers and the bundler don't apply any optimizations, which is why the bundle files are so large. The size doesn't matter because the browser is running on the same machine as the server and will load immediately.

Before an application is deployed, it is built using an optimizing process. To run this type of build, run the command shown in Listing 9-19 in the example folder.

Listing 9-19. Performing the Production Build

```
ng build
```

The `ng build` command performs the production compilation process, and the bundles it produces are smaller and contain only the code that is required by the application.

■ **Note**   The `angular.json` command defines default build modes for commands, and the default configuration uses development mode for the `ng serve` command and production mode for the `ng build` command. You can edit the configuration file to change these settings or override them on the command line with the `--configuation` argument.

You can see the details of the bundles that are produced in the messages generated by the compiler.

```
...
Initial Chunk Files          | Names           |       Size
styles.2bbd6476e9a18d40.css  | styles          | 230.36 kB
main.dcffd5dba104918c.js     | main            | 171.02 kB
polyfills.221f478e3706b78e.js | polyfills      |  36.19 kB
runtime.a2e8a93eb7a8cc89.js  | runtime         |   1.04 kB
                             | Initial Total   | 438.62 kB
...
```

Features such as hot reloading are not added to the bundles, and the large `vendor.js` bundle is no longer produced. Instead, the `main.js` bundle contains the application and just the parts of third-party code it relies on.

UNDERSTANDING AHEAD-OF-TIME COMPILATION

The development build process leaves the decorators, which describe the building blocks of an Angular application, in the output. These are then transformed into API calls by the Angular runtime in the browser, which is known as *just-in-time* (JIT) compilation. The production build process enables a feature named *ahead-of-time* (AOT) compilation, which transforms the decorators so that it doesn't have to be done every time the application runs.

Combined with the other build optimizations, the result is an Angular application that loads faster and starts up faster. The drawback is that the additional compilation requires time, which can be frustrating if you enable optimizing builds during development.

241

Running the Production Build

To test the production build, run the command shown in Listing 9-20 in the example folder.

Listing 9-20. Running the Production Build

```
npx http-server@14.0.0 dist/example --port 5000
```

This command will download and execute version 14.0.0 of the http-server package, which provides a simple, self-contained HTTP server. The command tells the http-server package to serve the contents of the dist/example folder and listen for requests on port 5000. Open a new web browser and request http://localhost:5000; you will see the production version of the example application, as shown in Figure 9-8 (although, unless you examine the HTTP requests sent by the browser to get the bundle files, you won't see any differences from the development version shown in earlier figures).

Figure 9-8. *Running the production build*

Once you have tested the production build, stop the HTTP server using Control+C.

Starting Development in an Angular Project

You have seen how the initial building blocks of an Angular application fit together and how the bootstrap process results in content being displayed to the user. In this section, I add a simple data model to the project, which is the typical starting point for most developers, and add features to the component, beyond the static content added earlier in the chapter.

Creating the Data Model

Of all the building blocks in an application, the data model is the one for which Angular is the least prescriptive. Elsewhere in the application, Angular requires specific decorators to be applied or parts of the API to be used, but the only requirement for the model is that it provides access to the data that the application requires; the details of how this is done and what that data looks like is left to the developer.

This can feel a little odd, and it can be difficult to know how to begin, but, at its heart, the model can be broken into three parts.

- One or more classes that describe the data in the model

- A data source that loads and saves data, typically to a server

- A repository that allows the data in the model to be manipulated

In the following sections, I create a simple model, which provides the functionality that I need to describe Angular features in the chapters that follow.

Creating the Descriptive Model Class

Descriptive classes, as the name suggests, describe the data in the application. In a real project, there will usually be a lot of classes to fully describe the data that the application operates on. To get started for this chapter, I am going to create a single, simple class as the foundation for the data model. I added a file named `product.model.ts` to the `src/app` folder with the code shown in Listing 9-21.

The name of the file follows the Angular descriptive naming convention. The `product` and `model` parts of the name tell you that this is the part of the data model that relates to products, and the `.ts` extension denotes a TypeScript file. You don't have to follow this convention, but Angular projects usually contain a lot of of files, and cryptic names make it difficult to navigate around the source code.

Listing 9-21. The Contents of the product.model.ts File in the src/app Folder

```
export class Product {

    constructor(public id?: number,
        public name?: string,
        public category?: string,
        public price?: number) { }
}
```

The `Product` class defines properties for a product identifier, the name of the product, its category, and the price. The properties are defined as optional constructor arguments, which is a useful approach if you are creating objects using an HTML form, which I demonstrate in Chapter 12.

Creating the Data Source

The data source provides the application with the data. The most common type of data source uses HTTP to request data from a web service, which I describe in Chapter 23. For this chapter, I need something simpler that I can reset to a known state each time the application is started to ensure that you get the expected results from the examples. I added a file called `datasource.model.ts` to the `src/app` folder with the code shown in Listing 9-22.

Listing 9-22. The Contents of the datasource.model.ts File in the src/app Folder

```
import { Product } from "./product.model";

export class SimpleDataSource {
    private data: Product[];

    constructor() {
        this.data = new Array<Product>(
            new Product(1, "Kayak", "Watersports", 275),
            new Product(2, "Lifejacket", "Watersports", 48.95),
            new Product(3, "Soccer Ball", "Soccer", 19.50),
            new Product(4, "Corner Flags", "Soccer", 34.95),
            new Product(5, "Thinking Cap", "Chess", 16));
    }
```

```
    getData(): Product[] {
        return this.data;
    }
}
```

The data in this class is hardwired, which means that any changes that are made in the application will be lost when the browser is reloaded. This is far from useful in a real application, but it is ideal for book examples.

Creating the Model Repository

The final step to complete the simple model is to define a repository that will provide access to the data from the data source and allow it to be manipulated in the application. I added a file called repository.model.ts in the src/app folder and used it to define the class shown in Listing 9-23.

Listing 9-23. The Contents of the repository.model.ts File in the src/app Folder

```typescript
import { Product } from "./product.model";
import { SimpleDataSource } from "./datasource.model";

export class Model {
    private dataSource: SimpleDataSource;
    private products: Product[];
    private locator = (p: Product, id: number | any) => p.id == id;

    constructor() {
        this.dataSource = new SimpleDataSource();
        this.products = new Array<Product>();
        this.dataSource.getData().forEach(p => this.products.push(p));
    }

    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }

    saveProduct(product: Product) {
        if (product.id == 0 || product.id == null) {
            product.id = this.generateID();
            this.products.push(product);
        } else {
            let index = this.products.findIndex(p => this.locator(p, product.id));
            this.products.splice(index, 1, product);
        }
    }
```

```
    deleteProduct(id: number) {
        let index = this.products.findIndex(p => this.locator(p, id));
        if (index > -1) {
            this.products.splice(index, 1);
        }
    }

    private generateID(): number {
        let candidate = 100;
        while (this.getProduct(candidate) != null) {
            candidate++;
        }
        return candidate;
    }
}
```

The Model class defines a constructor that gets the initial data from the data source class and provides access to it through a set of methods. These methods are typical of those defined by a repository and are described in Table 9-8.

Table 9-8. *The Types of Web Forms Code Nuggets*

Name	Description
getProducts	This method returns an array containing all the Product objects in the model.
getProduct	This method returns a single Product object based on its ID.
saveProduct	This method updates an existing Product object or adds a new one to the model.
deleteProduct	This method removes a Product object from the model based on its ID.

The implementation of the repository may seem odd because the data objects are stored in a standard JavaScript array, but the methods defined by the Model class present the data as though it were a collection of Product objects indexed by the id property. There are two main considerations when writing a repository for model data. The first is that it should present the data that will be displayed as efficiently as possible. For the example application, this means presenting all the data in the model in a form that can be iterated, such as an array. This is important because the iteration can happen often, as I explain in later chapters. The other operations of the Model class are inefficient, but they will be used less often.

The second consideration is being able to present unchanged data for Angular to work with. I explain why this is important in Chapter 11, but in terms of implementing the repository, it means that the getProducts method should return the same object when it is called multiple times unless one of the other methods or another part of the application has made a change to the data that the getProducts method provides. If a method returns a different object each time it is returned, even if they are different arrays containing the same objects, then Angular will report an error. Taking both points into account means that the best way to implement the repository is to store the data in an array and accept the inefficiencies.

Creating a Component and Template

Templates contain the HTML content that a component wants to present to the user. Templates can range from a single HTML element to a complex block of content.

To create a template, I added a file called template.html to the src/app folder and added the HTML elements shown in Listing 9-24.

245

Listing 9-24. The Contents of the template.html File in the src/app Folder

```
<div class="bg-info text-white p-2">
    There are {{model.getProducts().length}} products in the model
</div>
```

Most of this template is standard HTML, but the part between the double brace characters (the {{ and }} in the div element) is an example of a data binding. When the template is displayed, Angular will process its content, discover the binding, and evaluate the expression that it contains to produce the content that will be displayed by the data binding.

The logic and data required to support the template are provided by its component, which is a TypeScript class to which the @Component decorator has been applied. To provide a component for the template, I added a file called component.ts to the src/app folder and defined the class shown in Listing 9-25.

Listing 9-25. The Contents of the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();
}
```

The @Component decorator configures the component. The selector property specifies the HTML element that the directive will be applied to, which is app. The templateUrl property in the @Component directive specifies the content that will be used as the contents of the app element, and, for this example, this property specifies the template.html file.

The component class, which is ProductComponent for this example, is responsible for providing the template with the data and logic needed for its bindings. The ProductComponent class defines a single property, called model, which provides access to a Model object.

The app element I used for the component's selector isn't the same element that the ng new command uses when it creates a project and that is expected in the index.html file. In Listing 9-26, I have modified the index.html file to introduce an app element to match the component's selector.

Listing 9-26. Changing the Custom Element in the index.html File in the app Folder

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Example</title>
  <base href="/">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <link rel="icon" type="image/x-icon" href="favicon.ico">
  <link rel="preconnect" href="https://fonts.gstatic.com">
  <link href="https://fonts.googleapis.com/css2?
      family=Roboto:wght@300;400;500&display=swap" rel="stylesheet">
```

```
  <link href="https://fonts.googleapis.com/icon?family=Material+Icons"
      rel="stylesheet">
</head>
<body>
  <app></app>
</body>
</html>
```

This isn't something you need to do in a real project, but it further demonstrates that Angular applications fit together in simple and predictable ways and that you can change any part.

Configuring the Root Angular Module

The component that I created in the previous section won't be part of the application until I register it with the root Angular module. In Listing 9-27, I have used the import keyword to import the component, and I have used the @NgModule configuration properties to register the component.

Listing 9-27. Registering a Component in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';

@NgModule({
  declarations: [ProductComponent],
  imports: [
    BrowserModule,
    BrowserAnimationsModule
  ],
  providers: [],
  bootstrap: [ProductComponent]
})
export class AppModule { }
```

I used the name ProductComponent in the import statement, and I added this name to the declarations array, which configures the set of components and other features in the application. I also changed the value of the bootstrap property so that the new component is the one that is used when the application starts.

Run the command shown in Listing 9-28 in the example folder to start the Angular development tools.

Listing 9-28. Starting the Angular Development Tools

```
ng serve
```

Once the initial build process is complete, use a web browser to request http://localhost:4200, which will produce the response shown in Figure 9-9.

Figure 9-9. *The effect of a new component and template*

The standard Angular bootstrap sequence is performed, but the custom component and template that I created in the previous section are used, rather than the ones set up when the project was created.

Summary

In this chapter, I created an Angular project and used it to introduce the tools that it contains and explain how a simple Angular application works. In the next chapter, I start digging into the Angular features, starting with data bindings.

CHAPTER 10

■ ■ ■

Using Data Bindings

The example application in the previous chapter contains a simple template that was displayed to the user and that contained a data binding that showed how many objects were in the data model. In this chapter, I describe the basic data bindings that Angular provides and demonstrate how they can be used to produce dynamic content. In later chapters, I describe more advanced data bindings and explain how to extend the Angular binding system with custom features. Table 10-1 puts data bindings in context.

Table 10-1. *Putting Data Bindings in Context*

Question	Answer
What are they?	Data bindings are expressions embedded into templates and are evaluated to produce dynamic content in the HTML document.
Why are they useful?	Data bindings provide the link between the HTML elements in the HTML document and in template files with the data and code in the application.
How are they used?	Data bindings are applied as attributes on HTML elements or as special sequences of characters in strings.
Are there any pitfalls or limitations?	Data bindings contain simple JavaScript expressions that are evaluated to generate content. The main pitfall is including too much logic in a binding because such logic cannot be properly tested or used elsewhere in the application. Data binding expressions should be as simple as possible and rely on components (and other Angular features such as pipes) to provide complex application logic.
Are there any alternatives?	No. Data bindings are an essential part of Angular development.

Table 10-2 summarizes the chapter.

Table 10-2. *Chapter Summary*

Problem	Solution	Listing
Displaying data dynamically in the HTML document	Define a data binding	1–4
Configuring an HTML element	Use a standard property or attribute binding	5, 8
Setting the contents of an element	Use a string interpolation binding	6, 7
Configuring the classes to which an element is assigned	Use a class binding	9–13
Configuring the individual styles applied to an element	Use a style binding	14–17
Manually triggering a data model update	Use the browser's JavaScript console	18, 19

Preparing for This Chapter

For this chapter, I continue using the example project from Chapter 9. To prepare for this chapter, I added a method to the component class, as shown in Listing 10-1.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 10-1. Adding a Method in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getClasses(): string {
        return this.model.getProducts().length == 5 ? "bg-success" : "bg-warning";
    }
}
```

Run the following command in the example folder to start the Angular development tools:

```
ng serve
```

Open a new browser and navigate to `http://localhost:4200` to see the content, shown in Figure 10-1, that will be displayed.

Figure 10-1. *Running the example application*

Understanding One-Way Data Bindings

One-way data bindings are used to generate content for the user and are the basic feature used in Angular templates. The term *one-way* refers to the fact that the data flows in one direction, meaning that data flows *from* the component *to* the data binding so that it can be displayed in a template.

■ **Tip**   There are other types of Angular data binding, which I describe in later chapters. *Event bindings* flow in the other direction, from the elements in the template into the rest of the application, and they allow user interaction. *Two-way bindings* allow data to flow in both directions and are most often used in forms. See Chapters 11 and 12 for details of other bindings.

To get started with one-way data bindings, I have replaced the content of the template, as shown in Listing 10-2.

Listing 10-2.   The Contents of the template.html File in the src/app Folder

```
<div [ngClass]="getClasses()" >
    Hello, World.
</div>
```

When you save the changes to the template, the development tools will rebuild the application and trigger a browser reload, displaying the output shown in Figure 10-2.

Figure 10-2. *Using a one-way data binding*

This is a simple example, but it shows the basic structure of a data binding, which is illustrated in Figure 10-3.

Figure 10-3. *The anatomy of a data binding*

A data binding has these four parts:

- The *host element* is the HTML element that the binding will affect, by changing its appearance, content, or behavior.

- The *square brackets* tell Angular that this is a one-way data binding. When Angular sees square brackets in a data binding, it will evaluate the expression and pass the result to the binding's *target* so that it can modify the host element.

- The *target* specifies what the binding will do. There are two different types of target: a *directive* or a *property binding*.

- The *expression* is a fragment of JavaScript that is evaluated using the template's component to provide context, meaning that the component's property and methods can be included in the expression, like the getClasses method in the example binding.

Looking at the binding in Listing 10-2, you can see that the host element is a div element, meaning that's the element that the binding is intended to modify. The expression invokes the component's getClasses method, which was defined at the start of the chapter. This method returns a string containing a Bootstrap CSS class based on the number of objects in the data model.

```
...
getClasses(): string {
    return this.model.getProducts().length == 5 ? "bg-success" : "bg-warning";
}
...
```

If there are five objects in the data model, then the method returns bg-success, which is a Bootstrap class that applies a green background. Otherwise, the method returns bg-warning, which is a Bootstrap class that applies an amber background.

The target for the data binding is a *directive*, which is a class that is specifically written to support a data binding. Angular comes with some useful built-in directives, and you can create your own to provide custom functionality. The names of the built-in directives start with ng, which tells you that the ngClass target is one of the built-in directives. The target usually gives an indication of what the directive does, and as its name suggests, the ngClass directive will add or remove the host element from the class or classes whose names are returned when the expression is evaluated.

Putting it all together, the data binding will add the div element to the bg-success or bg-warning classes based on the number of items in the data model.

Since there are five objects in the model when the application starts (because the initial data is hard-coded into the SimpleDataSource class created in Chapter 9), the getClasses method returns bg-success and produces the result shown in Figure 10-3, adding a green background to the div element.

Understanding the Binding Target

When Angular processes the target of a data binding, it starts by checking to see whether it matches a directive. Most applications will rely on a mix of the built-in directives provided by Angular and custom directives that provide application-specific features. You can usually tell when a directive is the target of a data binding because the name will be distinctive and give some indication of what the directive is for. The built-in directives can be recognized by the ng prefix. The binding in Listing 10-2 gives you a hint that the target is a built-in directive that is related to the class membership of the host element. For quick reference, Table 10-3 describes the basic built-in Angular directives and where they are described in this book. (There are other directives described in later chapters, but these are the simplest and the ones you will use most often.)

Table 10-3. *The Basic Built-in Angular Directives*

Name	Description
ngClass	This directive is used to assign host elements to classes, as described in the "Setting Classes and Styles" section.
ngStyle	This directive is used to set individual styles, as described in the "Setting Classes and Styles" section.
ngIf	This directive is used to insert content in the HTML document when its expression evaluates as true, as described in Chapter 11.
ngFor	This directive inserts the same content into the HTML document for each item in a data source, as described in Chapter 11.
ngSwitch ngSwitchCase ngSwitchDefault	These directives are used to choose between blocks of content to insert into the HTML document based on the value of the expression, as described in Chapter 11.
ngTemplateOutlet	This directive is used to repeat a block of content, as described in Chapter 11.

Understanding Property Bindings

If the binding target doesn't correspond to a directive, then Angular checks to see whether the target can be used to create a property binding. There are five different types of property binding, which are listed in Table 10-4, along with the details of where they are described in detail.

Table 10-4. *The Angular Property Bindings*

Name	Description
[property]	This is the standard property binding, which is used to set a property on the JavaScript object that represents the host element in the Document Object Model (DOM), as described in the "Using the Standard Property and Attribute Bindings" section.
[attr.name]	This is the attribute binding, which is used to set the value of attributes on the host HTML element for which there are no DOM properties, as described in the "Using the Attribute Binding" section.
[class.name]	This is the special class property binding, which is used to configure class membership of the host element, as described in the "Using the Class Bindings" section.
[style.name]	This is the special style property binding, which is used to configure style settings of the host element, as described in the "Using the Style Bindings" section.

Understanding the Expression

The expression in a data binding is a fragment of JavaScript code that is evaluated to provide a value for the target. The expression has access to the properties and methods defined by the component, which is how the binding in Listing 10-2 can invoke the getClasses method to provide the ngClass directive with the name of the class that the host element should be added to.

Expressions are not restricted to calling methods or reading properties from the component; they can also perform most standard JavaScript operations. As an example, Listing 10-3 shows an expression that has a literal string value being concatenated with the result of the getClasses method.

Listing 10-3. Performing an Operation in the template.html File in the src/app Folder

```
<div [ngClass]="'text-white p-2 ' + getClasses()" >
    Hello, World.
</div>
```

The expression is enclosed in double quotes, which means that the string literal has to be defined using single quotes. The JavaScript concatenation operator is the + character, and the result from the expression will be the combination of both strings, like this:

```
text-white p-2 bg-success
```

The effect is that the ngClass directive will add the host element to four classes: text-white, m-2, and p-2, which Bootstrap uses to set the text color and add margin and padding around an element's content; and bg-success, which sets the background color. Figure 10-4 shows the combination of these classes.

Figure 10-4. *Combining classes in a JavaScript expression*

It is easy to get carried away when writing expressions and include complex logic in the template. This can cause problems because the expressions are not checked by the TypeScript compiler nor can they be easily unit tested, which means that bugs are more likely to remain undetected until the application has been deployed. To avoid this issue, expressions should be as simple as possible and, ideally, used only to retrieve data from the component and format it for display. All the complex retrieval and processing logic should be defined in the component or the model, where it can be compiled and tested.

Understanding the Brackets

The square brackets (the [and] characters) tell Angular that this is a one-way data binding that has an expression that should be evaluated. Angular will still process the binding if you omit the brackets and the target is a directive, but the expression won't be evaluated, and the content between the quote characters will be passed to the directive as a literal value. Listing 10-4 adds an element to the template with a binding that doesn't have square brackets.

Listing 10-4. Omitting the Brackets in a Data Binding in the template.html File in the src/app Folder

```
<div [ngClass]="'text-white p-2 ' + getClasses()">
  Hello, World.
</div>
<div ngClass="'text-white p-2 ' + getClasses()">
  Hello, World.
</div>
```

If you examine the HTML element in the browser's DOM viewer (by right-clicking in the browser window and selecting Inspect or Inspect Element from the pop-up menu), you will see that its `class` attribute has been set to the literal string, like this:

```
class="'text-white p-2 ' + getClasses()"
```

The browser will try to process the classes to which the host element has been assigned, but the element's appearance won't be as expected since the classes won't correspond to the names used by Bootstrap. This is a common mistake to make, so it is the first thing to check whether a binding doesn't have the effect you expected.

The square brackets are not the only ones that Angular uses in data bindings. For quick reference, Table 10-5 provides the complete set of brackets, the meaning of each, and where they are described in detail.

Table 10-5. *The Angular Brackets*

Name	Description
`[target]="expr"`	The square brackets indicate a one-way data binding where data flows from the expression to the target. The different forms of this type of binding are the topic of this chapter.
`{{expression}}`	This is the string interpolation binding, which is described in the "Using the String Interpolation Binding" section.
`(target) ="expr"`	The round brackets indicate a one-way binding where the data flows from the target to the destination specified by the expression. This is the binding used to handle events, as described in Chapter 12.
`[(target)] ="expr"`	This combination of brackets—known as the *banana-in-a-box*—indicates a two-way binding, where data flows in both directions between the target and the destination specified by the expression, as described in Chapter 12.

Understanding the Host Element

The host element is the simplest part of a data binding. Data bindings can be applied to any HTML element in a template, and an element can have multiple bindings, each of which can manage a different aspect of the element's appearance or behavior. You will see elements with multiple bindings in later examples.

Using the Standard Property and Attribute Bindings

If the target of a binding doesn't match a directive, Angular will try to apply a property binding. The sections that follow describe the most common property bindings: the standard property binding and the attribute binding.

Using the Standard Property Binding

The browser uses the Document Object Model to represent the HTML document. Each element in the HTML document, including the host element, is represented using a JavaScript object in the DOM. Like all JavaScript objects, the ones used to represent HTML elements have properties. These properties are used to manage the state of the element so that the value property, for example, is used to set the contents of an input element. When the browser parses an HTML document, it encounters each new HTML element, creates an object in the DOM to represent it, and uses the element's attributes to set the initial values for the object's properties.

The standard property binding lets you set the value of a property for the object that represents the host element, using the result of an expression. For example, setting the target of a binding to value will set the content of an input element, as shown in Listing 10-5.

Listing 10-5. Using the Standard Property Binding in the template.html File in the src/app Folder

```
<div [ngClass]="'text-white p-2 ' + getClasses()">
  Hello, World.
</div>
<div class="form-group m-2">
  <label>Name:</label>
  <input class="form-control" [value]="model.getProduct(1)?.name ?? 'None'" />
</div>
```

The new binding in this example specifies that the value property should be bound to the result of an expression that calls a method on the data model to retrieve a data object from the repository by specifying a key. It is possible that there is no data object with that key, in which case the repository method will return null.

To guard against using null for the host element's value property, the binding uses the null conditional operator (the ? character) to safely navigate the result returned by the method, like this:

```
...
<input class="form-control" [value]="model.getProduct(1)?.name ?? 'None'" />
...
```

If the result from the getProduct method isn't null, then the expression will read the value of the name property and use it as the result. But if the result from the method is null, then the name property won't be read, and the nullish coalescing operator (the ?? characters) will set the result to None instead.

GETTING TO KNOW THE HTML ELEMENT PROPERTIES

Using property bindings can require some work figuring out which property you need to set because there are inconsistencies in the HTML specification. The name of most properties matches the name of the attribute that sets their initial value so that if you are used to setting the value attribute on an input element, for example, then you can achieve the same effect by setting the value property. But some property names don't match their attribute names, and some properties are not configured by attributes at all.

The Mozilla Foundation provides a useful reference for all the objects that are used to represent HTML elements in the DOM at https://developer.mozilla.org/en-US/docs/Web/API. For each element, Mozilla provides a summary of the properties that are available and what each is used for. Start with HTMLElement (https://developer.mozilla.org/en-US/docs/Web/API/HTMLElement), which provides the functionality common to all elements. You can then branch out into the objects that are for specific elements, such as HTMLInputElement, which is used to represent input elements.

When you save the changes to the template, the browser will reload and display an input element whose content is the name property of the data object with the key of 1 in the model repository, as shown in Figure 10-5.

Figure 10-5. *Using the standard property binding*

Using the String Interpolation Binding

Angular provides a special version of the standard property binding, known as the *string interpolation binding*, that is used to include expression results in the text content of host elements. To understand why this special binding is useful, it helps to think about how the content of an element is set using the standard property binding. The textContent property is used to set the content of HTML elements, which means that the content of an element can be set using a data binding like the one shown in Listing 10-6.

Listing 10-6. Setting an Element's Content in the template.html File in the src/app Folder

```
<div [ngClass]="'text-white p-2 ' + getClasses()"
        [textContent]="'Name: ' + (model.getProduct(1)?.name ?? 'None')">
</div>
<div class="form-group m-2">
  <label>Name:</label>
  <input class="form-control" [value]="model.getProduct(1)?.name ?? 'None'" />
</div>
```

The expression in the new binding concatenates a literal string with the results of a method call to set the content of the div element.

The expression in this example is awkward to write, requiring careful attention to quotes, spaces, and brackets to ensure that the expected result is displayed in the output. The problem becomes worse for more complex bindings, where multiple dynamic values are interspersed among blocks of static content.

The string interpolation binding simplified this process by allowing fragments of expressions to be defined within the content of an element, as shown in Listing 10-7.

Listing 10-7. Using the String Interpolation Binding in the template.html File in the src/app Folder

```
<div [ngClass]="'text-white p-2 ' + getClasses()">
  Name: {{ model.getProduct(1)?.name ?? 'None' }}
</div>
<div class="form-group m-2">
  <label>Name:</label>
  <input class="form-control" [value]="model.getProduct(1)?.name ?? 'None'" />
</div>
```

The string interpolation binding is denoted using pairs of curly brackets ({{ and }}). A single element can contain multiple string interpolation bindings.

Angular combines the content of the HTML element with the contents of the brackets to create a binding for the textContent property. The result is the same as Listing 10-6, which is shown in Figure 10-6, but the process of writing the binding is simpler and less error-prone.

Figure 10-6. *Using the string interpolation binding*

Using the Attribute Binding

There are some oddities in the HTML and DOM specifications that mean that not all HTML element attributes have equivalent properties in the DOM API. For these situations, Angular provides the *attribute binding*, which is used to set an attribute on the host element rather than setting the value of the JavaScript object that represents it in the DOM.

The most often used attribute without a corresponding property is colspan, which is used to set the number of columns that a td element will occupy in a table. Listing 10-8 shows using the attribute binding to set the colspan element based on the number of objects in the data model.

Listing 10-8. Using an Attribute Binding in the template.html File in the src/app Folder

```
<div [ngClass]="'text-white p-2 ' + getClasses()">
  Name: {{ model.getProduct(1)?.name ?? 'None' }}
</div>
```

```
<div class="form-group m-2">
  <label>Name:</label>
  <input class="form-control" [value]="model.getProduct(1)?.name ?? 'None'" />
</div>
<table class="table mt-2">
  <tr>
      <th>1</th><th>2</th><th>3</th><th>4</th><th>5</th>
  </tr>
  <tr>
      <td [attr.colspan]="model.getProducts().length">
          {{model.getProduct(1)?.name ?? 'None'}}
      </td>
  </tr>
</table>
```

The attribute binding is applied by defining a target that prefixes the name of the attribute with `attr.` (the term `attr`, followed by a period). In the listing, I have used the attribute binding to set the value of the `colspan` element on one of the `td` elements in the table, like this:

```
...
<td [attr.colspan]="model.getProducts().length">
...
```

Angular will evaluate the expression and set the value of the `colspan` attribute to the result. Since the data model is hardwired to start with five data objects, the effect is that the `colspan` attribute creates a table cell that spans five columns, as shown in Figure 10-7.

Figure 10-7. Using an attribute binding

Setting Classes and Styles

Angular provides special support in property bindings for assigning the host element to classes and for configuring individual style properties. I describe these bindings in the sections that follow, along with details of the ngClass and ngStyle directives, which provide closely related features.

Using the Class Bindings

There are three different ways in which you can use data bindings to manage the class memberships of an element: the standard property binding, the special class binding, and the ngClass directive. All three are described in Table 10-6, and each works in a slightly different way and is useful in different circumstances, as described in the sections that follow.

Table 10-6. *The Angular Class Bindings*

Example	Description
`<div [class]="expr"></div>`	This binding evaluates the expression and uses the result to replace any existing class memberships.
`<div [class.myClass]="expr"></div>`	This binding evaluates the expression and uses the result to set the element's membership of myClass.
`<div [ngClass]="map"></div>`	This binding sets class membership of multiple classes using the data in a map object.

Setting All of an Element's Classes with the Standard Binding

The standard property binding can be used to set all of an element's classes in a single step, which is useful when you have a method or property in the component that returns all of the classes to which an element should belong in a single string, with the names separated by spaces. Listing 10-9 shows the revision of the getClasses method in the component that returns a different string of class names based on the price property of a Product object.

Listing 10-9. Providing All Classes in a Single String in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getClasses(key: number): string {
        let product = this.model.getProduct(key);
        return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    }
}
```

The result from the getClasses method will include the p-2 class, which adds padding around the host element's content, for all Product objects. If the value of the price property is less than 50, the bg-info class will be included in the result, and if the value is 50 or more, the bg-warning class will be included (these classes set different background colors). You must ensure that the names of the classes are separated by spaces.

Listing 10-10 replaces the contents of the template.html file to show the standard property binding being used to set the class property of host elements using the component's getClasses method.

Listing 10-10. Setting Class Memberships in the template.html File in the src/app Folder

```
<div class="text-white">
    <div [class]="getClasses(1)">
        The first product is {{model.getProduct(1)?.name}}.
    </div>
    <div [class]="getClasses(2)">
        The second product is {{model.getProduct(2)?.name}}
    </div>
</div>
```

When the standard property binding is used to set the class property, the result of the expression replaces any previous classes that an element belonged to, which means that it can be used only when the binding expression returns all the classes that are required, as in this example, producing the result shown in Figure 10-8.

Figure 10-8. *Setting class memberships*

Setting Individual Classes Using the Special Class Binding

The special class binding provides finer-grained control than the standard property binding and allows membership of a single class to be managed using an expression. This is useful if you want to build on the existing class memberships of an element, rather than replace them entirely. Listing 10-11 shows the use of the special class binding.

Listing 10-11. Using the Special Class Binding in the template.html File in the src/app Folder

```
<div class="text-white">
    <div [class]="getClasses(1)">
        The first product is {{model.getProduct(1)?.name}}.
    </div>
    <div class="p-2"
        [class.bg-success]="(model.getProduct(2)?.price ?? 0) < 50"
        [class.bg-info]="(model.getProduct(2)?.price ?? 0) >= 50">
            The second product is {{model.getProduct(2)?.name}}
    </div>
</div>
```

The special class binding is specified with a target that combines the term class, followed by a period, followed by the name of the class whose membership is being managed. In the listing, there are two special class bindings, which manage the membership of the bg-success and bg-info classes.

The special class binding will add the host element to the specified class if the result of the expression is *truthy* (as described in the "Understanding Truthy and Falsy" sidebar). In this case, the host element will be a member of the bg-success class if the price property is less than 50 and a member of the bg-info class if the price property is 50 or more.

These bindings act independently from one another and do not interfere with any existing classes that an element belongs to, such as the p-2 class, which Bootstrap uses to add padding around an element's content.

UNDERSTANDING TRUTHY AND FALSY

As explained in Chapter 3, JavaScript has an odd feature, where the result of an expression can be truthy or falsy, providing a pitfall for the unwary. The following results are always falsy:

- The false (boolean) value

- The 0 (number) value

- The empty string ("")

- null

- undefined

- NaN (a special number value)

All other values are truthy, which can be confusing. For example, "false" (a string whose content is the word false) is truthy. The best way to avoid confusion is to only use expressions that evaluate to the Boolean values true and false.

Setting Classes Using the ngClass Directive

The ngClass directive is a more flexible alternative to the standard and special property bindings and behaves differently based on the type of data that is returned by the expression, as described in Table 10-7.

Table 10-7. *The Expression Result Types Supported by the ngClass Directive*

Name	Description
String	The host element is added to the classes specified by the string. Multiple classes are separated by spaces.
Array	Each object in the array is the name of a class that the host element will be added to.
Object	Each property on the object is the name of one or more classes, separated by spaces. The host element will be added to the class if the value of the property is truthy.

The string and array features are useful, but it is the ability to use an object (known as a *map*) to create complex class membership policies that make the ngClass directive especially useful. Listing 10-12 shows the addition of a component method that returns a map object.

UNDERSTANDING THE NULLISH OPERATOR PRECEDENCE PITFALL

Care must be taken when using the nullish operator when it is combined with other JavaScript operations, especially when the results are combined to form strings. Here is an example of a problem statement:

```
...
return "p-2 " + (product?.price ?? 0 < 50 ? "bg-info" : "bg-warning");
...
```

The problem arises because the nullish operator has a lower precedence than the less than operator. Here is the same statement with the addition of parentheses that show how the statement is evaluated:

```
...
return "p-2 " + ((product?.price ?? (0 < 50)) ? "bg-info" : "bg-warning");
...
```

The effect is that the less than operator is applied only when the product.price property is null, and, even then, it is used only to determine if 0 is less than 50. Since JavaScript comparisons work on truthiness, the outcome from the ternary operator is always true: the product.price property will be truthy when it is not null, and the 0 < 50 expression is truthy when the product.price property is null. The effect is that the statement always returns the string "p-2 bg-info".

The solution is to use parentheses to group related terms together and avoid relying on JavaScript operator precedence, like this:

```
...
return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
...
```

This ensures that the expression evaluated by the ternary operator behaves as intended.

Listing 10-12. Returning a Class Map Object in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
```

```
@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getClasses(key: number): string {
        let product = this.model.getProduct(key);
        return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    }

    getClassMap(key: number): Object {
        let product = this.model.getProduct(key);
        return {
            "text-center bg-danger": product?.name == "Kayak",
            "bg-info": (product?.price ?? 0) < 50
        };
    }
}
```

The getClassMap method returns an object with properties whose values are one or more class names, with values based on the property values of the Product object whose key is specified as the method argument. As an example, when the key is 1, the method returns this object:

```
...
{
  "text-center bg-danger":true,
  "bg-info":false
}
...
```

The first property will assign the host element to the text-center class (which Bootstrap uses to center the text horizontally) and the bg-danger class (which sets the element's background color). The second property evaluates to false, which means that the host element will not be added to the bg-info class. It may seem odd to specify a property that doesn't result in an element being added to a class, but, as you will see shortly, the value of expressions is automatically updated to reflect changes in the application, and being able to define a map object that specifies memberships this way can be useful.

Listing 10-13 shows the getClassMap and the map objects it returns used as the expression for data bindings that target the ngClass directive.

Listing 10-13. Using the ngClass Directive in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="p-2" [ngClass]="getClassMap(1)">
      The first product is {{model.getProduct(1)?.name}}.
    </div>
    <div class="p-2" [ngClass]="getClassMap(2)">
      The second product is {{model.getProduct(2)?.name}}.
    </div>
```

```
    <div class="p-2" [ngClass]="{'bg-success': (model.getProduct(3)?.price ?? 0) < 50,
            'bg-info': (model.getProduct(3)?.price ?? 0) >= 50}">
        The third product is {{model.getProduct(3)?.name}}
    </div>
</div>
```

The first two div elements have bindings that use the getClassMap method. The third div element shows an alternative approach, which is to define the map in the template. For this element, membership of the bg-info and bg-warning classes is tied to the value of the price property of a Product object, as shown in Figure 10-9. Care should be taken with this technique because the expression contains JavaScript logic that cannot be readily tested.

Figure 10-9. *Using the ngClass directive*

Using the Style Bindings

There are three different ways in which you can use data bindings to set style properties of the host element: the standard property binding, the special style binding, and the ngStyle directive. All three are described in Table 10-8 and demonstrated in the sections that follow.

Table 10-8. *The Angular Style Bindings*

Example	Description
`<div [style.myStyle]="expr"></div>`	This is the standard property binding, which is used to set a single style property to the result of the expression.
`<div [style.myStyle.units]="expr"></div>`	This is the special style binding, which allows the units for the style value to be specified as part of the target.
`<div [ngStyle]="map"></div>`	This binding sets multiple style properties using the data in a map object.

Setting a Single Style Property

The standard property binding and the special style bindings are used to set the value of a single style property. The difference between these bindings is that the standard property binding must include the units required for the style, while the special binding allows for the units to be included in the binding target. To demonstrate the difference, Listing 10-14 adds two new properties to the component.

Listing 10-14. Adding Properties in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getClasses(key: number): string {
        let product = this.model.getProduct(key);
        return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    }

    getClassMap(key: number): Object {
        let product = this.model.getProduct(key);
        return {
            "text-center bg-danger": product?.name == "Kayak",
            "bg-info": (product?.price ?? 0) < 50
        };
    }

    fontSizeWithUnits: string = "30px";
    fontSizeWithoutUnits: string= "30";
}
```

The fontSizeWithUnits property returns a value that includes a quantity and the units that quantity is expressed in: 30 pixels. The fontSizeWithoutUnits property returns just the quantity, without any unit information. Listing 10-15 replaces the contents of the template.html file to show how these properties can be used with the standard and special bindings.

■ **Caution** Do not try to use the standard property binding to target the style property to set multiple style values. The object returned by the style property of the JavaScript object that represents the host element in the DOM is read-only. Some browsers will ignore this and allow changes to be made, but the results are unpredictable and cannot be relied on. If you want to set multiple style properties, then create a binding for each of them or use the ngStyle directive.

Listing 10-15. Using Style Bindings in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="p-2 bg-warning">
        The <span [style.fontSize]="fontSizeWithUnits">first</span>
        product is {{model.getProduct(1)?.name}}.
    </div>
    <div class="p-2 bg-info">
        The <span [style.fontSize.px]="fontSizeWithoutUnits">second</span>
        product is {{model.getProduct(2)?.name}}.
    </div>
</div>
```

The target for the binding is `style.fontSize`, which sets the size of the font used for the host element's content. The expression for this binding uses the `fontSizeWithUnits` property, whose value includes the units, px for pixels, required to set the font size.

The target for the special binding is `style.fontSize.px`, which tells Angular that the value of the expression specifies the number in pixels. This allows the binding to use the component's `fontSizeWithoutUnits` property, which doesn't include units.

■ **Tip**   You can specify style properties using the JavaScript property name format (`[style.fontSize]`) or using the CSS property name format (`[style.font-size]`).

The result of both bindings is the same, which is to set the font size of the `span` elements to 30 pixels, producing the result shown in Figure 10-10.

Figure 10-10. *Setting individual style properties*

Setting Styles Using the ngStyle Directive

The `ngStyle` directive allows multiple style properties to be set using a map object, similar to the way that the `ngClass` directive works. Listing 10-16 shows the addition of a component method that returns a map containing style settings.

Listing 10-16. Creating a Style Map Object in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getClasses(key: number): string {
        let product = this.model.getProduct(key);
        return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    }

    // getClassMap(key: number): Object {
    //     let product = this.model.getProduct(key);
    //     return {
    //         "text-center bg-danger": product?.name == "Kayak",
    //         "bg-info": (product?.price ?? 0) < 50
    //     };
    // }

    // fontSizeWithUnits: string = "30px";
    // fontSizeWithoutUnits: string= "30";

    getStyles(key: number) {
        let product = this.model.getProduct(key);
        return {
            fontSize: "30px",
            "margin.px": 100,
            color: (product?.price?? 0) > 50 ? "red" : "green"
        };
    }
}
```

The map object returned by the getStyle method shows that the ngStyle directive is able to support both of the formats that can be used with property bindings, including either the units in the value or the property name. Here is the map object that the getStyles method produces when the value of the key argument is 1:

```
...
{
  "fontSize":"30px",
  "margin.px":100,
  "color":"red"
}
...
```

Listing 10-17 shows data bindings in the template that use the ngStyle directive and whose expressions call the getStyles method.

Listing 10-17. Using the ngStyle Directive in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="p-2 bg-warning">
        The <span [ngStyle]="getStyles(1)">first</span>
        product is {{model.getProduct(1)?.name}}.
    </div>
    <div class="p-2 bg-info">
        The <span [ngStyle]="getStyles(2)">second</span>
        product is {{model.getProduct(2)?.name}}.
    </div>
</div>
```

The result is that each span element receives a tailored set of styles, based on the argument passed to the getStyles method, as shown in Figure 10-11.

Figure 10-11. *Using the ngStyle directive*

Updating the Data in the Application

When you start out with Angular, it can seem like a lot of effort to deal with the data bindings, remembering which binding is required in different situations. You might be wondering if it is worth the effort.

Bindings are worth understanding because their expressions are re-evaluated when the data they depend on changes. As an example, if you are using a string interpolation binding to display the value of a property, then the binding will automatically update when the value of the property is changed.

To provide a demonstration, I am going to jump ahead and show you how to take manual control of the updating process. This is not a technique that is required in normal Angular development, but it provides a solid demonstration of why bindings are so important. Listing 10-18 shows some changes to the component that enables the demonstration.

Listing 10-18. Preparing the Component in the component.ts File in the src/app Folder

```typescript
import { ApplicationRef, Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    constructor(ref: ApplicationRef) {
        (<any>window).appRef = ref;
        (<any>window).model = this.model;
    }

    getProductByPosition(position: number): Product {
        return this.model.getProducts()[position];
    }

    getClassesByPosition(position: number): string {
        let product = this.getProductByPosition(position);
        return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    }

    // getClasses(key: number): string {
    //     let product = this.model.getProduct(key);
    //     return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    // }

    // getStyles(key: number) {
    //     let product = this.model.getProduct(key);
    //     return {
    //         fontSize: "30px",
    //         "margin.px": 100,
    //         color: (product?.price?? 0) > 50 ? "red" : "green"
    //     };
    // }
}
```

I have imported the ApplicationRef type from the @angular/core module. When Angular performs the bootstrapping process, it creates an ApplicationRef object to represent the application. Listing 10-18 adds a constructor to the component that receives an ApplicationRef object as an argument, using the Angular dependency injection feature, which I describe in Chapter 17. Without going into detail now, declaring a constructor argument like this tells Angular that the component wants to receive the ApplicationRef object when a new instance is created.

Within the constructor, there are two statements that make a demonstration possible but would undermine many of the benefits of using TypeScript and Angular if used in a real project.

```
...
(<any>window).appRef = ref;
(<any>window).model = this.model;
...
```

These statements define variables in the global namespace and assign the ApplicationRef and Model objects to them. It is good practice to keep the global namespace as clear as possible, but exposing these objects allows them to be manipulated through the browser's JavaScript console, which is important for this example.

The other methods added to the constructor allow a Product object to be retrieved from the repository based on its position, rather than by its key, and to generate a class map that differs based on the value of the price property.

Listing 10-19 shows the corresponding changes to the template, which uses the ngClass directive to set class memberships and the string interpolation binding to display the value of the Product.name property.

Listing 10-19. Preparing for Changes in the template.html File in the src/app Folder

```
<div class="text-white">
    <div [ngClass]="getClassesByPosition(0)">
        The first product is {{getProductByPosition(0).name}}.
    </div>
    <div [ngClass]="getClassesByPosition(1)">
        The second product is {{getProductByPosition(1).name}}
    </div>
</div>
```

Save the changes to the component and template. Once the browser has reloaded the page, enter the following statement into the browser's JavaScript console and press Return:

```
model.products.shift()
```

This statement calls the shift method on the array of Product objects in the model, which removes the first item from the array and returns it. You won't see any changes yet because Angular doesn't know that the model has been modified. To tell Angular to check for changes, enter the following statement into the browser's JavaScript console and press Return:

```
appRef.tick()
```

The tick method starts the Angular change detection process, where Angular looks at the data in the application and the expressions in the data binding and processes any changes. The data bindings in the template use specific array indexes to display data, and now that an object has been removed from the model, the bindings will be updated to display new values, as shown in Figure 10-12.

Figure 10-12. *Manually updating the application model*

It is worth taking a moment to think about what happened when the change detection process ran. Angular re-evaluated the expressions on the bindings in the template and updated their values. In turn, the ngClass directive and the string interpolation binding reconfigured their host elements by changing their class memberships and displaying new content.

This happens because Angular data bindings are *live*, meaning that the relationship between the expression, the target, and the host element continues to exist after the initial content is displayed to the user and dynamically reflects changes to the application state. This effect is, I admit, much more impressive when you don't have to make changes using the JavaScript console. I explain how Angular allows the user to trigger changes using events and forms in Chapter 12.

Summary

In this chapter, I described the structure of Angular data bindings and showed you how they are used to create relationships between the data in the application and the HTML elements that are displayed to the user. I introduced the property bindings and described how two of the built-in directives—ngClass and ngStyle—are used. In the next chapter, I explain how more of the built-in directives work.

CHAPTER 11

■ ■ ■

Using the Built-in Directives

In this chapter, I describe the built-in directives that are responsible for some of the most commonly required functionality for creating web applications: selectively including content, choosing between different fragments of content, and repeating content. I also describe some limitations that Angular puts on the expressions that are used for one-way data bindings and the directives that provide them. Table 11-1 puts the built-in template directives in context.

Table 11-1. *Putting the Built-in Directives in Context*

Question	Answer
What are they?	The built-in directives described in this chapter are responsible for selectively including content, selecting between fragments of content, and repeating content for each item in an array. There are also directives for setting an element's styles and class memberships, as described in Chapter 11.
Why are they useful?	The tasks that can be performed with these directives are the most common and fundamental in web application development, and they provide the foundation for adapting the content shown to the user based on the data in the application.
How are they used?	The directives are applied to HTML elements in templates. There are examples throughout this chapter (and in the rest of the book).
Are there any pitfalls or limitations?	The syntax for using the built-in template directives requires you to remember that some of them (including `ngIf` and `ngFor`) must be prefixed with an asterisk, while others (including `ngClass`, `ngStyle`, and `ngSwitch`) must be enclosed in square brackets. I explain why this is required in the "Understanding Micro-Template Directives" sidebar, but it is easy to forget and get an unexpected result.
Are there any alternatives?	You could write your own custom directives—a process that I described in Chapters 13 and 14—but the built-in directives are well-written and comprehensively tested. For most applications, using the built-in directives is preferable, unless they cannot provide exactly the functionality that is required.

Table 11-2 summarizes the chapter.

Table 11-2. *Chapter Summary*

Problem	Solution	Listing
Conditionally displaying content based on a data binding expression	Use the ngIf directive	1–3
Choosing between different content based on the value of a data binding expression	Use the ngSwitch directive	4, 5
Generating a section of content for each object produced by a data binding expression	Use the ngFor directive	6–12
Repeating a block of content	Use the ngTemplateOutlet directive	13–14
Apply a directive without using an HTML element	Use the ng-container element	15
Preventing template errors	Avoid modifying the application state as a side effect of a data binding expression	16–20
Avoiding context errors	Ensure that data binding expressions use only the properties and methods provided by the template's component	21–23

Preparing the Example Project

This chapter relies on the example project that was created in Chapter 9 and modified in Chapter 10. To prepare for the topic of this chapter, Listing 11-1 shows changes to the component class that remove features that are no longer required and adds new methods and a property.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 11-1. Changes in the component.ts File in the src/app Folder

```
import { ApplicationRef, Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
      selector: "app",
      templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();
```

```
    constructor(ref: ApplicationRef) {
        (<any>window).appRef = ref;
        (<any>window).model = this.model;
    }

    getProductByPosition(position: number): Product {
        return this.model.getProducts()[position];
    }

    // getClassesByPosition(position: number): string {
    //     let product = this.getProductByPosition(position);
    //     return "p-2 " + ((product?.price ?? 0) < 50 ? "bg-info" : "bg-warning");
    // }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    getProductCount(): number {
        return this.getProducts().length;
    }

    targetName: string = "Kayak";
}
```

Listing 11-2 shows the contents of the template file, which displays the number of products in the data model by calling the component's new getProductCount method.

Listing 11-2. The Contents of the template.html File in the src/app Folder

```
<div class="text-white">
  <div class="bg-info p-2">
    There are {{getProductCount()}} products.
  </div>
</div>
```

Run the following command from the command line in the example folder to start the TypeScript compiler and the development HTTP server:

```
ng serve
```

Open a new browser window and navigate to `http://localhost:4200` to see the content shown in Figure 11-1.

Figure 11-1. *Running the example application*

Using the Built-in Directives

Angular comes with a set of built-in directives that provide features commonly required in web applications. Table 11-3 describes the directives that are available, which I demonstrate in the sections that follow (except for the ngClass and ngStyle directives, which are covered in Chapter 10).

Table 11-3. *The Built-in Directives*

Example	Description
`<div *ngIf="expr"></div>`	The ngIf directive is used to include an element and its content in the HTML document if the expression evaluates as true. The asterisk before the directive name indicates that this is a micro-template directive, as described in the "Understanding Micro-Template Directives" sidebar.

`<div [ngSwitch]="expr">`
`  <span *ngSwitchCase="expr">`
`  </span>`
`  <span *ngSwitchDefault></span>`
`</div>`
	The ngSwitch directive is used to choose between multiple elements to include in the HTML document based on the result of an expression, which is then compared to the result of the individual expressions defined using ngSwitchCase directives. If none of the ngSwitchCase values matches, then the element to which the ngSwitchDefault directive has been applied will be used. The asterisks before the ngSwitchCase and ngSwitchDefault directives indicate they are micro-template directives, as described in the "Understanding Micro-Template Directives" sidebar.

`<div *ngFor="#item of expr">` `</div>`	The ngFor directive is used to generate the same set of elements for each object in an array. The asterisk before the directive name indicates that this is a micro-template directive, as described in the "Understanding Micro-Template Directives" sidebar.
`<div ngClass="expr"></div>`	The ngClass directive is used to manage class membership, as described in Chapter 10.

(*continued*)

Table 11-3. (*continued*)

Example	Description
`<div ngStyle="expr"></div>`	The ngStyle directive is used to manage styles applied directly to elements (as opposed to applying styles through classes), as described in Chapter 10.
`<ng-template [ngTemplateOutlet]="myTempl"> </ngtemplate>`	The ngTemplateOutlet directive is used to repeat a block of content in a template.

Using the ngIf Directive

ngIf is the simplest of the built-in directives and is used to include a fragment of HTML in the document when an expression evaluates as true, as shown in Listing 11-3.

Listing 11-3. Using the ngIf Directive in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div *ngIf="getProductCount() > 4" class="bg-info p-2 mt-1">
        There are more than 4 products in the model
    </div>

    <div *ngIf="getProductByPosition(0).name != 'Kayak'" class="bg-info p-2 mt-1">
        The first product isn't a Kayak
    </div>
</div>
```

The ngIf directive has been applied to two div elements, with expressions that check the number of Product objects in the model and whether the name of the first Product is Kayak.

The first expression evaluates as true, which means that div element and its content will be included in the HTML document; the second expression evaluates as false, which means that the second div element will be excluded. Figure 11-2 shows the result.

■ **Note**   The ngIf directive adds and removes elements from the HTML document, rather than just showing or hiding them. Use the property or style bindings, described in Chapter 10, if you want to leave elements in place and control their visibility, either by setting the hidden element property to true or by setting the display style property to none.

Figure 11-2. *Using the ngIf directive*

UNDERSTANDING MICRO-TEMPLATE DIRECTIVES

Some directives, such as ngFor, ngIf, and the nested directives used with ngSwitch, are prefixed with an asterisk, as in *ngFor, *ngIf, and *ngSwitch. The asterisk is shorthand for using directives that rely on content provided as part of the template, known as a *micro-template*. Directives that use micro-templates are known as *structural directives*, a description that I revisit in Chapter 14 when I show you how to create them.

Listing 11-3 applied the ngIf directive to div elements, telling the directive to use the div element and its content as the micro-template for each of the objects that it processes. Behind the scenes, Angular expands the micro-template and the directive like this:

```
...
<ng-template ngIf="model.getProductCount() > 4">
    <div class="bg-info p-2 mt-1">
        There are more than 4 products in the model
    </div>
</ng-template>
...
```

You can use either syntax in your templates, but if you use the compact syntax, then you must remember to use the asterisk. I explain how to create your own micro-template directives in Chapter 12.

Like all directives, the expression used for ngIf will be re-evaluated to reflect changes in the data model. Run the following statements in the browser's JavaScript console to remove the first data object and to run the change detection process:

```
model.products.shift()
appRef.tick()
```

The effect of modifying the model is to remove the first div element because there are too few Product objects now and to add the second div element because the name property of the first Product in the array is no longer Kayak. Figure 11-3 shows the change.

Figure 11-3. *The effect of reevaluating directive expressions*

Using the ngSwitch Directive

The ngSwitch directive selects one of several elements based on the expression result, similar to a JavaScript switch statement. Listing 11-4 shows the ngSwitch directive being used to choose an element based on the number of objects in the model.

Listing 11-4. Using the ngSwitch Directive in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="bg-info p-2 mt-1" [ngSwitch]="getProductCount()">
        <span *ngSwitchCase="2">There are two products</span>
        <span *ngSwitchCase="5">There are five products</span>
        <span *ngSwitchDefault>This is the default</span>
    </div>
</div>
```

The ngSwitch directive syntax can be confusing to use. The element that the ngSwitch directive is applied to is always included in the HTML document, and the directive name isn't prefixed with an asterisk. It must be specified within square brackets, like this:

```
...
<div class="bg-info p-2 mt-1" [ngSwitch]="getProductCount()">
...
```

Each of the inner elements, which are span elements in this example, is a micro-template, and the directives that specify the target expression result are prefixed with an asterisk, like this:

```
...
<span *ngSwitchCase="5">There are five products</span>
...
```

The ngSwitchCase directive is used to specify an expression result. If the ngSwitch expression evaluates to the specified result, then that element and its contents will be included in the HTML document. If the expression doesn't evaluate to the specified result, then the element and its contents will be excluded from the HTML document.

The ngSwitchDefault directive is applied to a fallback element—equivalent to the default label in a JavaScript switch statement—which is included in the HTML document if the expression result doesn't match any of the results specified by the ngSwitchCase directives.

For the initial data in the application, the directives in Listing 11-4 produce the following HTML:

```
...
<div class="bg-info p-2 mt-1" ng-reflect-ng-switch="5">
    <span>There are five products</span>
</div>
...
```

The div element, to which the ngSwitch directive has been applied, is always included in the HTML document. For the initial data in the model, the span element whose ngSwitchCase directive has a result of 5 is also included, producing the result shown on the left of Figure 11-4.

Figure 11-4. *Using the ngSwitch directive*

The ngSwitch binding responds to changes in the data model, which you can test by executing the following statements in the browser's JavaScript console:

```
model.products.shift()
appRef.tick()
```

These statements remove the first item from the model and force Angular to run the change detection process. Neither of the results for the two ngSwitchCase directives matches the result from the getProductCount expression, so the ngSwitchDefault element is included in the HTML document, as shown on the right of Figure 11-4.

Avoiding Literal Value Problems

A common problem arises when using the ngSwitchCase directive to specify literal string values, and care must be taken to get the right result, as shown in Listing 11-5.

Listing 11-5. Component and String Literal Values in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="bg-info p-2 mt-1" [ngSwitch]="getProduct(1)?.name">
        <span *ngSwitchCase="targetName">Kayak</span>
        <span *ngSwitchCase="'Lifejacket'">Lifejacket</span>
        <span *ngSwitchDefault>Other Product</span>
    </div>
</div>
```

The values assigned to the ngSwitchCase directives are also expressions, which means you can invoke methods, perform simple inline operations, and read property values, just as you would for the basic data bindings.

As an example, this expression tells Angular to include the span element to which the directive has been applied when the result of evaluating the ngSwitch expression matches the value of the targetName property defined by the component:

```
...
<span *ngSwitchCase="targetName">Kayak</span>
...
```

If you want to compare a result to a specific string, then you must double quote it, like this:

```
...
<span *ngSwitchCase="'Lifejacket'">Lifejacket</span>
...
```

This expression tells Angular to include the span element when the value of the ngSwitch expression is equal to the literal string value Lifejacket, producing the result shown in Figure 11-5.

Figure 11-5. Using expressions and literal values with the ngSwitch directive

Using the ngFor Directive

The ngFor directive repeats a section of content for each object in an array, providing the template equivalent of a foreach loop. In Listing 11-6, I have used the ngFor directive to populate a table by generating a row for each Product object in the model.

Listing 11-6. Using the ngFor Directive in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="p-1">
        <table class="table table-sm table-bordered text-dark">
            <tr><th>Name</th><th>Category</th><th>Price</th></tr>
            <tr *ngFor="let item of getProducts()">
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td>{{item.price}}</td>
            </tr>
        </table>
    </div>
</div>
```

The expression used with the ngFor directive is more complex than for the other built-in directives, but it will start to make sense when you see how the different parts fit together. Here is the directive that I used in the example:

```
...
<tr *ngFor="let item of getProducts()">
...
```

The asterisk before the name is required because the directive is using a micro-template, as described in the "Understanding Micro-Template Directives" sidebar. This will make more sense as you become familiar with Angular, but at first, you just have to remember that this directive requires an asterisk (or, as I often do, forget until you see an error displayed in the browser's JavaScript console and *then* remember).

For the expression itself, there are two distinct parts, joined with the of keyword. The right-hand part of the expression provides the data source that will be enumerated.

```
...
<tr *ngFor="let item of getProducts()">
...
```

This example specifies the component's getProducts method as the source of data, which allows content to be for each of the Product objects in the model. The right-hand side is an expression in its own right, which means you can prepare data or perform simple manipulation operations within the template.

The left-hand side of the ngFor expression defines a *template variable*, denoted by the let keyword, which is how data is passed between elements within an Angular template.

```
...
<tr *ngFor="let item of getProducts()">
...
```

The ngFor directive assigns the variable to each object in the data source so that it is available for use by the nested elements. The local template variable in the example is called item, and it is used to access the Product object's properties for the td elements, like this:

```
...
<td>{{item.name}}</td>
...
```

Put together, the directive in the example tells Angular to enumerate the objects returned by the component's getProducts method, assign each of them to a variable called item, and then generate a tr element and its td children, evaluating the template expressions they contain.

For the example in Listing 11-6, the result is a table where the ngFor directive is used to generate table rows for each of the Product objects in the model and where each table row contains td elements that display the value of the Product object's name, category, and price properties, as shown in Figure 11-6.

Figure 11-6. *Using the ngFor directive to create table rows*

Using Other Template Variables

The most important template variable is the one that refers to the data object being processed, which is item in the previous example. But the ngFor directive supports a range of other values that can also be assigned to variables and then referred to within the nested HTML elements, as described in Table 11-4 and demonstrated in the sections that follow.

Table 11-4. *The ngFor Local Template Values*

Name	Description
index	This number value is assigned to the position of the current object.
count	This number value is assigned the number of elements in the data source.
odd	This boolean value returns true if the current object has an odd-numbered position in the data source.
even	This boolean value returns true if the current object has an even-numbered position in the data source.
first	This boolean value returns true if the current object is the first one in the data source.
last	This boolean value returns true if the current object is the last one in the data source.

Using the Index and Count Value

The index value is set to the position of the current data object and is incremented for each object in the data source. The count value is set to the number of data values in the data source.

In Listing 11-7, I have defined a table that is populated using the ngFor directive and that assigns the index and count values to local template variables, which are then used in a string interpolation binding.

Listing 11-7. Using the Index Value in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="p-1">
        <table class="table table-sm table-bordered text-dark">
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
            <tr *ngFor="let item of getProducts(); let i = index; let c = count">
                <td>{{ i + 1 }} of {{ c }}</td>
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td>{{item.price}}</td>
            </tr>
        </table>
    </div>
</div>
```

A new term is added to the ngFor expression, separated using a semicolon (the ; character). The new expressions uses the let keyword to assign the index value to a local template variable called i and the count value to a local template variable named c, like this:

```
...
<tr *ngFor="let item of getProducts(); let i = index; let c = count">
...
```

This allows the values to be accessed within the nested elements using bindings, like this:

```
...
<td>{{ i + 1 }} of {{ c }}</td>
...
```

The index value is zero-based, and adding 1 to the template variable creates a simple counter, producing the result shown in Figure 11-7.

Figure 11-7. *Using the index value*

Using the Odd and Even Values

The odd value is true when the index value for a data item is odd. Conversely, the even value is true when the index value for a data item is even. In general, you only need to use either the odd or even value since they are boolean values where odd is true when even is false, and vice versa. In Listing 11-8, the odd value is used to manage the class membership of the tr elements in the table.

Listing 11-8. Using the odd Value in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="p-1">
        <table class="table table-sm table-bordered text-dark">
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
            <tr *ngFor="let item of getProducts(); let i = index;
                    let c = count; let odd = odd"
```

```
                class="text-white" [class.bg-primary]="odd"
                [class.bg-info]="!odd">
            <td>{{ i + 1 }} of {{ c }}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
    </div>
</div>
```

I have used a semicolon and added another term to the ngFor expression that assigns the odd value to a local template variable that is also called odd.

```
...
<tr *ngFor="let item of getProducts(); let i = index;
    let c = count; let odd = odd"
    class="text-white" [class.bg-primary]="odd"
    [class.bg-info]="!odd">
...
```

This may seem redundant, but you cannot access the ngFor values directly and must use a local variable even if it has the same name. I use the class binding and the odd variable to assign alternate rows to the bg-primary and bg-info classes, which are Bootstrap background color classes that stripe the table rows, as shown in Figure 11-8.

Figure 11-8. *Using the odd value*

EXPANDING THE *NGFOR DIRECTIVE

Notice that in Listing 11-8, I can use the template variable in expressions applied to the same `tr` element that defines it. This is possible because `ngFor` is a micro-template directive—denoted by the `*` that precedes the name—and so Angular expands the HTML so that it looks like this:

```
...
<table class="table table-sm table-bordered text-dark">
    <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
    <ng-template ngFor let-item [ngForOf]="getProducts()"
            let-i="index"  let-c="count" let-odd="odd">
        <tr class="text-white" [class.bg-primary]="odd" [class.bg-info]="!odd">
            <td>{{ i + 1 }} of {{ c }}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </ng-template>
</table>
...
```

You can see that the `ng-template` element defines the variables, using the somewhat awkward `let-<name>` attributes, which are then accessed by the `tr` and `td` elements within it. As with so much in Angular, what appears to happen by magic turns out to be straightforward once you understand what is going on behind the scenes, and I explain these features in detail in Chapter 14. A good reason to use the `*ngFor` syntax is that it provides a more elegant way to express the directive expression, especially when there are multiple template variables.

Using the First and Last Values

The `first` value is `true` only for the first object in the sequence provided by the data source and is `false` for all other objects. Conversely, the `last` value is `true` only for the last object in the sequence. Listing 11-9 uses these values to treat the first and last objects differently from the others in the sequence.

Listing 11-9. Using the first and last Values in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="p-1">
        <table class="table table-sm table-bordered text-dark">
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
            <tr *ngFor="let item of getProducts(); let i = index;
                    let c = count; let odd = odd; let first = first;
                    let last = last"
```

```
                      class="text-white" [class.bg-primary]="odd"
                      [class.bg-info]="!odd"
                      [class.bg-warning]="first || last">
                <td>{{ i + 1 }} of {{ c }}</td>
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td *ngIf="!last">{{item.price}}</td>
            </tr>
        </table>
    </div>
</div>
```

The new terms in the ngFor expression assign the first and last values to template variables called first and last. These variables are then used by a class binding on the tr element, which assigns the element to the bg-warning class when either is true, and are used by the ngIf directive on one of the td elements, which will exclude the element for the last item in the data source, producing the effect shown in Figure 11-9.

Figure 11-9. *Using the first and last values*

Minimizing Element Operations

When there is a change to the data model, the ngFor directive evaluates its expression and updates the elements that represent its data objects. The update process can be expensive, especially if the data source is replaced with one that contains different objects representing the same data. Replacing the data source may seem like an odd thing to do, but it happens often in web applications, especially when the data is retrieved from a web service, like the ones I describe in Chapter 23. The same data values are represented by new objects, which presents an efficiency problem for Angular. To demonstrate the problem, I added a method to the component that replaces one of the Product objects in the data model, as shown in Listing 11-10.

Listing 11-10. Replacing an Object in the repository.model.ts File in the src/app Folder

```
import { Product } from "./product.model";
import { SimpleDataSource } from "./datasource.model";

export class Model {
    private dataSource: SimpleDataSource;
    private products: Product[];
    private locator = (p: Product, id: number | any) => p.id == id;

    constructor() {
        this.dataSource = new SimpleDataSource();
        this.products = new Array<Product>();
        this.dataSource.getData().forEach(p => this.products.push(p));
    }

    // ...methods omitted for brevity...

    swapProduct() {
        let p = this.products.shift();
        if (p != null) {
            this.products.push(new Product(p.id, p.name, p.category, p.price));
        }
    }
}
```

The swapProduct method removes the first object from the array and adds a new object that has the same values for the id, name, category, and price properties. This is an example of data values being represented by a new object.

Run the following statements using the browser's JavaScript console to modify the data model and run the change-detection process:

```
model.swapProduct()
appRef.tick()
```

When the ngFor directive examines its data source, it sees it has two operations to perform to reflect the change to the data. The first operation is to destroy the HTML elements that represent the first object in the array. The second operation is to create a new set of HTML elements to represent the new object at the end of the array.

Angular has no way of knowing that the data objects it is dealing with have the same values and that it could perform its work more efficiently by simply moving the existing elements within the HTML document.

This problem affects only two elements in this example, but the problem is much more severe when the data in the application is refreshed from an external data source, such as a web service, where all the data model objects can be replaced each time that a response is received. Since it is not aware that there have been few real changes, the ngFor directive has to destroy all of its HTML elements and create new ones, which can be an expensive and time-consuming operation.

To improve the efficiency of an update, you can define a component method that will help Angular determine when two different objects represent the same data, as shown in Listing 11-11.

Listing 11-11. Adding the Object Comparison Method in the component.ts File in the src/app Folder

```
import { ApplicationRef, Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
        selector: "app",
        templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    // ...constructor and methods omitted for brevity...

    targetName: string = "Kayak";

    getKey(index: number, product: Product) {
        return product.id;
    }
}
```

The method has to define two parameters: the position of the object in the data source and the data object. The result of the method uniquely identifies an object, and two objects are considered to be equal if they produce the same result.

Two Product objects will be considered equal if they have the same id value. Telling the ngFor expression to use the comparison method is done by adding a trackBy term to the expression, as shown in Listing 11-12.

Listing 11-12. Providing an Equality Method in the template.html File in the src/app Folder

```
<div class="text-white">
    <div class="bg-info p-2">
        There are {{getProductCount()}} products.
    </div>

    <div class="p-1">
        <table class="table table-sm table-bordered text-dark">
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
            <tr *ngFor="let item of getProducts(); let i = index;
                    let c = count; let odd = odd; let first = first;
                    let last = last; trackBy:getKey"
                    class="text-white" [class.bg-primary]="odd"
                    [class.bg-info]="!odd"
                    [class.bg-warning]="first || last">
                <td>{{ i + 1 }} of {{ c }}</td>
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td *ngIf="!last">{{item.price}}</td>
            </tr>
        </table>
    </div>
</div>
```
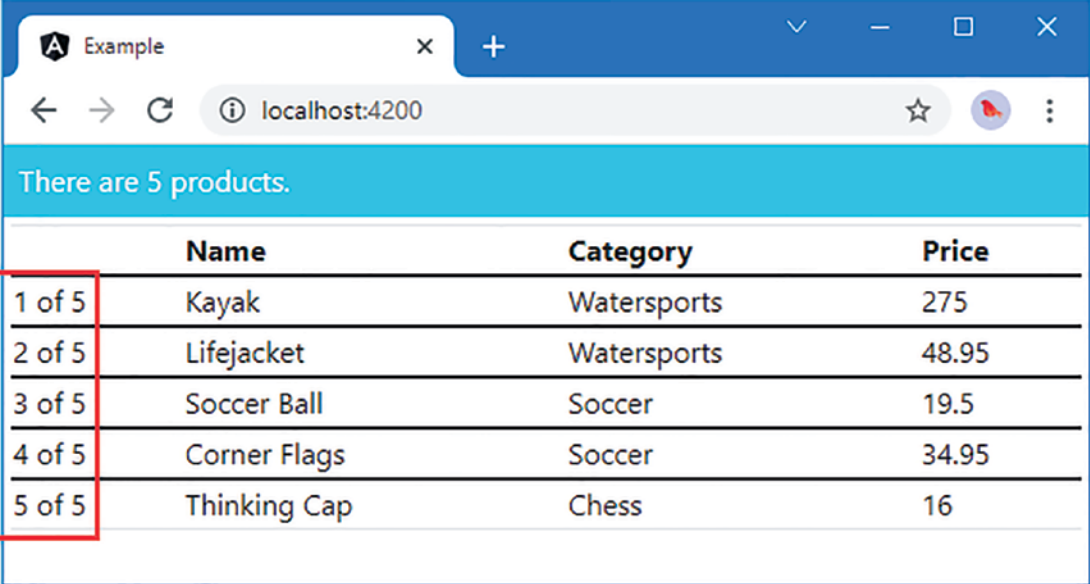

With this change, the ngFor directive will know that the Product that is removed from the array using the swapProduct method defined in Listing 11-12 is equivalent to the one that is added to the array, even though they are different objects. Rather than delete and create elements, the existing elements can be moved, which is a much simpler and quicker task to perform.

Changes can still be made to the elements—such as by the ngIf directive, which will remove one of the td elements because the new object will be the last item in the data source, but even this is faster than treating the objects separately.

TESTING THE EQUALITY METHOD

Checking whether the equality method has an effect is a little tricky. The best way that I have found requires using the browser's F12 developer tools, in this case using the Chrome browser.

Once the application has loaded, right-click the td element that contains the word *Kayak* in the browser window and select Inspect from the pop-up menu. This will open the Developer Tools window and show the Elements panel.

Click the ellipsis button (marked `...`) in the left margin and select Add Attribute from the menu. Add an id attribute with the value old. This will result in an element that looks like this:

```
<td id="old">Kayak</td>
```

Adding an id attribute makes it possible to access the object that represents the HTML element using the JavaScript console. Switch to the Console panel and enter the following statement:

```
window.old
```

When you hit Return, the browser will locate the element by its id attribute value and display the following result:

```
<td id="old">Kayak</td>
```

Now execute the following statements in the JavaScript console, hitting Return after each one:

```
model.swapProduct()
appRef.tick()
```

Once the change to the data model has been processed, executing the following statement in the JavaScript console will determine whether the td element to which the id attribute was added has been moved or destroyed:

```
window.old
```

If the element has been moved, then you will see the element shown in the console, like this:

```
<td id="old">Kayak</td>
```

If the element has been destroyed, then there won't be an element whose id attribute is old, and the browser will display the word undefined.

Using the ngTemplateOutlet Directive

The ngTemplateOutlet directive is used to repeat a block of content at a specified location, which can be useful when you need to generate the same content in different places and want to avoid duplication. Listing 11-13 replaces the contents of the template.html file to show the ngTemplateOutlet directive in use.

Listing 11-13. Replacing the Contents of the template.html File in the src/app Folder

```
<ng-template #titleTemplate>
    <h4 class="p-2 bg-success text-white">Repeated Content</h4>
  </ng-template>

  <ng-template [ngTemplateOutlet]="titleTemplate"></ng-template>

  <div class="bg-info p-2 m-2 text-white">
    There are {{getProductCount()}} products.
  </div>

<ng-template [ngTemplateOutlet]="titleTemplate"></ng-template>
```

The first step is to define the template that contains the content that you want to repeat using the directive. This is done using the ng-template element and assigning it a name using a *reference variable*, like this:

```
...
<ng-template #titleTemplate let-title="title">
  <h4 class="p-2 bg-success text-white">Repeated Content</h4>
</ng-template>
...
```

When Angular encounters the reference variable, it sets its value to the element to which it has been defined, which is the ng-template element in this case. The second step is to insert the content into the HTML document, using the ngTemplateOutlet directive, like this:

```
...
<ng-template [ngTemplateOutlet]="titleTemplate"></ng-template>
...
```

The expression is the name of the reference variable that was assigned to the content that should be inserted. The directive replaces the host element with the contents of the specified ng-template element. Neither the ng-template element that contains the repeated content nor the one that is the host element for the binding is included in the HTML document. Figure 11-10 shows how the directive has used the repeated content.

Figure 11-10. *Using the ngTemplateOutlet directive*

Providing Context Data

The ngTemplateOutlet directive can be used to provide the repeated content with a context object that can be used in data bindings defined within the ng-template element, as shown in Listing 11-14.

Listing 11-14. Providing Context Data in the template.html File in the src/app Folder

```
<ng-template #titleTemplate let-text="title">
    <h4 class="p-2 bg-success text-white">{{text}}</h4>
</ng-template>

<ng-template [ngTemplateOutlet]="titleTemplate"
    [ngTemplateOutletContext]="{title: 'Header'}">
</ng-template>

<div class="bg-info p-2 m-2 text-white">
    There are {{getProductCount()}} products.
</div>

<ng-template [ngTemplateOutlet]="titleTemplate"
  [ngTemplateOutletContext]="{title: 'Footer'}">
</ng-template>
```

To receive the context data, the ng-template element that contains the repeated content defines a let-attribute that specifies the name of a variable, similar to the expanded syntax used for the ngFor directive. The value of the expression assigns the let- variable a value, like this:

```
...
<ng-template #titleTemplate let-text="title">
...
```

The let- attribute in this example creates a variable called text, which is assigned a value by evaluating the expression title. To provide the data against which the expression is evaluated, the ng-template element to which the ngTemplateOutletContext directive has been applied provides a map object, like this:

```
...
<ng-template [ngTemplateOutlet]="titleTemplate"
        [ngTemplateOutletContext]="{title: 'Footer'}">
</ng-template>
...
```

The target of this new binding is ngTemplateOutletContext, which looks like another directive but is actually an example of an *input property*, which some directives use to receive data values and that I describe in detail in Chapter 13. The expression for the binding is a map object whose property name corresponds to the let- attribute on the other ng-template element. The result is that the repeated content can be tailored using bindings, as shown in Figure 11-11.

Figure 11-11. *Providing context data for repeated content*

Using Directives Without an HTML Element

The ng-container element can be used to apply directives without using an HTML element, which can be useful when you want to generate content without adding to the structure of the HTML document displayed by the browser, as shown in Listing 11-15, which replaces the contents of the template.html file.

Listing 11-15. Generating Content Without an Element in the template.html File in the src/app Folder

```
<div class="bg-info p-2 text-white">
    Product Names:
    <ng-container *ngFor="let item of getProducts(); let last = last">
        {{ item.name}}<ng-container *ngIf="!last">,</ng-container>
    </ng-container>
</div>
```

The ng-container element doesn't appear in the HTML displayed by the browser, which means that it can be used to generate content within elements. In this example, the ng-container element is used to apply the ngFor directive, and the content it produces contains a second ng-container element that applies the ngIf directive. The result is a string that introduces no new elements, as shown in Figure 11-12.

Figure 11-12. *Using directives without an HTML element*

Understanding One-Way Data Binding Restrictions

Although the expressions used in one-way data binding and directives look like JavaScript code, you can't use all the JavaScript—or TypeScript—language features. I explain the restrictions and the reasons for them in the sections that follow.

Using Idempotent Expressions

One-way data bindings must be *idempotent*, meaning that they can be evaluated repeatedly without changing the state of the application. To demonstrate why, I added a debugging statement to the component's getProducts method, as shown in Listing 11-16.

■ **Note**   Angular *does* support modifying the application state, but it must be done using the techniques I describe in Chapter 12.

Listing 11-16. Adding a Statement in the component.ts File in the src/app Folder

```
...
getProducts(): Product[] {
    console.log("getProducts invoked");
    return this.model.getProducts();
}
...
```

When the changes are saved and the browser reloads the page, you will see a long series of messages like these in the browser's JavaScript console:

```
...
getProducts invoked
getProducts invoked
getProducts invoked
getProducts invoked
...
```

As the messages show, Angular evaluates the binding expression several times before displaying the content in the browser. If an expression modifies the state of an application, such as removing an object from a queue, you won't get the results you expect by the time the template is displayed to the user. To avoid this problem, Angular restricts the way that expressions can be used. In Listing 11-17, I added a counter property to the component to help demonstrate.

Listing 11-17. Adding a Property in the component.ts File in the src/app Folder

```
import { ApplicationRef, Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
        selector: "app",
        templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    // ...members omitted for brevity...

    getKey(index: number, product: Product) {
        return product.id;
    }

    counter: number = 1;
}
```

In Listing 11-18, I added a binding whose expression increments the counter when it is evaluated.

Listing 11-18. Adding a Binding in the template.html File in the src/app Folder

```
<div class="bg-info p-2 text-white">
    Product Names:
    <ng-container *ngFor="let item of getProducts(); let last = last">
        {{ item.name}}<ng-container *ngIf="!last">,</ng-container>
    </ng-container>
</div>
```

```
<div class="bg-info p-2">
    Counter: {{counter = counter + 1}}
</div>
```

When the browser loads the page, you will see the following error:

```
...
Error: src/app/template.html:9:5 - error NG5002: Parser Error:
    Bindings cannot contain assignments at column 11 in
    [ Counter: {{counter = counter + 1}} ] in C:\example\src\app\template.html@8:4
 9     Counter: {{counter = counter + 1}}
       ~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
10   </div>
  ~~
  src/app/component.ts:7:15
    7  templateUrl: "template.html"
                     ~~~~~~~~~~~~~~~
    Error occurs in the template of component ProductComponent.
...
```

Angular will report an error if a data binding expression contains an operator that can be used to perform an assignment, such as =, +=, -+, ++, and --. In addition, when Angular is running in development mode, it performs an additional check to make sure that one-way data bindings have not been modified after their expressions are evaluated. To demonstrate, Listing 11-19 adds a property to the component that removes and returns a Product object from the model array.

Listing 11-19. Modifying Data in the component.ts File in the src/app Folder

```
import { ApplicationRef, Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
        selector: "app",
        templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    // ...members omitted for brevity...

    counter: number = 1;

    get nextProduct(): Product | undefined {
        return this.model.getProducts().shift();
    }
}
```

In Listing 11-20, you can see the data binding that I used to read the nextProduct property.

Listing 11-20. Binding to a Property in the template.html File in the src/app Folder

```
<div class="bg-info p-2 text-white">
    Product Names:
    <ng-container *ngFor="let item of getProducts(); let last = last">
        {{ item.name}}<ng-container *ngIf="!last">,</ng-container>
    </ng-container>
</div>
```

```
<div class="bg-info p-2 text-white">
    Next Product is {{nextProduct?.name}}
</div>
```

When the browser reloads, you will see the following error in the JavaScript console:

```
...
ERROR Error: NG0100: ExpressionChangedAfterItHasBeenCheckedError: Expression has changed
after it was checked. Previous value: 'Lifejacket'. Current value: 'Corner Flags'.. Find
more at https://angular.io/errors/NG0100
...
```

Understanding the Expression Context

When Angular evaluates an expression, it does so in the context of the template's component, which is how the template can access methods and properties without any kind of prefix, like this:

```
...
<div class="bg-info p-2 text-white">
    Next Product is {{nextProduct?.name}}
</div>
...
```

When Angular processes these expressions, the component provides the nextProduct property, which Angular incorporates into the HTML document. The component is said to provide the template's *expression context.*

The expression context means you can't access objects defined outside of the template's component, and in particular, templates can't access the global namespace. The global namespace is used to define common utilities, such as the console object, which defines the log method I have been using to write out debugging information to the browser's JavaScript console. The global namespace also includes the Math object, which provides access to some useful arithmetic methods, such as min and max.

To demonstrate this restriction, Listing 11-21 adds a string interpolation binding to the template that relies on the Math.floor method to round down a number value to the nearest integer.

Listing 11-21. Accessing the Global Namespace in the template.html File in the src/app Folder

```
<div class="bg-info p-2 text-white">
    Product Names:
    <ng-container *ngFor="let item of getProducts(); let last = last">
        {{ item.name}}<ng-container *ngIf="!last">,</ng-container>
    </ng-container>
</div>

<div class='bg-info p-2'>
    The rounded price is {{Math.floor(getProduct(1)?.price)}}
</div>
```

When Angular processes the template, it will produce the following error in the browser's JavaScript console:

```
error TS2339: Property 'Math' does not exist on type 'ProductComponent'.
```

The error message doesn't specifically mention the global namespace. Instead, Angular has tried to evaluate the expression using the component as the context and failed to find a Math property.

If you want to access functionality in the global namespace, then it must be provided by the component, acting on behalf of the template. In the case of the example, the component could just define a Math property that is assigned to the global object, but template expressions should be as clear and simple as possible, so a better approach is to define a method that provides the template with the specific functionality it requires, as shown in Listing 11-22.

Listing 11-22. Defining a Method in the component.ts File in the src/app Folder

```
import { ApplicationRef, Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
        selector: "app",
        templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    // ...members omitted for brevity...

    get nextProduct(): Product | undefined {
        return this.model.getProducts().shift();
    }

    getProductPrice(index: number): number {
        return Math.floor(this.getProduct(index)?.price ?? 0);
    }
}
```

In Listing 11-23, I have changed the data binding in the template to use the newly defined method.

Listing 11-23. Access Global Namespace Functionality in the template.html File in the src/app Folder

```
<div class="bg-info p-2 text-white">
    Product Names:
    <ng-container *ngFor="let item of getProducts(); let last = last">
        {{ item.name}}<ng-container *ngIf="!last">,</ng-container>
    </ng-container>
</div>

<div class="bg-info p-2">
    The rounded price is {{getProductPrice(2)}}
</div>
```

When Angular processes the template, it will call the getProductPrice method and indirectly take advantage of the Math object in the global namespace, producing the result shown in Figure 11-13.

Figure 11-13. *Accessing global namespace functionality*

Summary

In this chapter, I explained how to use the built-in template directives. I showed you how to select content with the ngIf and ngSwitch directives and how to repeat content using the ngFor directive. I explained why some directive names are prefixed with an asterisk and described the limitations that are placed on template expressions used with these directives and with one-way data bindings in general. In the next chapter, I describe how data bindings are used for events and form elements.

CHAPTER 12

■ ■ ■

Using Events and Forms

In this chapter, I continue describing the basic Angular functionality, focusing on features that respond to user interaction. I explain how to create event bindings and how to use two-way bindings to manage the flow of data between the model and the template. One of the main forms of user interaction in a web application is the use of HTML forms, and I explain how event bindings and two-way data bindings are used to support them and validate the content that the user provides. Table 12-1 puts events and forms in context.

Table 12-1. *Putting Event Bindings and Forms in Context*

Question	Answer
What are they?	Event bindings evaluate an expression when an event is triggered, such as a user pressing a key, moving the mouse, or submitting a form. The broader form-related features build on this foundation to create forms that are automatically validated to ensure that the user provides useful data.
Why are they useful?	These features allow the user to change the state of the application, changing or adding to the data in the model.
How are they used?	Each feature is used differently. See the examples for details.
Are there any pitfalls or limitations?	In common with all Angular bindings, the main pitfall is using the wrong kind of bracket to denote a binding. Pay close attention to the examples in this chapter and check the way you have applied bindings when you don't get the results you expect.
Are there any alternatives?	No. These features are a core part of Angular.

Table 12-2 summarizes the chapter.

Table 12-2. *Chapter Summary*

Problem	Solution	Listing
Enabling forms support	Add the @angular/forms module to the application	1–3
Responding to an event	Use an event binding	4–6
Getting details of an event	Use the $event object	7–9
Referring to elements in the template	Define template variables	10
Enabling the flow of data in both directions between the element and the component	Use a two-way data binding	11, 12
Capturing user input	Use an HTML form	13, 14
Validating the data provided by the user	Perform form validation	15–26

Preparing the Example Project

For this chapter, I will continue using the example project that I created in Chapter 9 and have been modifying in the chapters since.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Importing the Forms Module

The features demonstrated in this chapter rely on the Angular forms module, which must be imported to the Angular module, as shown in Listing 12-1.

Listing 12-1. Declaring a Dependency in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule } from "@angular/forms";

@NgModule({
  declarations: [ProductComponent],
  imports: [
    BrowserModule,
```

```
        BrowserAnimationsModule,
        FormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The `imports` property of the `NgModule` decorator specifies the dependencies of the application. Adding `FormsModule` to the list of dependencies enables the form features and makes them available for use throughout the application.

Preparing the Component and Template

Listing 12-2 removes the constructor and some of the methods from the component class and adds a new property, named `selectedProduct`.

Listing 12-2. Simplifying the Component in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    selectedProduct: string | undefined;
}
```

Listing 12-3 simplifies the component's template, leaving just a table that is populated using the `ngFor` directive.

Listing 12-3. Simplifying the Template in the template.html File in the src/app Folder

```
<div class="p-2">
  <table class="table table-sm table-bordered">
    <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
    <tr *ngFor="let item of getProducts(); let i = index">
      <td>{{i + 1}}</td>
```

```
        <td>{{item.name}}</td>
        <td>{{item.category}}</td>
        <td>{{item.price}}</td>
    </tr>
  </table>
</div>
```

To start the development server, open a command prompt, navigate to the `example` folder, and run the following command:

```
ng serve
```

Open a new browser window and navigate to `http://localhost:4200` to see the table shown in Figure 12-1.

Figure 12-1. *Running the example application*

Using the Event Binding

The *event binding* is used to respond to the events sent by the host element. Listing 12-4 demonstrates the event binding, which allows a user to interact with an Angular application.

Listing 12-4. Using the Event Binding in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{selectedProduct ?? '(None)'}}
    </div>
```

```
    <table class="table table-sm table-bordered">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        <tr *ngFor="let item of getProducts(); let i = index">
            <td (mouseover)="selectedProduct=item.name">{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
</div>
```

When you save the changes to the template, you can test the binding by moving the mouse pointer over the first column in the HTML table, which displays a series of numbers. As the mouse moves from row to row, the name of the product displayed in that row is displayed at the top of the page, as shown in Figure 12-2.

Figure 12-2. *Using an event binding*

This is a simple example, but it shows the structure of an event binding, which is illustrated in Figure 12-3.

Figure 12-3. *The anatomy of an event binding*

An event binding has these four parts:

- The *host element* is the source of events for the binding.

- The *round brackets* tell Angular that this is an event binding, which is a form of one-way binding where data flows from the element to the rest of the application.

- The *event* specifies which event the binding is for.

- The *expression* is evaluated when the event is triggered.

Looking at the binding in Listing 12-4, you can see that the host element is a td element, meaning that this is the element that will be the source of events. The binding specifies the mouseover event, which is triggered when the mouse pointer moves over the part of the screen occupied by the host element.

Unlike one-way bindings, the expressions in event bindings can make changes to the state of the application and can contain assignment operators, such as =. The expression for the binding assigns the value of the item.name property to a variable called selectedProduct. The selectedProduct variable is used in a string interpolation binding at the top of the template, like this:

```
...
<div class="bg-info text-white p-2">
    Selected Product: {{selectedProduct ?? '(None)'}}
</div>
...
```

The value displayed by the string interpolation binding is updated when the value of the selectedProduct variable is changed by the event binding. Manually starting the change detection process using the ApplicationRef.tick method is no longer required because the bindings and directives in this chapter take care of the process automatically.

WORKING WITH DOM EVENTS

If you are unfamiliar with the events that an HTML element can send, then there is a good summary available at https://developer.mozilla.org/en-US/docs/Web/Events. There are a lot of events, however, and not all of them are supported widely or consistently in all browsers. A good place to start is the "DOM Events" and "HTML DOM Events" sections of the mozilla.org page, which define the basic interactions that a user has with an element (clicking, moving the pointer, submitting forms, and so on) and that can be relied on to work in most browsers.

If you use the less common events, then you should make sure they are available and work as expected in your target browsers. The excellent http://caniuse.com provides details of which features are implemented by different browsers, but you should also perform thorough testing.

The expression that displays the selected product uses the nullish coalescing operator to ensure that the user always sees a message, even when no product is selected. A neater approach is to define a method that performs this check, as shown in Listing 12-5.

Listing 12-5. Enhancing the Component in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    selectedProduct: string | undefined;

    getSelected(product: Product): boolean {
        return product.name == this.selectedProduct;
    }
}
```

I have defined a method called getSelected that accepts a Product object and compares its name to the selectedProduct property. In Listing 12-6, the getSelected method is used by a class binding to control membership of the bg-info class, which is a Bootstrap class that assigns a background color to an element.

Listing 12-6. Setting Class Membership in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{selectedProduct ?? '(None)'}}
    </div>
    <table class="table table-sm table-bordered">
        <tr *ngFor="let item of getProducts(); let i = index"
            [class.bg-info]="getSelected(item)">
            <td (mouseover)="selectedProduct=item.name">{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
</div>
```

The result is that tr elements are added to the bg-info class when the selectedProduct property value matches the Product object used to create them, which is changed by the event binding when the mouseover event is triggered, as shown in Figure 12-4.

Figure 12-4. *Highlighting table rows through an event binding*

This example shows how user interaction drives new data into the application and starts the change-detection process, causing Angular to reevaluate the expressions used by the string interpolation and class bindings. This flow of data is what brings Angular applications to life: the bindings and directives described in Chapters 10 and 11 respond dynamically to changes in the application state, creating content generated and managed entirely within the browser.

Using Event Data

The previous example used the event binding to connect two pieces of data provided by the component: when the mouseevent is triggered, the binding's expression sets the selectedProduct property using a data value that was provided to the ngfor directive by the component's getProducts method.

The event binding can also be used to introduce new data into the application from the event itself, using details that are provided by the browser. Listing 12-7 adds an input element to the template and uses the event binding to listen for the input event, which is triggered when the content of the input element changes.

Listing 12-7. Using an Event Object in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{selectedProduct ?? '(None)'}}
    </div>
    <table class="table table-sm table-bordered">
        <tr *ngFor="let item of getProducts(); let i = index"
            [class.bg-info]="getSelected(item)">
            <td (mouseover)="selectedProduct=item.name">{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
    <div class="form-group">
        <label>Product Name</label>
        <input class="form-control"
            (input)="selectedProduct=$any($event).target.value" />
    </div>
</div>
```

When the browser triggers an event, it provides an Event object that describes it. There are different types of event objects for different categories of events (mouse events, keyboard events, form events, and so on), but all events share the three properties described in Table 12-3.

Table 12-3. *The Properties Common to All DOM Event Objects*

Name	Description
type	This property returns a string that identifies the type of event that has been triggered.
target	This property returns the object that triggered the event, which will generally be the object that represents the HTML element in the DOM.
timeStamp	This property returns a number that contains the time that the event was triggered, expressed as milliseconds since January 1, 1970.

The Event object is assigned to a template variable called $event, and the binding expression in Listing 12-7 uses this variable to access the event and its target property, like this:

```
...
<input class="form-control" (input)="selectedProduct=$any($event).target.value" />
...
```

This expression highlights a limitation of the way that data types are checked in Angular templates.

When the input element is triggered, the browser's DOM API creates an InputEvent object, and it is this object that is assigned to the $event variable. The InputEvent.target property returns an HTMLInputElement object, which is how the DOM represents the input element that triggered the event. The HTMLInputElement.value property returns the content of the input element. Putting these types together means that reading the value of $event.target.value will produce the contents of the input element that triggered the event.

Unfortunately, Angular assumes that the $event variable is always assigned an Event object, which defines the features common to all events. The Event.target property returns an InputTarget object, which defines just the methods required to set up event handlers and doesn't provide access to element-specific features.

TypeScript was designed to accommodate this sort of problem using type assertions, as I explained in Chapter 3. But Angular doesn't allow the use of the as keyword in template expressions, which means that I am unable to tell the Angular and TypeScript build tools that the $event variable contains an InputEvent object.

Angular templates do support the special $any function, which disables type checking by treating a value as the special any type:

```
...
<input class="form-control" (input)="selectedProduct=$any($event).target.value" />
...
```

By passing $event to the $any function, I can read the target.value property without causing a compiler error. Care must be taken when using the $any function because it effectively disables the compiler's type checks, which can result in errors if the specified property or methods names do not exist at runtime.

The effect of the event binding is that the selectedProduct variable is assigned the contents of the input element after each keystroke. As the user types into the input element, the text that has been entered is displayed at the top of the browser window using the string interpolation binding.

The `ngClass` binding applied to the `tr` elements sets the background color of the table rows when the `selectedProduct` property matches the name of the product they represent. And, now that the value of the `selectedProduct` property is driven by the contents of the `input` element, typing the name of a product will cause the appropriate row to be highlighted, as shown in Figure 12-5.

Figure 12-5. *Using event data*

Using different bindings to work together is at the heart of effective Angular development and makes it possible to create applications that respond immediately to user interaction and to changes in the data model.

Handling Events in the Component

Although type assertions cannot be performed in templates, they can be used in the component class, as shown in Listing 12-8, which provides a way to handle events without needing to use the any type.

Listing 12-8. Defining a Method in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
```

```
export class ProductComponent {
    model: Model = new Model();

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    selectedProduct: string | undefined;

    getSelected(product: Product): boolean {
        return product.name == this.selectedProduct;
    }

    handleInputEvent(ev: Event) {
        if (ev.target instanceof HTMLInputElement) {
            this.selectedProduct = ev.target.value
        }
    }
}
```

The handleInputEvent method receives an Event object and uses the instanceof operator to determine if the event's target property returns an HTMLInputElement. If it does, then the value property is assigned to the selectedProduct property. Listing 12-9 updates the template to use the new method to handle events.

Listing 12-9. Handling an Event with a Method in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{selectedProduct ?? '(None)'}}
    </div>
    <table class="table table-sm table-bordered">
        <tr *ngFor="let item of getProducts(); let i = index"
            [class.bg-info]="getSelected(item)">
            <td (mouseover)="selectedProduct=item.name">{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
    <div class="form-group">
        <label>Product Name</label>
        <input class="form-control" (input)="handleInputEvent($event)" />
    </div>
</div>
```

The effect is the same as the previous example, but the event is handled without disabling type checking.

313

Using Template Reference Variables

In Chapter 11, I explained how template variables are used to pass data around within a template, such as defining a variable for the current object when using the ngFor directive. *Template reference variables* are a form of template variable that can be used to refer to elements *within* the template, as shown in Listing 12-10.

Listing 12-10. Using a Template Variable in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{product.value ?? '(None)'}}
    </div>
    <table class="table table-sm table-bordered">
        <tr *ngFor="let item of getProducts(); let i = index"
            [class.bg-info]="product.value == item.name">
            <td (mouseover)="product.value = item.name ?? ''">{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
    <div class="form-group">
        <label>Product Name</label>
        <input #product class="form-control" (input)="false" />
    </div>
</div>
```

Reference variables are defined using the # character, followed by the variable name. In the listing, I defined a variable called product like this:

```
...
<input #product class="form-control" (input)="false" />
...
```

When Angular encounters a reference variable in a template, it sets its value to the element to which it has been applied. For this example, the product reference variable is assigned the object that represents the input element in the DOM, the HTMLInputElement object. Reference variables can be used by other bindings in the same template. This is demonstrated by the string interpolation binding, which also uses the product variable, like this:

```
...
Selected Product: {{product.value ?? '(None)'}}
...
```

This binding displays the value property defined by the HTMLInputElement that has been assigned to the product variable or the string (None) if the value property returns null or undefined. Template variables can also be used to change the state of the element, as shown in this binding:

```
...
<td (mouseover)="product.value = item.name ?? ''">{{i + 1}}</td>
...
```

The event binding responds to the mouseover event by setting the value property on the HTMLInputElement that has been assigned to the product variable. The result is that moving the mouse over one of the td elements in the first table column will update the contents of the input element.

There is one awkward aspect to this example, which is the binding for the input event on the input element.

```
...
<input #product class="form-control" (input)="false" />
...
```

Angular won't update the data bindings in the template when the user edits the contents of the input element unless there is an event binding on that element. Setting the binding to false gives Angular something to evaluate just so the update process will begin and distribute the current contents of the input element throughout the template. This is a quirk of stretching the role of a template reference variable a little too far and isn't something you will need to do in most real projects. Most data bindings rely on variables defined by the template's component, as demonstrated in the previous section.

FILTERING KEY EVENTS

The input event is triggered every time the content in the input element is changed. This provides an immediate and responsive set of changes, but it isn't what every application requires, especially if updating the application state involves expensive operations.

The event binding has built-in support to be more selective when binding to keyboard events, which means that updates will be performed only when a specific key is pressed. Here is a binding that responds to every keystroke:

```
...
<input #product class="form-control" (keyup)="selectedProduct=product.value" />
...
```

The keyup event is a standard DOM event, and the result is that application is updated as the user releases each key while typing in the input element. I can be more specific about which key I am interested in by specifying its name as part of the event binding, like this:

```
...
<input #product class="form-control"
    (keyup.enter)="selectedProduct=product.value" />
...
```

The key that the binding will respond to is specified by appending a period after the DOM event name, followed by the name of the key. This binding is for the Enter key, and the result is that the changes in the input element won't be pushed into the rest of the application until that key is pressed.

Using Two-Way Data Bindings

Bindings can be combined to create a two-way flow of data for a single element, allowing the HTML document to respond when the application model changes and also allowing the application to respond when the element emits an event, as shown in Listing 12-11.

Listing 12-11. Creating a Two-Way Binding in the template.html File in the src/app Folder

```html
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{ selectedProduct ?? '(None)' }}
    </div>
    <table class="table table-sm table-bordered">
        <tr *ngFor="let item of getProducts(); let i = index"
                [class.bg-info]="getSelected(item)">
            <td (mouseover)="selectedProduct=item.name">{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </table>
    <div class="form-group">
        <label>Product Name</label>
        <input class="form-control"
            (input)="selectedProduct=$any($event).target.value"
            [value]="selectedProduct ?? ''" />
    </div>
    <div class="form-group">
        <label>Product Name</label>
        <input class="form-control"
            (input)="selectedProduct=$any($event).target.value"
            [value]="selectedProduct ?? ''" />
    </div>
</div>
```

Each of the input elements has an event binding and a property binding. The event binding responds to the input event by updating the component's selectedProduct property. The property binding ties the value of the selectedProduct property to the element's value property.

The result is that the contents of the two input elements are synchronized, and editing one causes the other to be updated as well. And, since there are other bindings in the template that depend on the selectedProduct property, editing the contents of an input element also changes the data displayed by the string interpolation binding and changes the highlighted table row, as shown in Figure 12-6.

Figure 12-6. *Creating a two-way data binding*

This is an example that makes the most sense when you experiment with it in the browser. Enter some text into one of the `input` elements, and you will see the same text displayed in the other `input` element and in the `div` element whose content is managed by the string interpolation binding. If you enter the name of a product into one of the input elements, such as Kayak or Lifejacket, then you will also see the corresponding row in the table highlighted.

The event binding for the `mouseover` event still takes effect, which means as you move the mouse pointer over the first row in the table, the changes to the `selectedProduct` value will cause the `input` elements to display the product name.

Using the ngModel Directive

The `ngModel` directive is used to simplify two-way bindings so that you don't have to apply both an event and a property binding to the same element. Listing 12-12 shows how to replace the separate bindings with the `ngModel` directive.

Listing 12-12. Using the ngModel Directive in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white p-2">
        Selected Product: {{ selectedProduct ?? '(None)' }}
    </div>
    <table class="table table-sm table-bordered">
```

317

```
    <tr *ngFor="let item of getProducts(); let i = index"
            [class.bg-info]="getSelected(item)">
        <td (mouseover)="selectedProduct=item.name">{{i + 1}}</td>
        <td>{{item.name}}</td>
        <td>{{item.category}}</td>
        <td>{{item.price}}</td>
    </tr>
  </table>
  <div class="form-group">
      <label>Product Name</label>
      <input class="form-control" [(ngModel)]="selectedProduct" />
    </div>
    <div class="form-group">
      <label>Product Name</label>
      <input class="form-control" [(ngModel)]="selectedProduct" />
    </div>
</div>
```

Using the ngModel directive requires combining the syntax of the property and event bindings, as illustrated in Figure 12-7.

Figure 12-7. *The anatomy of a two-way data binding*

A combination of square and round brackets is used to denote a two-way data binding, with the round brackets placed inside the square ones: [(and)]. The Angular development team refers to this as the *banana-in-a-box* binding because that's what the brackets and parentheses look like when placed like this [()]. Well, sort of.

The target for the binding is the ngModel directive, which is included in Angular to simplify creating two-way data bindings on form elements, such as the input elements used in the example.

The expression for a two-way data binding is the name of a property, which is used to set up the individual bindings behind the scenes. When the contents of the input element change, the new content will be used to update the value of the selectedProduct property. Equally, when the value of the selectedProduct value changes, it will be used to update the contents of the element.

The ngModel directive knows the combination of events and properties that the standard HTML elements define. Behind the scenes, an event binding is applied to the input event, and a property binding is applied to the value property.

■ **Tip**   You must remember to use both brackets and parentheses with the ngModel binding. If you use just parentheses—(ngModel)—then you are setting an event binding for an event called ngModel, which doesn't exist. The result is an element that won't be updated or won't update the rest of the application. You can use the ngModel directive with just square brackets—[ngModel]—and Angular will set the initial value of the element but won't listen for events, which means that changes made by the user won't be automatically reflected in the application model.

Working with Forms

Most web applications rely on forms for receiving data from users, and the two-way ngModel binding described in the previous section provides the foundation for using forms in Angular applications. In this section, I create a form that allows new products to be created and added to the application's data model and then describe some of the more advanced form features that Angular provides.

Adding a Form to the Example Application

Listing 12-13 shows some enhancements to the component that will be used when the form is created and removes some features that are no longer required.

Listing 12-13. Enhancing the Component in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    // selectedProduct: string | undefined;

    // getSelected(product: Product): boolean {
    //     return product.name == this.selectedProduct;
    // }

    // handleInputEvent(ev: Event) {
```

```
//      if (ev.target instanceof HTMLInputElement) {
//          this.selectedProduct = ev.target.value
//      }
// }

newProduct: Product = new Product();

get jsonProduct() {
    return JSON.stringify(this.newProduct);
}

addProduct(p: Product) {
    console.log("New Product: " + this.jsonProduct);
}
}
```

The listing adds a new property called newProduct, which will be used to store the data entered into the form by the user. There is also a jsonProduct property with a getter that returns a JSON representation of the newProduct property and that will be used in the template to show the effect of the two-way bindings. (I can't create a JSON representation of an object directly in the template because the JSON object is defined in the global namespace, which, as I explained in Chapter 11, cannot be accessed directly from template expressions.)

The final addition is an addProduct method that writes out the value of the jsonProduct method to the console; this will let me demonstrate some basic form-related features before adding support for updating the data model later in the chapter.

In Listing 12-14, the template content has been replaced with a series of input elements for each of the properties defined by the Product class.

Listing 12-14. Replacing the Contents of the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white mb-2 p-2">Model Data: {{jsonProduct}}</div>
    <div class="form-group">
      <label>Name</label>
      <input class="form-control" [(ngModel)]="newProduct.name" />
    </div>
    <div class="form-group">
      <label>Category</label>
      <input class="form-control" [(ngModel)]="newProduct.category" />
    </div>
    <div class="form-group">
      <label>Price</label>
      <input class="form-control" [(ngModel)]="newProduct.price" />
    </div>
    <button class="btn btn-primary mt-2" (click)="addProduct(newProduct)">
        Create
    </button>
</div>
```

Each input element is grouped with a label and contained in a div element, which is styled using the Bootstrap form-group class. Individual input elements are assigned to the Bootstrap form-control class to manage the layout and style.

The ngModel binding has been applied to each input element to create a two-way binding with the corresponding property on the component's newProduct object, like this:

```
...
<input class="form-control" [(ngModel)]="newProduct.name" />
...
```

There is also a button element, which has a binding for the click event that calls the component's addProduct method, passing in the newProduct value as an argument.

```
...
<button class="btn btn-primary" (click)="addProduct(newProduct)">Create</button>
...
```

Finally, a string interpolation binding is used to display a JSON representation of the component's newProduct property at the top of the template, like this:

```
...
<div class="bg-info text-white mb-2 p-2">Model Data: {{jsonProduct}}</div>
...
```

The overall result, illustrated in Figure 12-8, is a set of input elements that update the properties of a Product object managed by the component, which are reflected immediately in the JSON data.

Figure 12-8. *Using the form elements to create a new object in the data model*

When the Create button is clicked, the JSON representation of the component's `newProduct` property is written to the browser's JavaScript console, producing a result like this:

```
New Product: {"name":"Running Shoes","category":"Running","price":"120.23"}
```

Adding Form Data Validation

At the moment, any data can be entered into the `input` elements in the form. Data validation is essential in web applications because users will enter a surprising range of data values, either in error or because they want to get to the end of the process as quickly as possible and enter garbage values to proceed.

Angular provides an extensible system for validating the content of form elements, based on the approach used by the HTML5 standard. Table 12-4 lists the attributes that you can add to `input` elements, each of which defines a validation rule.

Table 12-4. *The Built-in Angular Validation Attributes*

Attribute	Description
email	This attribute is used to specify a well-formatted email address.
required	This attribute is used to specify a value that must be provided.
minlength	This attribute is used to specify a minimum number of characters.
maxlength	This attribute is used to specify a maximum number of characters. This type of validation cannot be applied directly to form elements because it conflicts with the HTML5 attribute of the same name. It can be used with model-based forms, which are described later in the chapter.
min	This attribute is used to specify a minimum value.
max	This attribute is used to specify a maximum value.
pattern	This attribute is used to specify a regular expression that the value provided by the user must match.

You may be familiar with these attributes because they are part of the HTML specification, but Angular builds on these properties with some additional features. Listing 12-15 removes all but one of the `input` elements to demonstrate the process of adding validation to the form as simply as possible. (I restore the missing elements at the end of the chapter.)

Listing 12-15. Adding Form Validation in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white mb-2 p-2">Model Data: {{jsonProduct}}</div>

    <form (ngSubmit)="addProduct(newProduct)">
        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
```

```
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
        </div>
        <button class="btn btn-primary mt-2" type="submit">
            Create
        </button>
    </form>
</div>
```

Angular requires elements being validated to define the name attribute, which is used to identify the element in the validation system. Since this input element is being used to capture the value of the Product. name property, the name attribute on the element has been set to name.

This listing adds three of the validation attributes to the input element. The required attribute specifies that the user must provide a value, the minlength attribute specifies that there should be at least three characters, and the pattern attribute specifies that only alphabetic characters and spaces are allowed.

Finally, notice that a form element has been added to the template. Although you can use input elements independently, the Angular validation features work only when there is a form element present, and Angular will report an error if you add the ngControl directive to an element that is not contained in a form.

When using a form element, the convention is to use an event binding for a special event called ngSubmit like this:

```
...
<form (ngSubmit)="addProduct(newProduct)">
...
```

The ngSubmit binding handles the form element's submit event. You can achieve the same effect binding to the click event on individual button elements within the form if you prefer.

Styling Elements Using Validation Classes

Once you have saved the template changes in Listing 12-15 and the browser has reloaded the HTML, right-click the input element in the browser window and select Inspect or Inspect Element from the pop-up window. The browser will display the HTML representation of the element in the Developer Tools window, and you will see that the input element has been added to three classes, like this:

```
...
<input name="name" required="" minlength="5" pattern="^[A-Za-z ]+$"
    class="form-control ng-pristine ng-invalid ng-touched" ng-reflect-required=""
    ng-reflect-minlength="5" ng-reflect-pattern="^[A-Za-z ]+$" ng-reflect-name="name">
...
```

The classes to which an input element is assigned provide details of its validation state. There are three pairs of validation classes, which are described in Table 12-5. Elements will always be members of one class from each pair, for a total of three classes. The same classes are applied to the form element to show the overall validation status of all the elements it contains. As the status of the input element changes, the ngControl directive switches the classes automatically for both the individual elements and the form element.

Table 12-5. *The Angular Form Validation Classes*

Name	Description
ng-untouchedng-touched	An element is assigned to the ng-untouched class if it has not been visited by the user, which is typically done by tabbing through the form fields. Once the user has visited an element, it is added to the ng-touched class.
ng-pristineng-dirty	An element is assigned to the ng-pristine class if its contents have not been changed by the user and to the ng-dirty class otherwise. Once the contents have been edited, an element remains in the ng-dirty class, even if the user then returns to the previous contents.
ng-validng-invalid	An element is assigned to the ng-valid class if its contents meet the criteria defined by the validation rules that have been applied to it and to the ng-invalid class otherwise.
ng-pending	Elements are assigned to the ng-pending class when their contents are being validated asynchronously. See Chapters 21 and 22 for details.

These classes can be used to style form elements to provide the user with validation feedback. Add the styles shown in Listing 12-16 to the styles.css file in the src folder.

Listing 12-16. Defining Validation Feedback Styles in the styles.css File in the src/app Folder

```
html, body { height: 100%; }
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }
```

```
input.ng-dirty.ng-invalid { border: 2px solid #ff0000 }
input.ng-dirty.ng-valid { border: 2px solid #6bc502 }
```

These styles set green and red borders for input elements whose content has been edited and is valid (and so belong to both the ng-dirty and ng-valid classes) and whose content is invalid (and so belong to the ng-dirty and ng-invalid classes). Using the ng-dirty class means that the appearance of the elements won't be changed until after the user has entered some content.

Angular validates the contents and changes the class memberships of the input elements after each keystroke or focus change. The browser detects the changes to the elements and applies the styles dynamically, which provides users with validation feedback as they enter data into the form, as shown in Figure 12-9.

Figure 12-9. *Providing validation feedback*

As I start to type, the input element is shown as invalid because there are not enough characters to satisfy the minlength attribute. Once there are five characters, the border is green, indicating that the data is valid. When I type the 2 character, the border turns red again because the pattern attribute is set to allow only letters and spaces.

■ **Tip** If you look at the JSON data at the top of the page in Figure 12-9, you will see that the data bindings are still being updated, even when the data values are not valid. Validation runs alongside data bindings, and you should not act on form data without checking that the overall form is valid, as described in the "Validating the Entire Form" section.

Displaying Field-Level Validation Messages

Using colors to provide validation feedback tells the user that something is wrong but doesn't provide any indication of what the user should do about it. The ngModel directive provides access to the validation status of the elements it is applied to, which can be used to display guidance to the user. Listing 12-17 adds validation messages for each of the attributes applied to the input element using the support provided by the ngModel directive.

Listing 12-17. Adding Validation Messages in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white mb-2 p-2">Model Data: {{jsonProduct}}</div>

    <form (ngSubmit)="addProduct(newProduct)">
        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
                #name="ngModel"
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
        <ul class="text-danger list-unstyled mt-1"
                *ngIf="name.dirty && name.invalid">
            <li *ngIf="name.errors?.['required']">
                You must enter a product name
            </li>
            <li *ngIf="name.errors?.['pattern']">
                Product names can only contain letters and spaces
            </li>
            <li *ngIf="name.errors?.['minlength']">
                Product names must be at least
                {{ name.errors?.['minlength'].requiredLength }} characters
            </li>
        </ul>
        </div>
        <button class="btn btn-primary mt-2" type="submit">
```

```
            Create
        </button>
    </form>
</div>
```

To get validation working, I have to create a template reference variable to access the validation state in expressions, which I do like this:

```
...
<input class="form-control" name="name" [(ngModel)]="newProduct.name"
    #name="ngModel" required minlength="5" pattern="^[A-Za-z ]+$"/>
...
```

I create a template reference variable called name and set its value to ngModel. This use of an ngModel value is a little confusing: it is a feature provided by the ngModel directive to give access to the validation status. This will make more sense once you have read Chapters 13 and 16, in which I explain how to create custom directives and you see how they provide access to their features. For this chapter, it is enough to know that to display validation messages, you need to create a template reference variable and assign it ngModel to access the validation data for the input element. The object that is assigned to the template reference variable defines the properties that are described in Table 12-6. All of the properties described in the table are nullable.

Table 12-6. *The Validation Object Properties*

Name	Description
path	This property returns the name of the element.
valid	This property returns true if the element's contents are valid and false otherwise.
invalid	This property returns true if the element's contents are invalid and false otherwise.
pristine	This property returns true if the element's contents have not been changed.
dirty	This property returns true if the element's contents have been changed.
touched	This property returns true if the user has visited the element.
untouched	This property returns true if the user has not visited the element.
errors	This property returns a ValidationErrors object whose properties correspond to each attribute for which there is a validation error.
value	This property returns the value of the element, which is used when defining custom validation rules, as described in the "Creating Custom Form Validators" section.

Listing 12-17 displays the validation messages in a list. The list should be shown only if there is at least one validation error, so I applied the ngIf directive to the ul element, with an expression that uses the dirty and invalid properties, like this:

```
...
<ul class="text-danger list-unstyled mt-1" *ngIf="name.dirty && name.invalid">
...
```

Within the ul element, there is an li element that corresponds to each validation error that can occur. Each li element has an ngIf directive that uses the errors property described in Table 12-6, like this:

```
...
<li *ngIf="name.errors?.['required']">
    You must enter a product name
</li>
...
```

The errors.[required] property will be defined only if the element's contents have failed the required validation check, which ties the visibility of the li element to the outcome of that validation check.

Each property defined by the errors object returns an object whose properties provide details of why the content has failed the validation check for its attribute, which can be used to make the validation messages more helpful to the user. Table 12-7 describes the error properties provided for each attribute.

Table 12-7. *The Angular Form Validation Error Description Properties*

Name	Description
email	This property returns true if the email attribute has been applied to the input element. This is not especially useful because this can be deduced from the fact that the property exists.
required	This property returns true if the required attribute has been applied to the input element. This is not especially useful because this can be deduced from the fact that the property exists.
minlength.requiredLength	This property returns the number of characters required to satisfy the minlength attribute.
minlength.actualLength	This property returns the number of characters entered by the user.
maxlength.requiredLength	This property returns the number of characters required to satisfy the maxlength attribute.
maxlength.actualLength	This property returns the number of characters entered by the user.
min.actual	This property returns the value entered by the user.
min.min	This property returns the minimum value required to satisfy the min attribute.
max.actual	This property returns the value entered by the user.
max.max	This property returns the minimum value required to satisfy the max attribute.
pattern.requiredPattern	This property returns the regular expression that has been specified using the pattern attribute.
pattern.actualValue	This property returns the contents of the element.

These properties are not displayed directly to the user, who is unlikely to understand an error message that includes a regular expression, although they can be useful during development to figure out validation problems. The exception is the `minlength.requiredLength` property, which can be useful for avoiding the duplication of the value assigned to the `minlength` attribute on the element, like this:

```
...
<li *ngIf="name.errors?.['minlength']">
    Product names must be at least
    {{ name.errors?.['minlength'].requiredLength }} characters
</li>
...
```

The overall result is a set of validation messages that are shown as soon as the user starts editing the `input` element and that change to reflect each new keystroke, as illustrated in Figure 12-10.

Figure 12-10. *Displaying validation messages*

Using the Component to Display Validation Messages

Including separate elements for all possible validation errors quickly becomes verbose in complex forms. A better approach is to add logic to the component to prepare the validation messages in a method, which can then be displayed to the user through the `ngFor` directive in the template. Listing 12-18 shows the addition of a component method that accepts the validation state for an `input` element and produces an array of validation messages.

Listing 12-18. Generating Validation Messages in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
import { NgModel, ValidationErrors } from "@angular/forms";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    newProduct: Product = new Product();

    get jsonProduct() {
        return JSON.stringify(this.newProduct);
    }

    addProduct(p: Product) {
        console.log("New Product: " + this.jsonProduct);
    }

    getMessages(errs : ValidationErrors | null, name: string) : string[] {
        let messages: string[] = [];
        for (let errorName in errs) {
            switch (errorName) {
                case "required":
                    messages.push(`You must enter a ${name}`);
                    break;
                case "minlength":
                    messages.push(`A ${name} must be at least
                        ${errs['minlength'].requiredLength}
                        characters`);
                    break;
                case "pattern":
                    messages.push(`The ${name} contains
                        illegal characters`);
                    break;
            }
        }
        return messages;
    }
```

```
    getValidationMessages(state: NgModel, thingName?: string) {
        let thing: string = state.path?.[0] ?? thingName;
        return this.getMessages(state.errors, thing)
    }
}
```

The getValidationMessages and getMessages methods use the properties described in Table 12-6 to produce validation messages for each error, returning them in a string array. To make this code as widely applicable as possible, the method accepts a value that describes the data item that an input element is intended to collect from the user, which is then used to generate error messages, like this:

```
...
messages.push(`You must enter a ${name}`);
...
```

This is an example of the JavaScript string interpolation feature, which allows strings to be defined like templates, without having to use the + operator to include data values. Note that the template string is denoted with backtick characters (the ` character and not the regular JavaScript ' character). The getValidationMessages method defaults to using the path property as the descriptive string if an argument isn't received when the method is invoked, like this:

```
...
let thing: string = state.path?.[0] ?? thingName;
...
```

Listing 12-19 shows how the getValidationMessages can be used in the template to generate validation error messages for the user without needing to define separate elements and bindings for each one.

Listing 12-19. Getting Validation Messages in the template.html File in the src/app Folder

```
<div class="p-2">
    <div class="bg-info text-white mb-2 p-2">Model Data: {{jsonProduct}}</div>

    <form (ngSubmit)="addProduct(newProduct)">
        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
                #name="ngModel"
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
        <ul class="text-danger list-unstyled mt-1"
                *ngIf="name.dirty && name.invalid">
            <li *ngFor="let error of getValidationMessages(name)">
                {{error}}
            </li>
        </ul>
        </div>
```

```
        <button class="btn btn-primary mt-2" type="submit">
            Create
        </button>
    </form>
</div>
```

There is no visual change, but the same method can be used to produce validation messages for multiple elements, which results in a simpler template that is easier to read and maintain.

Validating the Entire Form

Displaying validation error messages for individual fields is useful because it helps emphasize where problems need to be fixed. But it can also be useful to validate the entire form. Care must be taken not to overwhelm the user with error messages until they try to submit the form, at which point a summary of any problems can be useful. In preparation, Listing 12-20 adds two new members to the component.

Listing 12-20. Enhancing the Component in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
import { NgModel, ValidationErrors, NgForm } from "@angular/forms";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    // ...other methods omitted for brevity...

    formSubmitted: boolean = false;

    submitForm(form: NgForm) {
        this.formSubmitted = true;
        if (form.valid) {
            this.addProduct(this.newProduct);
            this.newProduct = new Product();
            form.resetForm();
            this.formSubmitted = false;
        }
    }
}
```

The formSubmitted property will be used to indicate whether the form has been submitted and will be used to prevent validation of the entire form until the user has tried to submit.

The submitForm method will be invoked when the user submits the form and receives an NgForm object as its argument. This object represents the form and defines the set of validation properties; these properties are used to describe the overall validation status of the form so that, for example, the invalid property will be true if there are validation errors on any of the elements contained by the form. In addition to the

validation property, NgForm provides the resetForm method, which resets the validation status of the form and returns it to its original and pristine state.

The effect is that the whole form will be validated when the user performs a submit, and if there are no validation errors, a new object will be added to the data model before the form is reset so that it can be used again. Listing 12-21 shows the changes required to the template to take advantage of these new features and implement form-wide validation.

Listing 12-21. Performing Form-Wide Validation in the template.html File in the src/app Folder

```
<div class="p-2">
    <form #form="ngForm" (ngSubmit)="submitForm(form)">

        <div class="bg-danger text-white p-2 mb-2"
                *ngIf="formSubmitted && form.invalid">
            There are problems with the form
        </div>

        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
                #name="ngModel"
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
            <ul class="text-danger list-unstyled mt-1"
                    *ngIf="(formSubmitted || name.dirty) && name.invalid">
                <li *ngFor="let error of getValidationMessages(name)">
                    {{error}}
                </li>
            </ul>
        </div>
        <button class="btn btn-primary mt-2" type="submit">
            Create
        </button>
    </form>
</div>
```

The form element now defines a reference variable called form, which has been assigned to ngForm. This is how the ngForm directive provides access to its functionality, through a process that I describe in Chapter 13. For now, however, it is important to know that the validation information for the entire form can be accessed through the form reference variable.

The listing also changes the expression for the ngSubmit binding so that it calls the submitForm method defined by the controller, passing in the template variable, like this:

```
...
<form ngForm="productForm" #form="ngForm" (ngSubmit)="submitForm(form)">
...
```

It is this object that is received as the argument of the submitForm method and that is used to check the validation status of the form and to reset the form so that it can be used again.

Listing 12-21 also adds a div element that uses the formSubmitted property from the component along with the valid property (provided by the form template variable) to show a warning message when the form contains invalid data, but only after the form has been submitted.

In addition, the ngIf binding has been updated to display the field-level validation messages so that they will be shown when the form has been submitted, even if the element itself hasn't been edited. The result is a validation summary that is shown only when the user submits the form with invalid data, as illustrated by Figure 12-11.

Figure 12-11. *Displaying a validation summary message*

Displaying Summary Validation Messages

In a complex form, it can be helpful to provide the user with a summary of all the validation errors that have to be resolved. The NgForm object assigned to the form template reference variable provides access to the individual elements through a property named controls. This property returns an object that has properties for each of the individual elements in the form. For example, there is a name property that represents the input element in the example, which is assigned an object that represents that element and defines the same validation properties that are available for individual elements. In Listing 12-22, I have added a method to the component that receives the object assigned to the form element's template reference variables and uses its controls property to generate a list of error messages for the entire form.

Listing 12-22. Generating Form-Wide Validation Messages in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
import { NgModel, ValidationErrors, NgForm } from "@angular/forms";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
```

```
export class ProductComponent {
    model: Model = new Model();

    // ...other methods omitted for brevity...

    getFormValidationMessages(form: NgForm): string[] {
        let messages: string[] = [];
        Object.keys(form.controls).forEach(k => {
            this.getMessages(form.controls[k].errors, k)
                .forEach(m => messages.push(m));
        });
        return messages;
    }
}
```

The getFormValidationMessages method builds its list of messages by calling the getMessages method for each control in the form. The Object.keys method creates an array from the properties defined by the object returned by the controls property, which is enumerated using the forEach method.

In Listing 12-23, I have used this method to include the individual messages at the top of the form, which will be visible once the user clicks the Create button.

Listing 12-23. Displaying Form-Wide Validation Messages in the template.html File in the src/app Folder

```
<div class="p-2">
    <form #form="ngForm" (ngSubmit)="submitForm(form)">

        <div class="bg-danger text-white p-2 mb-2"
                *ngIf="formSubmitted && form.invalid">
            There are problems with the form
            <ul>
                <li *ngFor="let error of getFormValidationMessages(form)">
                  {{error}}
                </li>
            </ul>
        </div>

        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
                #name="ngModel"
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
            <ul class="text-danger list-unstyled mt-1"
                    *ngIf="(formSubmitted || name.dirty) && name.invalid">
                <li *ngFor="let error of getValidationMessages(name)">
                    {{error}}
                </li>
            </ul>
        </div>
```

```
        <button class="btn btn-primary mt-2" type="submit">
            Create
        </button>
    </form>
</div>
```

The result is that validation messages are displayed alongside the input element and collected at the top of the form once it has been submitted, as shown in Figure 12-12.

Figure 12-12. *Displaying an overall validation summary*

Disabling the Submit Button

The next step is to disable the button once the user has submitted the form, preventing the user from clicking it again until all the validation errors have been resolved. This is a commonly used technique even though it has little bearing on the example application, which won't accept the data from the form while it contains invalid values but provides useful reinforcement to the user that they cannot proceed until the validation problems have been resolved. In Listing 12-24, I have used the property binding on the button element.

Listing 12-24. Disabling the Button in the template.html File in the src/app Folder

```html
<div class="p-2">
    <form #form="ngForm" (ngSubmit)="submitForm(form)">

        <div class="bg-danger text-white p-2 mb-2"
                *ngIf="formSubmitted && form.invalid">
            There are problems with the form
            <ul>
                <li *ngFor="let error of getFormValidationMessages(form)">
                    {{error}}
                </li>
            </ul>
        </div>

        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
                #name="ngModel"
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
            <ul class="text-danger list-unstyled mt-1"
                    *ngIf="(formSubmitted || name.dirty) && name.invalid">
                <li *ngFor="let error of getValidationMessages(name)">
                    {{error}}
                </li>
            </ul>
        </div>
        <button class="btn btn-primary mt-2" type="submit"
            [disabled]="formSubmitted && form.invalid"
            [class.btn-secondary]="formSubmitted && form.invalid">
                Create
        </button>
    </form>
</div>
```

For extra emphasis, I used the class binding to add the `button` element to the `btn-secondary` class when the form has been submitted and has invalid data. This class applies a Bootstrap CSS style, as shown in Figure 12-13.

Figure 12-13. *Disabling the submit button*

Completing the Form

Now that the validation features are done, I can complete the form. Listing 12-25 restores the input elements for the category and price fields, which I removed earlier in the chapter. I also removed the validation messages for the name element so that only the form-wide error messages are displayed.

Listing 12-25. Adding Form Elements in the template.html File in the src/app Folder

```
<div class="p-2">
    <form #form="ngForm" (ngSubmit)="submitForm(form)">

        <div class="bg-danger text-white p-2 mb-2"
                *ngIf="formSubmitted && form.invalid">
            There are problems with the form
            <ul>
                <li *ngFor="let error of getFormValidationMessages(form)">
                  {{error}}
                </li>
             </ul>
        </div>

        <div class="form-group">
            <label>Name</label>
            <input class="form-control"
                name="name"
                [(ngModel)]="newProduct.name"
                #name="ngModel"
                required
                minlength="5"
                pattern="^[A-Za-z ]+$" />
        </div>
```

337

```
    <div class="form-group">
        <label>Category</label>
        <input class="form-control" name="category"
            [(ngModel)]="newProduct.category" required />
    </div>

    <div class="form-group">
        <label>Price</label>
        <input class="form-control" name="price"
            [(ngModel)]="newProduct.price" required type="number"/>
    </div>

    <button class="btn btn-primary mt-2" type="submit"
        [disabled]="formSubmitted && form.invalid"
        [class.btn-secondary]="formSubmitted && form.invalid">
        Create
    </button>
</form>
</div>
```

The final change is to adjust the selectors for the CSS styles that indicate valid and invalid input elements, as shown in Listing 12-26.

Listing 12-26. Adjusting the CSS Selectors in the styles.css File in the src Folder

```
html, body { height: 100%; }
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

form.ng-submitted input.ng-invalid { border: 2px solid #ff0000 }
form.ng-submitted input.ng-valid { border: 2px solid #6bc502 }
```

In addition to the classes described in Table 12-5, Angular adds form elements to the ng-submitted class when they have been submitted. This allows me to select elements that are invalid once the form has been submitted, regardless of whether the user has edited the elements.

Save the changes and click the Create button; you will see the validation messages and CSS styles shown in Figure 12-14. As you address each validation error, the input elements will turn green, and you will be able to submit the form when there are no validation errors remaining.

Figure 12-14. *Finishing the form*

Summary

In this chapter, I introduced the way that Angular supports user interaction using events and forms. I explained how to create event bindings, how to create two-way bindings, and how they can be simplified using the ngModel directive. I also described the support that Angular provides for managing and validating HTML forms. In the next chapter, I explain how to create custom directives.

CHAPTER 13

▪ ▪ ▪ ▪

Creating Attribute Directives

In this chapter, I describe how custom directives can be used to supplement the functionality provided by the built-in ones of Angular. The focus of this chapter is *attribute directives*, which are the simplest type that can be created and that change the appearance or behavior of a single element. In Chapter 14, I explain how to create *structural directives*, which are used to change the layout of the HTML document. Components are also a type of directive, and I explain how they work in Chapter 15.

Throughout these chapters, I describe how custom directives work by re-creating the features provided by some of the built-in directives. This isn't something you would typically do in a real project, but it provides a useful baseline against which the process can be explained. Table 13-1 puts attribute directives into context.

Table 13-1. *Putting Attribute Directives in Context*

Question	Answer
What are they?	Attribute directives are classes that can modify the behavior or appearance of the element they are applied to. The style and class bindings described in Chapter 10 are examples of attribute directives.
Why are they useful?	The built-in directives cover the most common tasks required in web application development but don't deal with every situation. Custom directives allow application-specific features to be defined.
How are they used?	Attribute directives are classes to which the `@Directive` decorator has been applied. They are enabled in the `directives` property of the component responsible for a template and applied using a CSS selector.
Are there any pitfalls or limitations?	The main pitfall when creating a custom directive is the temptation to write code to perform tasks that can be better handled using directive features such as input and output properties and host element bindings.
Are there any alternatives?	Angular supports two other types of directive—structural directives and components—that may be more suitable for a given task. You can sometimes combine the built-in directives to create a specific effect if you prefer to avoid writing custom code, although the result can be brittle and lead to complex HTML that is hard to read and maintain.

Table 13-2 summarizes the chapter.

Table 13-2. *Chapter Summary*

Problem	Solution	Listing
Creating an attribute directive	Apply @Directive to a class	1–5
Accessing host element attribute values	Apply the @Attribute decorator to a constructor parameter	6–9
Creating a data-bound input property	Apply the @Input decorator to a class property	10–11
Receiving a notification when a data-bound input property value changes	Implement the ngOnChanges method	12
Defining an event	Apply the @Output decorator	13, 14
Creating a property binding or event binding on the host element	Apply the @HostBinding or @HostListener decorator	15–19
Exporting a directive's functionality for use in the template	Use the exportAs property of the @Directive decorator	20, 21

Preparing the Example Project

As I have been doing throughout this part of the book, I will continue using the example project from the previous chapter. To prepare for this chapter, I have redefined the form so that it updates the component's newProduct property rather than the model-based form used in Chapter 12, as shown in Listing 13-1.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 13-1. Replacing the Contents of the template.html File in the src/app Folder

```
<div class="row p-2">
  <div class="col-6">
    <form class="m-2" (ngSubmit)="submitForm()">
      <div class="form-group">
          <label>Name</label>
          <input class="form-control" name="name" [(ngModel)]="newProduct.name" />
      </div>
      <div class="form-group">
        <label>Category</label>
        <input class="form-control" name="category"
            [(ngModel)]="newProduct.category" />
      </div>
```

```
    <div class="form-group">
      <label>Price</label>
      <input class="form-control" name="price" [(ngModel)]="newProduct.price" />
    </div>
    <button class="btn btn-primary" type="submit">Create</button>
  </form>
</div>

<div class="col">
  <table class="table table-sm table-bordered table-striped">
    <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
    <tr *ngFor="let item of getProducts(); let i = index">
      <td>{{i + 1}}</td>
      <td>{{item.name}}</td>
      <td>{{item.category}}</td>
      <td>{{item.price}}</td>
    </tr>
  </table>
</div>
</div>
```

This listing uses the Bootstrap grid layout to position the form and the table side by side. Listing 13-2 simplifies the component and updates the component's addProduct method so that it adds a new object to the data model.

Listing 13-2. Replacing the Contents of the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    newProduct: Product = new Product();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
```

343

```
    submitForm() {
        this.addProduct(this.newProduct);
    }
}
```

To start the application, navigate to the example project folder and run the following command:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the form in Figure 13-1. A new item will be added to the data model and displayed in the table when you submit the form. When the form is submitted, the CSS validation styles will be displayed because Angular adds form elements to the validation classes, even when no validation is performed.

Figure 13-1. *Running the example application*

Creating a Simple Attribute Directive

The best place to start is to jump in and create a directive to see how they work. I added a file called attr. directive.ts to the src/app folder with the code shown in Listing 13-3. The name of the file indicates that it contains a directive. I set the first part of the filename to attr to indicate that this is an example of an attribute directive.

Listing 13-3. The Contents of the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef } from "@angular/core";

@Directive({
    selector: "[pa-attr]",
})
export class PaAttrDirective {

    constructor(element: ElementRef) {
        element.nativeElement.classList.add("table-success", "fw-bold");
    }
}
```

Directives are classes to which the @Directive decorator has been applied. The decorator requires the selector property, which is used to specify how the directive is applied to elements, expressed using a standard CSS style selector. The selector I used is [pa-attr], which will match any element that has an attribute called pa-attr, regardless of the element type or the value assigned to the attribute.

Custom directives are given a distinctive prefix so they can be easily recognized. The prefix can be anything meaningful to your application. I have chosen the prefix Pa for my directive, reflecting the title of this book, and this prefix is used in the attribute specified by the selector decorator property and the name of the attribute class. The case of the prefix is changed to reflect its use so that an initial lowercase character is used for the selector attribute name (pa-attr) and an initial uppercase character is used in the name of the directive class (PaAttrDirective).

■ **Note**   The prefix Ng/ng is reserved for use for built-in Angular features and should not be used.

The directive constructor defines a single ElementRef parameter, which Angular provides when it creates a new instance of the directive and which represents the host element. The ElementRef class defines a single property, nativeElement, which returns the object used by the browser to represent the element in the Domain Object Model. This object provides access to the methods and properties that manipulate the element and its contents, including the classList property, which can be used to manage the class membership of the element, like this:

```
...
element.nativeElement.classList.add("table-success", "fw-bold");
...
```

To summarize, the PaAttrDirective class is a directive that is applied to elements that have a pa-attr attribute and adds those elements to the table-success and fw-bold classes, which the Bootstrap CSS library uses to assign background color and font weight to elements.

Applying a Custom Directive

There are two steps to apply a custom directive. The first is to update the template so that there are one or more elements that match the selector that the directive uses. In the case of the example directive, this means adding the pa-attr attribute to an element, as shown in Listing 13-4.

345

Listing 13-4. Adding a Directive Attribute in the template.html File in the src/app Folder

```
...
<div class="col">
    <table class="table table-bordered table-striped">
        <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
    </thead>
    <tbody>
        <tr *ngFor="let item of getProducts(); let i = index" pa-attr>
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
        </tr>
    </tbody>
    </table>
</div>
...
```

The directive's selector matches any element that has the `pa-attr` attribute, regardless of whether a value has been assigned to it or what that value is. The second step to applying a directive is to change the configuration of the Angular module, as shown in Listing 13-5.

Listing 13-5. Configuring the Component in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";

@NgModule({
  declarations: [ProductComponent, PaAttrDirective],
  imports: [
    BrowserModule,
    BrowserAnimationsModule,
    FormsModule, ReactiveFormsModule
  ],
  providers: [],
  bootstrap: [ProductComponent]
})
export class AppModule { }
```

The `declarations` property of the `NgModule` decorator declares the directives and components that the application will use. Don't worry if the relationship and differences between directives and components seem muddled at the moment; this will all become clear in Chapter 15.

Once both steps have been completed, the effect is that the pa-attr attribute applied to the tr element in the template will trigger the custom directive, which uses the DOM API to add the element to the bg-success and text-white classes. Since the tr element is part of the micro-template used by the ngFor directive, all the rows in the table are affected, as shown in Figure 13-2. (You may have to restart the Angular development tools to see the change.)

Figure 13-2. *Applying a custom directive*

Accessing Application Data in a Directive

The example in the previous section shows the basic structure of a directive, but it doesn't do anything that couldn't be performed just by using a class property binding on the tr element. Directives become useful when they can interact with the host element and with the rest of the application.

Reading Host Element Attributes

The simplest way to make a directive more useful is to configure it using attributes applied to the host element, which allows each instance of the directive to be provided with its own configuration information and to adapt its behavior accordingly.

As an example, Listing 13-6 applies the directive to some of the td elements in the template table and adds an attribute that specifies the class that the host element should be added to. The directive's selector means that it will match any element that has the pa-attr attribute, regardless of the tag type, and will work as well on td elements as it does on tr elements. This listing also removes the pa-attr attribute from the tr element.

347

Listing 13-6. Adding Attributes in the template.html File in the src/app Folder

```
...
<tbody>
    <tr *ngFor="let item of getProducts(); let i = index">
        <td>{{i + 1}}</td>
        <td>{{item.name}}</td>
        <td pa-attr pa-attr-class="table-warning">{{item.category}}</td>
        <td pa-attr pa-attr-class="table-info">{{item.price}}</td>
    </tr>
</tbody>
...
```

The pa-attr attribute has been applied to two of the td elements, along with a new attribute called pa-attr-class, which has been used to specify the class to which the directive should add the host element. Listing 13-7 shows the changes required to the directive to get the value of the pa-attr-class attribute and use it to change the element.

Listing 13-7. Reading an Attribute in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Attribute } from "@angular/core";

@Directive({
    selector: "[pa-attr]",
})
export class PaAttrDirective {

    constructor(element: ElementRef, @Attribute("pa-attr-class") bgClass: string) {
        element.nativeElement.classList.add(bgClass || "table-success", "fw-bold");
    }
}
```

To receive the value of the pa-attr-class attribute, I added a new constructor parameter called bgClass to which the @Attribute decorator has been applied. This decorator is defined in the @angular/core module, and it specifies the name of the attribute that should be used to provide a value for the constructor parameter when a new instance of the directive class is created. Angular creates a new instance of the decorator for each element that matches the selector and uses that element's attributes to provide the values for the directive constructor arguments that have been decorated with @Attribute.

Within the constructor, the value of the attribute is passed to the classList.add method, with a default value that allows the directive to be applied to elements that have the pa-attr attribute but not the pa-attr-class attribute. Notice that I used the null coalescing operator (||) and not the nullish operator (??) in Listing 13-7. I want the fallback value to be used if an element defines the pa-attr-class attribute but does not assign it a value, in which case the bgClass parameter will be set to the empty string, which the || operator evaluates as false.

The result is that the class to which elements are added can now be specified using an attribute, producing the result shown in Figure 13-3.

Figure 13-3. *Configuring a directive using a host element attribute*

Using a Single Host Element Attribute

Using one attribute to apply a directive and another to configure it is redundant, and it makes more sense to make a single attribute do double duty, as shown in Listing 13-8.

Listing 13-8. Reusing an Attribute in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Attribute } from "@angular/core";

@Directive({
    selector: "[pa-attr]",
})
export class PaAttrDirective {

    constructor(element: ElementRef, @Attribute("pa-attr") bgClass: string) {
        element.nativeElement.classList.add(bgClass || "table-success", "fw-bold");
    }
}
```

The @Attribute decorator now specifies the pa-attr attribute as the source of the bgClass parameter value. In Listing 13-9, I have updated the template to reflect the dual-purpose attribute.

Listing 13-9. Applying a Directive in the template.html File in the src/app Folder

```
...
<tbody>
    <tr *ngFor="let item of getProducts(); let i = index">
        <td>{{i + 1}}</td>
        <td>{{item.name}}</td>
```

```
        <td pa-attr pa-attr-class="table-warning">{{item.category}}</td>
        <td pa-attr pa-attr-class="table-info">{{item.price}}</td>
    </tr>
</tbody>
...
```

There is no visual change in the result produced by this example, but it has simplified the way that the directive is applied in the HTML template.

Creating Data-Bound Input Properties

The main limitation of reading attributes with @Attribute is that values are static. The real power in Angular directives comes through support for expressions that are updated to reflect changes in the application state and that can respond by changing the host element.

Directives receive expressions using *data-bound input properties*, also known as *input properties* or, simply, *inputs*. Listing 13-10 changes the application's template so that the pa-attr attributes applied to the tr and td elements contain expressions, rather than just static class names.

Listing 13-10. Using Expressions in the template.html File in the src/app Folder

```
...
<tbody>
    <tr *ngFor="let item of getProducts(); let i = index"
            [pa-attr]="getProducts().length < 6 ? 'table-success' : 'table-warning'">
        <td>{{i + 1}}</td>
        <td>{{item.name}}</td>
        <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
            {{item.category}}
        </td>
        <td [pa-attr]="'table-info'">{{item.price}}</td>
    </tr>
</tbody>
...
```

There are three expressions in the listing. The first, which is applied to the tr element, uses the number of objects returned by the component's getProducts method to select a class.

```
...
<tr *ngFor="let item of getProducts(); let i = index"
    [pa-attr]="getProducts().length < 6 ? 'table-success' : 'table-warning'">
...
```

The second expression, which is applied to the td element for the Category column, specifies the table-info class for Product objects whose Category property returns Soccer and null for all other values.

```
...
<td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
...
```

The third and final expression returns a fixed string value, which I have enclosed in single quotes, since this is an expression and not a static attribute value.

```
...
<td [pa-attr]="'table-info'">{{item.price}}</td>
...
```

Notice that the attribute name is enclosed in square brackets. That's because the way to receive an expression in a directive is to create a data binding, just like the built-in directives that are described in Chapters 11 and 12.

■ **Tip**   Forgetting to use the square brackets is a common mistake. Without them, Angular will just pass the raw text of the expression to the directive without evaluating it. This is the first thing to check if you encounter an error when applying a custom directive.

Implementing the other side of the data binding means creating an input property in the directive class and telling Angular how to manage its value, as shown in Listing 13-11.

Listing 13-11. Defining an Input Property in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Input } from "@angular/core";

@Directive({
    selector: "[pa-attr]"
})
export class PaAttrDirective {

    constructor(private element: ElementRef) {}

    @Input("pa-attr")
    bgClass: string | null = "";

    ngOnInit() {
        this.element.nativeElement.classList.add(this.bgClass || "table-success",
            "fw-bold");
    }
}
```

Input properties are defined by applying the @Input decorator to a property and using it to specify the name of the attribute that contains the expression. This listing defines a single input property, which tells Angular to set the value of the directive's bgClass property to the value of the expression contained in the pa-attr attribute.

■ **Tip**   You don't need to provide an argument to the @Input decorator if the name of the property corresponds to the name of the attribute on the host element. So, if you apply @Input() to a property called myVal, then Angular will look for a myVal attribute on the host element.

The role of the constructor has changed in this example. When Angular creates a new instance of a directive class, the constructor is invoked to create a new directive object, and only then is the value of the input property set. This means that the constructor cannot access the input property value because its value will not be set by Angular until after the constructor has completed and the new directive object has been produced. To address this, directives can implement *lifecycle hook methods*, which Angular uses to provide directives with useful information after they have been created and while the application is running, as described in Table 13-3.

Table 13-3. *The Directive Lifecycle Hook Methods*

Name	Description
ngOnInit	This method is called after Angular has set the initial value for all the input properties that the directive has declared.
ngOnChanges	This method is called when the value of an input property has changed and also just before the ngOnInit method is called.
ngDoCheck	This method is called when Angular runs its change detection process so that directives have an opportunity to update any state that isn't directly associated with an input property.
ngAfterContentInit	This method is called when the directive's content has been initialized. See the "Receiving Query Change Notifications" section in Chapter 14 for an example that uses this method.
ngAfterContentChecked	This method is called after the directive's content has been inspected as part of the change detection process.
ngOnDestroy	This method is called immediately before Angular destroys a directive.

To set the class on the host element, the directive in Listing 13-11 implements the ngOnInit method, which is called after Angular has set the value of the bgClass property. The constructor is still needed to receive the ElementRef object that provides access to the host element, which is assigned to a property called element.

The result is that Angular will create a directive object for each tr element, evaluate the expressions specified in the pa-attr attribute, use the results to set the value of the input properties, and then call the ngOnInit methods, which allows the directives to respond to the new input property values.

To see the effect, use the form to add a new product to the example application. Since there are initially five items in the model, the expression for the tr element will select the bg-success class. When you add a new item, Angular will create another instance of the directive class and evaluate the expression to set the value of the input property; since there are now six items in the model, the expression will select the bg-warning class, which provides the new row with a different background color, as shown in Figure 13-4.

Figure 13-4. *Using an input property in a custom directive*

Responding to Input Property Changes

Something odd happened in the previous example: adding a new item affected the appearance of the new elements but not the existing elements. Behind the scenes, Angular has updated the value of the bgClass property for each of the directives that it created—one for each td element in the table column—but the directives didn't notice because changing a property value doesn't automatically cause directives to respond.

To handle changes, a directive must implement the ngOnChanges method to receive notifications when the value of an input property changes, as shown in Listing 13-12.

Listing 13-12. Receiving Change Notifications in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Input, SimpleChanges } from "@angular/core";

@Directive({
    selector: "[pa-attr]"
})
export class PaAttrDirective {

    constructor(private element: ElementRef) {}

    @Input("pa-attr")
    bgClass: string | null = "";

    // ngOnInit() {
    //      this.element.nativeElement.classList.add(this.bgClass || "table-success",
```

```
    //          "fw-bold");
    // }

    ngOnChanges(changes: SimpleChanges) {
        let change = changes["bgClass"];
        let classList = this.element.nativeElement.classList;
        if (!change.isFirstChange() && classList.contains(change.previousValue)) {
            classList.remove(change.previousValue);
        }
        if (!classList.contains(change.currentValue)) {
            classList.add(change.currentValue);
        }
    }
}
```

The ngOnChanges method is called once before the ngOnInit method and then called again each time there are changes to any of a directive's input properties. The ngOnChanges parameter is a SimpleChanges object, which is a map whose keys refer to each changed input property and whose values are SimpleChange objects, which are defined in the @angular/core module. The SimpleChange class defines the members shown in Table 13-4.

Table 13-4. *The Properties and Method of the SimpleChange Class*

Name	Description
previousValue	This property returns the previous value of the input property.
currentValue	This property returns the current value of the input property.
isFirstChange()	This method returns true if this is the call to the ngOnChanges method that occurs before the ngOnInit method.

When responding to changes to the input property value, a directive has to make sure to account for the effect of previous updates. In the case of the example directive, this means removing the element from the previousValue class and adding it to the currentValue class instead.

It is important to use the isFirstChange method so that you don't undo a value that hasn't actually been applied since the ngOnChanges method is called the first time a value is assigned to the input property.

The result of handling these change notifications is that the directive responds when Angular reevaluates the expressions and updates the input properties. Now when you add a new product to the application, the background colors for all the tr elements are updated, as shown in Figure 13-5.

Figure 13-5. *Responding to input property changes*

Creating Custom Events

Output properties are the Angular feature that allows directives to add custom events to their host elements, through which details of important changes can be sent to the rest of the application. Output properties are defined using the @Output decorator, which is defined in the @angular/core module, as shown in Listing 13-13.

Listing 13-13. Defining an Output Property in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Input, SimpleChanges, Output, EventEmitter }
    from "@angular/core";
import { Product } from "./product.model";

@Directive({
    selector: "[pa-attr]"
})
export class PaAttrDirective {

    constructor(private element: ElementRef) {
        this.element.nativeElement.addEventListener("click", () => {
            if (this.product != null) {
                this.click.emit(this.product.category);
            }
        });
    }

    @Input("pa-attr")
    bgClass: string | null = "";

    @Input("pa-product")
    product: Product = new Product();

    @Output("pa-category")
    click = new EventEmitter<string>();
```

```
    ngOnChanges(changes: SimpleChanges) {
        let change = changes["bgClass"];
        let classList = this.element.nativeElement.classList;
        if (!change.isFirstChange() && classList.contains(change.previousValue)) {
            classList.remove(change.previousValue);
        }
        if (!classList.contains(change.currentValue)) {
            classList.add(change.currentValue);
        }
    }
}
```

The `EventEmitter<T>` interface provides the event mechanism for Angular directives. The listing creates an `EventEmitter<string>` object and assigns it to a variable called `click`, like this:

```
...
@Output("pa-category")
click = new EventEmitter<string>();
...
```

The `string` type parameter indicates that listeners to the event will receive a `string` when the event is triggered. Directives can provide any type of object to their event listeners, but common choices are `string` and `number` values, data model objects, and JavaScript `Event` objects.

The custom event in the listing is triggered when the mouse button is clicked on the host element, and the event provides its listeners with the `category` of the `Product` object that was used to create the table row using the ngFor directive. The effect is that the directive is responding to a DOM event on the host element and generating its own custom event in response. The listener for the DOM event is set up in the directive class constructor using the browser's standard `addEventListener` method, like this:

```
...
constructor(private element: ElementRef) {
    this.element.nativeElement.addEventListener("click", () => {
        if (this.product != null) {
            this.click.emit(this.product.category);
        }
    });
}
...
```

The directive defines an input property to receive the `Product` object whose category will be sent in the event. (The directive can refer to the value of the input property value in the constructor because Angular will have set the property value before the function assigned to handle the DOM event is invoked.)

The most important statement in the listing is the one that uses the `EventEmitter<string>` object to send the event, which is done using the `EventEmitter.emit` method, which is described in Table 13-5 for quick reference. The argument to the `emit` method is the value that you want the event listeners to receive, which is the value of the `category` property for this example.

Table 13-5. *The EventEmitter Method*

Name	Description
emit(value)	This method triggers the custom event associated with the EventEmitter, providing the listeners with the object or value received as the method argument.

Tying everything together is the @Output decorator, which creates a mapping between the directive's EventEmitter<string> property and the name that will be used to bind to the event in the template, like this:

```
...
@Output("pa-category")
click = new EventEmitter<string>();
...
```

The argument to the decorator specifies the attribute name that will be used in event bindings applied to the host element. You can omit the argument if the TypeScript property name is also the name you want for the custom event. I have specified pa-category in the listing, which allows me to refer to the event as click within the directive class but requires a more meaningful name externally.

Binding to a Custom Event

Angular makes it easy to bind to custom events in templates by using the same binding syntax that is used for built-in events, which was described in Chapter 12. Listing 13-14 adds the pa-product attribute to the tr element in the template to provide the directive with its Product object and adds a binding for the pa-category event.

Listing 13-14. Binding to a Custom Event in the template.html File in the src/app Folder

```
...
<tbody>
    <tr *ngFor="let item of getProducts(); let i = index"
            [pa-attr]="getProducts().length < 6 ? 'table-success' : 'table-warning'"
            [pa-product]="item" (pa-category)="newProduct.category = $event">
        <td>{{i + 1}}</td>
        <td>{{item.name}}</td>
        <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
            {{item.category}}
        </td>
        <td [pa-attr]="'table-info'">{{item.price}}</td>
    </tr>
</tbody>
...
```

The term $event is used to access the value the directive passed to the EventEmitter<string>.emit method. That means $event will be a string value containing the product category in this example. The value received from the event is used to set the value of the category input element, meaning that clicking a row in the table displays the product's category in the form, as shown in Figure 13-6.

Figure 13-6. *Defining and receiving a custom event using an output property*

■ **Note** Behind the scenes, Angular uses the Reactive Extensions package to distribute events. The `EventEmitter<T>` interface extends the RxJS `Subject<T>` interface, which, in turn, extends the `Observable<T>` interface.

Creating Host Element Bindings

The example directive relies on the browser's DOM API to manipulate its host element, both to add and remove class memberships and to receive the `click` event. Working with the DOM API in an Angular application is a useful technique, but it does mean that your directive can be used only in applications that are run in a web browser. Angular is intended to be run in a range of different execution environments, and not all of them can be assumed to provide the DOM API.

Even if you are sure that a directive will have access to the DOM, the same results can be achieved in a more elegant way using standard Angular directive features: property and event bindings. Rather than use the DOM to add and remove classes, a class binding can be used on the host element. And rather than use the `addEventListener` method, an event binding can be used to deal with the mouse click.

Behind the scenes, Angular implements these features using the DOM API when the directive is used in a web browser—or some equivalent mechanism when the directive is used in a different environment.

Bindings on the host element are defined using two decorators, `@HostBinding` and `@HostListener`, both of which are defined in the `@angular/core` module, as shown in Listing 13-15.

Listing 13-15. Creating Host Bindings in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Input, SimpleChanges, Output,
    EventEmitter, HostListener, HostBinding } from "@angular/core";
import { Product } from "./product.model";

@Directive({
    selector: "[pa-attr]"
})
export class PaAttrDirective {

    // constructor(private element: ElementRef) {
    //     this.element.nativeElement.addEventListener("click", () => {
    //         if (this.product != null) {
    //             this.click.emit(this.product.category);
    //         }
    //     });
    // }

    @Input("pa-attr")
    @HostBinding("class")
    bgClass: string | null = "";

    @Input("pa-product")
    product: Product = new Product();

    @Output("pa-category")
    click = new EventEmitter<string>();

    // ngOnChanges(changes: SimpleChanges) {
    //     let change = changes["bgClass"];
    //     let classList = this.element.nativeElement.classList;
    //     if (!change.isFirstChange() && classList.contains(change.previousValue)) {
    //         classList.remove(change.previousValue);
    //     }
    //     if (!classList.contains(change.currentValue)) {
    //         classList.add(change.currentValue);
    //     }
    // }

    @HostListener("click")
    triggerCustomEvent() {
        if (this.product != null) {
            this.click.emit(this.product.category);
        }
    }
}
```

The @HostBinding decorator is used to set up a property binding on the host element and is applied to a directive property. The listing sets up a binding between the class property on the host element and the decorator's bgClass property.

■ **Tip**   If you want to manage the contents of an element, you can use the @HostBinding decorator to bind to the textContent property. See Chapter 17 for an example.

The @HostListener decorator is used to set up an event binding on the host element and is applied to a method. The listing creates an event binding for the click event that invokes the triggerCustomEvent method when the mouse button is pressed and released. The triggerCustomEvent method uses the EventEmitter.emit method to dispatch the custom event through the output property.

Using the host element bindings means that the directive constructor can be removed since there is no longer any need to access the HTML element via the ElementRef object. Instead, Angular takes care of setting up the event listener and setting the element's class membership through the property binding.

Although the directive code is much simpler, the effect of the directive is the same: clicking a table row sets the value of one of the input elements, and adding a new item using the form triggers a change in the background color of the table cells for products that are not part of the Soccer category.

Creating a Two-Way Binding on the Host Element

Directives can support two-way bindings, which means they can be used with the banana-in-a-box bracket style that ngModel uses and can bind to a model property in both directions.

The two-way binding feature relies on a naming convention. To demonstrate how it works, Listing 13-16 adds some new elements and bindings to the template.html file.

Listing 13-16. Applying a Directive in the template.html File in the src/app Folder

```
...
<div class="col">

    <div class="form-group bg-info text-white p-2">
        <label>Name:</label>
        <input class="bg-primary text-white form-control"
            [paModel]="newProduct.name"
            (paModelChange)="newProduct.name = $event" />
    </div>

    <table class="table table-bordered table-striped">
        <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <tr *ngFor="let item of getProducts(); let i = index"
                    [pa-attr]="getProducts().length < 6
                        ? 'table-success' : 'table-warning'"
                    [pa-product]="item" (pa-category)="newProduct.category = $event">
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
                    {{item.category}}
                </td>
                <td [pa-attr]="'table-info'">{{item.price}}</td>
            </tr>
```

```
        </tbody>
    </table>
</div>
...
```

The binding whose target is paModel will be updated when the value of the newProduct.name property changes, which provides a flow of data from the application to the directive and will be used to update the contents of the input element. The custom event, paModelChange, will be triggered when the user changes the contents of the name input element and will provide a flow of data from the directive to the rest of the application.

To implement the directive, I added a file called twoway.directive.ts to the src/app folder and used it to define the directive shown in Listing 13-17.

Listing 13-17. The Contents of the twoway.directive.ts File in the src/app Folder

```
import {
    Input, Output, EventEmitter, Directive,
    HostBinding, HostListener, SimpleChange
} from "@angular/core";

@Directive({
    selector: "input[paModel]"
})
export class PaModel {

    @Input("paModel")
    modelProperty: string | undefined = "";

    @HostBinding("value")
    fieldValue: string = "";

    ngOnChanges(changes: { [property: string]: SimpleChange }) {
        let change = changes["modelProperty"];
        if (change.currentValue != this.fieldValue) {
            this.fieldValue = changes["modelProperty"].currentValue || "";
        }
    }

    @Output("paModelChange")
    update = new EventEmitter<string>();

    @HostListener("input", ["$event.target.value"])
    updateValue(newValue: string) {
        this.fieldValue = newValue;
        this.update.emit(newValue);
    }
}
```

This directive uses features that have been described previously. The selector property for this directive specifies that it will match input elements that have a paModel attribute. The built-in ngModel two-way directive has support for a range of form elements and knows which events and properties each of them

uses, but I want to keep this example simple, so I am going to support just input elements, which define a value property that gets and sets the element content.

The paModel binding is implemented using an input property and the ngOnChanges method, which responds to changes in the expression value by updating the contents of the input element through a host binding on the input element's value property.

The paModelChange event is implemented using a host listener on the input event, which then sends an update through an output property. Notice that the method invoked by the event can receive the event object by specifying an additional argument to the @HostListener decorator, like this:

```
...
@HostListener("input", ["$event.target.value"])
updateValue(newValue: string) {
...
```

The first argument to the @HostListener decorator specifies the name of the event that will be handled by the listener. The second argument is an array that will be used to provide the decorated methods with arguments. In this example, the input event will be handled by the listener, and when the updateValue method is invoked, its newValue argument will be set to the target.value property of the Event object, which is referred to using $event.

To enable the directive, I added it to the Angular module, as shown in Listing 13-18.

Listing 13-18. Registering the Directive in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";

@NgModule({
  declarations: [ProductComponent, PaAttrDirective, PaModel],
  imports: [
    BrowserModule,
    BrowserAnimationsModule,
    FormsModule, ReactiveFormsModule
  ],
  providers: [],
  bootstrap: [ProductComponent]
})
export class AppModule { }
```

When you save the changes and the browser has reloaded, you will see a new input element that responds to changes to a model property and updates the model property if its host element's content is changed. The expressions in the bindings specify the same model property used by the Name field in the form on the left side of the HTML document, which provides a convenient way to test the relationship between them, as shown in Figure 13-7.

Figure 13-7. *Testing the two-way flow of data*

■ **Tip**   You may need to stop the Angular development tools, restart them, and reload the browser for this example. The Angular development tools don't always process the changes correctly.

The final step is to simplify the bindings and apply the banana-in-a-box style of brackets, as shown in Listing 13-19.

Listing 13-19. Simplifying the Bindings in the template.html File in the src/app Folder

```
...
<div class="col">

    <div class="form-group bg-info text-white p-2">
        <label>Name:</label>
        <input class="bg-primary text-white form-control"
            [(paModel)]="newProduct.name" />
    </div>

    <table class="table table-bordered table-striped">
        <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <tr *ngFor="let item of getProducts(); let i = index"
                    [pa-attr]="getProducts().length < 6
                        ? 'table-success' : 'table-warning'"
                    [pa-product]="item" (pa-category)="newProduct.category = $event">
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
                    {{item.category}}
                </td>
```

```
                <td [pa-attr]="'table-info'">{{item.price}}</td>
            </tr>
        </tbody>
    </table>
</div>
...
```

When Angular encounters the [()] brackets, it expands the binding to match the format used in Listing 13-16, targeting the paModel input property and setting up the paModelChange event. As long as a directive exposes these to Angular, it can be targeted using the banana-in-a-box brackets, producing a simpler template syntax.

Exporting a Directive for Use in a Template Variable

In earlier chapters, I used template variables to access functionality provided by built-in directives, such as ngForm. As an example, here is an element from Chapter 12:

```
...
<form #form="ngForm" (ngSubmit)="submitForm(form)">
...
```

The form template variable is assigned ngForm, which is then used to access validation information for the HTML form. This is an example of how a directive can provide access to its properties and methods so they can be used in data bindings and expressions.

Listing 13-20 modifies the directive from the previous section so that it provides details of whether it has expanded the text in its host element.

Listing 13-20. Exporting a Directive in the twoway.directive.ts File in the src/app Folder

```
import {
    Input, Output, EventEmitter, Directive,
    HostBinding, HostListener, SimpleChange
} from "@angular/core";

@Directive({
    selector: "input[paModel]",
    exportAs: "paModel"
})
export class PaModel {

    direction: string = "None";

    @Input("paModel")
    modelProperty: string | undefined = "";

    @HostBinding("value")
    fieldValue: string = "";

    ngOnChanges(changes: { [property: string]: SimpleChange }) {
        let change = changes["modelProperty"];
        if (change.currentValue != this.fieldValue) {
```

```
            this.fieldValue = changes["modelProperty"].currentValue || "";
            this.direction = "Model";
        }
    }

    @Output("paModelChange")
    update = new EventEmitter<string>();

    @HostListener("input", ["$event.target.value"])
    updateValue(newValue: string) {
        this.fieldValue = newValue;
        this.update.emit(newValue);
        this.direction = "Element";
    }
}
```

The exportAs property of the @Directive decorator specifies a name that will be used to refer to the directive in template variables. This example uses paModel as the value—also known as the *identifier*—for the exportAs property, and you should try to use names that make it clear which directive is providing the functionality.

The listing adds a property called direction to the directive, which used to indicate when data is flowing from the model to the element or from the element to the model.

When you use the exportAs decorator, you are providing access to all the methods and properties defined by the directive to be used in template expressions and data bindings. Some developers prefix the names of the methods and properties that are not for use outside of the directive with an underscore (the _ character) or apply the private keyword. This is an indication to other developers that some methods and properties should not be used but isn't enforced by Angular. Listing 13-21 creates a template variable for the directive's exported functionality and uses it in a style binding.

Listing 13-21. Using Exported Directive Functionality in the template.html File in the src/app Folder

```
...
<div class="form-group bg-info text-white p-2">
    <label>Name:</label>
    <input class="bg-primary text-white form-control"
        [(paModel)]="newProduct.name" #paModel="paModel" />
    <div class="bg-info text-white p-1">Direction: {{paModel.direction}}</div>
</div>
...
```

The template variable is called paModel, and its value is the name used in the directive's exportAs property.

```
...
#paModel="paModel"
...
```

■ **Tip** You don't have to use the same names for the variable and the directive, but it does help to make the source of the functionality clear.

Once the template variable has been defined, it can be used in interpolation bindings or as part of a binding expression. I opted for a string interpolation binding whose expression uses the value of the directive's `direction` property.

```
...
<div class="bg-info text-white p-1">Direction: {{paModel.direction}}</div>
...
```

The result is that you can see the effect of typing text into the two `input` elements that are bound to the `newProduct.name` model property. When you type into the one that uses the `ngModel` directive, then the string interpolation binding will display `Model`. When you type into the element that uses the `paModel` directive, the string interpolation binding will display `Element`, as shown in Figure 13-8.

Figure 13-8. *Exporting functionality from a directive*

Summary

In this chapter, I described how to define and use attribute directives, including the use of input and output properties and host bindings. In the next chapter, I explain how structural directives work and how they can be used to change the layout or structure of the HTML document.

CHAPTER 14

■ ■ ■

Creating Structural Directives

Structural directives change the layout of the HTML document by adding and removing elements. They build on the core features available for attribute directives, described in Chapter 13, with additional support for micro-templates, which are small fragments of contents defined within the templates used by components. You can recognize when a structural directive is being used because its name will be prefixed with an asterisk, such as *ngIf or *ngFor. In this chapter, I explain how structural directives are defined and applied, how they work, and how they respond to changes in the data model. Table 14-1 puts structural directives in context.

Table 14-1. *Putting Structural Directives in Context*

Question	Answer
What are they?	Structural directives use micro-templates to add content to the HTML document.
Why are they useful?	Structural directives allow content to be added conditionally based on the result of an expression or for the same content to be repeated for each object in a data source, such as an array.
How are they used?	Structural directives are applied to an `ng-template` element, which contains the content and bindings that comprise its micro-template. The template class uses objects provided by Angular to control the inclusion of the content or to repeat the content.
Are there any pitfalls or limitations?	Unless care is taken, structural directives can make a lot of unnecessary changes to the HTML document, which can ruin the performance of a web application. It is important to make changes only when they are required, as explained in the "Dealing with Collection-Level Data Changes" section later in the chapter.
Are there any alternatives?	You can use the built-in directives for common tasks, but writing custom structural directives provides the ability to tailor behavior to your application.

Table 14-2 summarizes the chapter.

Table 14-2. *Chapter Summary*

Problem	Solution	Listing
Creating a structural directive	Apply the @Directive decorator to a class that receives view container and template constructor parameters	1–6
Creating an iterating structural directive	Define a ForOf input property in a structural directive class and iterate over its value	7–12
Handling data changes in a structural directive	Use a differ to detect changes in the ngDoCheck method	13–19
Querying the content of the host element to which a structural directive has been applied	Use the @ContentChild or @ContentChildren decorator	20–26

Preparing the Example Project

In this chapter, I continue working with the example project that I created in Chapter 9 and have been using since. To prepare for this chapter, I simplified the template to remove the form, leaving only the table, as shown in Listing 14-1. (I'll add the form back in later in the chapter.)

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book— from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 14-1. Simplifying the Template in the template.html File in the src/app Folder

```
<div class="p-2">
    <table class="table table-bordered table-striped">
        <thead>
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <tr *ngFor="let item of getProducts(); let i = index"
              [pa-attr]="getProducts().length < 6 ? 'table-success' : 'table-warning'"
              [pa-product]="item" (pa-category)="newProduct.category = $event">
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
                    {{item.category}}
                </td>
                <td [pa-attr]="'table-info'">{{item.price}}</td>
            </tr>
        </tbody>
    </table>
</div>
```

Run the following command in the example folder to start the development tools:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 14-1.

Figure 14-1. *Running the example application*

Creating a Simple Structural Directive

A good place to start with structural directives is to re-create the functionality provided by the ngIf directive, which is relatively simple, is easy to understand, and provides a good foundation for explaining how structural directives work. I start by making changes to the template and working backward to write the code that supports it. Listing 14-2 shows the template changes.

Listing 14-2. Applying a Structural Directive in the template.html File in the src/app Folder

```
<div class="p-2">

    <div class="form-check m-2">
        <input type="checkbox" class="form-check-input" [(ngModel)]="showTable" />
        <label class="form-check-label">Show Table</label>
    </div>

    <ng-template [paIf]="showTable">
        <table class="table table-bordered table-striped">
            <thead>
```

```
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <tr *ngFor="let item of getProducts(); let i = index"
              [pa-attr]="getProducts().length < 6
                ? 'table-success' : 'table-warning'"
              [pa-product]="item" (pa-category)="newProduct.category = $event">
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
                    {{item.category}}
                </td>
                <td [pa-attr]="'table-info'">{{item.price}}</td>
            </tr>
        </tbody>
    </table>
</ng-template>
</div>
```

This listing uses the full template syntax, in which the directive is applied to an ng-template element, which contains the content that will be used by the directive. In this case, the ng-template element contains the table element and all its contents, including bindings, directives, and expressions. (There is also a concise syntax, which I use later in the chapter.)

The ng-template element has a standard one-way data binding, which targets a directive called paIf, like this:

```
...
<ng-template [paIf]="showTable">
...
```

The expression for this binding uses the value of a property called showTable. This is the same property that is used in the other new binding in the template, which has been applied to a checkbox, as follows:

```
...
<input type="checkbox" class="form-check-input" [(ngModel)]="showTable" />
...
```

The objectives in this section are to create a structural directive that will add the contents of the ng-template element to the HTML document when the showTable property is true, which will happen when the checkbox is checked, and to remove the contents of the ng-template element when the showTable property is false, which will happen when the checkbox is unchecked. Listing 14-3 adds the showTable property to the component.

Listing 14-3. Adding a Property in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
```

```
})
export class ProductComponent {
    model: Model = new Model();
    showTable: boolean = false;

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    newProduct: Product = new Product();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }

    submitForm() {
        this.addProduct(this.newProduct);
    }
}
```

Implementing the Structural Directive Class

You know from the template what the directive should do. To implement the directive, I added a file called `structure.directive.ts` in the `src/app` folder and added the code shown in Listing 14-4.

Listing 14-4. The Contents of the structure.directive.ts File in the src/app Folder

```
import {
    Directive, SimpleChanges, ViewContainerRef, TemplateRef, Input
} from "@angular/core";

@Directive({
    selector: "[paIf]"
})
export class PaStructureDirective {

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>) { }

    @Input("paIf")
    expressionResult: boolean | undefined;

    ngOnChanges(changes:  SimpleChanges) {
        let change = changes["expressionResult"];
        if (!change.isFirstChange() && !change.currentValue) {
            this.container.clear();
```

```
        } else if (change.currentValue) {
            this.container.createEmbeddedView(this.template);
        }
    }
}
}
```

The selector property of the @Directive decorator is used to match host elements that have the paIf attribute; this corresponds to the template additions that I made in Listing 14-1.

There is an input property called expressionResult, which the directive uses to receive the results of the expression from the template. The directive implements the ngOnChanges method to receive change notifications so it can respond to changes in the data model.

The first indication that this is a structural directive comes from the constructor, which asks Angular to provide parameters using some new types.

```
...
constructor(private container: ViewContainerRef,
    private template: TemplateRef<Object>) {}
...
```

The ViewContainerRef object is used to manage the contents of the *view container*, which is the part of the HTML document where the ng-template element appears and for which the directive is responsible.

As its name suggests, the view container is responsible for managing a collection of *views*. A view is a region of HTML elements that contains directives, bindings, and expressions, and they are created and managed using the methods and properties provided by the ViewContainerRef class, the most useful of which are described in Table 14-3.

Table 14-3. Useful ViewContainerRef Methods and Properties

Name	Description
element	This property returns an ElementRef object that represents the container element.
createEmbeddedView(template)	This method uses a template to create a new view. See the text after the table for details. This method also accepts optional arguments for context data (as described in the "Creating Iterating Structural Directives" section) and an index position that specifies where the view should be inserted. The result is a ViewRef object that can be used with the other methods in this table.
clear()	This method removes all the views from the container.
length	This property returns the number of views in the container.
get(index)	This method returns the ViewRef object representing the view at the specified index.
indexOf(view)	This method returns the index of the specified ViewRef object.
insert(view, index)	This method inserts a view at the specified index.
remove(Index)	This method removes and destroys the view at the specified index.
detach(index)	This method detaches the view from the specified index without destroying it so that it can be repositioned with the insert method.

Two of the methods from Table 14-3 are required to re-create the ngIf directive's functionality: createEmbeddedView to show the ng-template element's content to the user and clear to remove it again.

The createEmbeddedView method adds a view to the view container. This method's argument is a TemplateRef object, which represents the content of the ng-template element.

The directive receives the TemplateRef object as one of its constructor arguments, for which Angular will provide a value automatically when creating a new instance of the directive class.

Putting everything together, when Angular processes the template.html file, it discovers the ng-template element, examines its binding, and determines that it needs to create a new instance of the PaStructureDirective class. Angular examines the PaStructureDirective constructor and can see that it needs to provide it with ViewContainerRef and TemplateRef objects.

```
...
constructor(private container: ViewContainerRef,
    private template: TemplateRef<Object>) {}
...
```

The ViewContainerRef object represents the place in the HTML document occupied by the ng-template element, and the TemplateRef object represents the ng-template element's contents. Angular passes these objects to the constructor and creates a new instance of the directive class.

Angular then starts processing the expressions and data bindings. As described in Chapter 13, Angular invokes the ngOnChanges method during initialization (just before the ngOnInit method is invoked) and again whenever the value of the directive's expression changes.

The PaStructureDirective class's implementation of the ngOnChanges method uses the SimpleChanges object that it receives to show or hide the contents of the ng-template element based on the current value of the expression. When the expression is true, the directive displays the ng-template element's content by adding them to the container view.

```
...
this.container.createEmbeddedView(this.template);
...
```

When the result of the expression is false, the directive clears the view container, which removes the elements from the HTML document.

```
...
this.container.clear();
...
```

The directive doesn't have any insight into the contents of the ng-template element and is responsible only for managing its visibility.

Enabling the Structural Directive

The directive must be enabled in the Angular module before it can be used, as shown in Listing 14-5.

Listing 14-5. Enabling the Directive in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
```

```
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel, PaStructureDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Structural directives are enabled in the same way as attribute directives and are specified in the module's declarations array.

Once you save the changes, the browser will reload the HTML document, and you can see the effect of the new directive: the table element, which is the content of the ng-template element, will be shown only when the checkbox is checked, as shown in Figure 14-2. (If you don't see the changes or the table isn't shown when you check the box, restart the Angular development tools and then reload the browser window.)

■ **Note** The contents of the ng-template element are being destroyed and re-created, not simply hidden and revealed. If you want to show or hide content without removing it from the HTML document, then you can use a style binding to set the display or visibility property.

Figure 14-2. *Creating a structural directive*

Using the Concise Structural Directive Syntax

The use of the ng-template element helps illustrate the role of the view container in structural directives. The concise syntax does away with the ng-template element and applies the directive and its expression to the outermost element that it would contain, as shown in Listing 14-6.

■ **Tip**   The concise structural directive syntax is intended to be easier to use and read, but it is just a matter of preference as to which syntax you use.

Listing 14-6. Using the Concise Structural Directive Syntax in the template.html File in the src/app Folder

```
<div class="p-2">

    <div class="form-check m-2">
        <input type="checkbox" class="form-check-input" [(ngModel)]="showTable" />
        <label class="form-check-label">Show Table</label>
    </div>

    <table *paIf="showTable" class="table table-sm table-bordered table-striped">
        <thead>
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <tr *ngFor="let item of getProducts(); let i = index"
                [pa-attr]="getProducts().length < 6
                ? 'table-success' : 'table-warning'"
                [pa-product]="item" (pa-category)="newProduct.category = $event">
```

375

```
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td [pa-attr]="item.category == 'Soccer' ? 'table-info' : null">
                    {{item.category}}
                </td>
                <td [pa-attr]="'table-info'">{{item.price}}</td>
            </tr>
        </tbody>
    </table>
</div>
```

The ng-template element has been removed, and the directive has been applied to the table element, like this:

```
...
<table *paIf="showTable" class="table table-sm table-bordered table-striped">
...
```

The directive's name is prefixed with an asterisk (the * character) to tell Angular that this is a structural directive that uses the concise syntax. When Angular parses the template.html file, it discovers the directive and the asterisk and handles the elements as though there were an ng-template element in the document. No changes are required to the directive class to support the concise syntax.

Creating Iterating Structural Directives

Angular provides special support for directives that need to iterate over a data source. The best way to demonstrate this is to re-create another of the built-in directives: ngFor.

To prepare for the new directive, I have removed the ngFor directive from the template.html file, inserted an ng-template element, and applied a new directive attribute and expression, as shown in Listing 14-7.

Listing 14-7. Preparing for a New Structural Directive in the template.html File in the src/app Folder

```
<div class="m-2">
    <div class="checkbox">
      <label>
        <input type="checkbox" [(ngModel)]="showTable" />
        Show Table
      </label>
    </div>

    <table *paIf="showTable" class="table table-sm table-bordered table-striped">
        <thead>
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <ng-template [paForOf]="getProducts()" let-item>
                <tr><td colspan="4">{{item.name}}</td></tr>
            </ng-template>
        </tbody>
    </table>
</div>
```

The full syntax for iterating structural directives is a little odd. In the listing, the ng-template element has two attributes that are used to apply the directive. The first is a standard binding whose expression obtains the data required by the directive, bound to an attribute called paForOf.

```
...
<ng-template [paForOf]="getProducts()" let-item>
...
```

The name of this attribute is important. When using an ng-template element, the name of the data source attribute must end with Of to support the concise syntax, which I will introduce shortly.

The second attribute is used to define the *implicit value*, which allows the currently processed object to be referred to within the ng-template element as the directive iterates through the data source. Unlike other template variables, the implicit variable isn't assigned a value, and its purpose is only to define the variable name.

```
...
<ng-template [paForOf]="getProducts()" let-item>
...
```

In this example, I have used let-item to tell Angular that I want the implicit value to be assigned to a variable called item, which is then used within a string interpolation binding to display the name property of the current data item.

```
...
<td colspan="4">{{item.name}}</td>
...
```

Looking at the ng-template element, you can see that the purpose of the new directive is to iterate through the component's getProducts method and generate a table row for each of them that displays the name property. To implement this functionality, I created a file called iterator.directive.ts in the src/app folder and defined the directive shown in Listing 14-8.

Listing 14-8. The Contents of the iterator.directive.ts File in the src/app Folder

```
import { Directive, ViewContainerRef, TemplateRef, Input}
    from "@angular/core";

@Directive({
    selector: "[paForOf]"
})
export class PaIteratorDirective {

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>) { }

    @Input("paForOf")
    dataSource: any;

    ngOnInit() {
        this.container.clear();
        for (let i = 0; i < this.dataSource.length; i++) {
            this.container.createEmbeddedView(this.template,
                new PaIteratorContext(this.dataSource[i]));
        }
```

```
    }
}

class PaIteratorContext {
    constructor(public $implicit: any) { }
}
```

The `selector` property in the `@Directive` decorator matches elements with the `paForOf` attribute, which is also the source of the data for the `dataSource` input property and which provides the source of objects that will be iterated.

The `ngOnInit` method will be called once the value of the input property has been set, and the directive empties the view container using the `clear` method and adds a new view for each object using the `createEmbeddedView` method.

When calling the `createEmbeddedView` method, the directive provides two arguments: the `TemplateRef` object received through the constructor and a context object. The `TemplateRef` object provides the content to insert into the container, and the context object provides the data for the implicit value, which is specified using a property called `$implicit`. It is this object, with its `$implicit` property, that is assigned to the `item` template variable and that is referred to in the string interpolation binding. To provide templates with the context object in a type-safe way, I defined a class called `PaIteratorContext`, whose only property is called `$implicit`.

The `ngOnInit` method reveals some important aspects of working with view containers. First, a view container can be populated with multiple views—in this case, one view per object in the data source. The `ViewContainerRef` class provides the functionality required to manage these views once they have been created, as you will see in the sections that follow.

Second, a template can be reused to create multiple views. In this example, the contents of the `ng-template` element will be used to create identical `tr` and `td` elements for each object in the data source. The `td` element contains a data binding, which is processed by Angular when each view is created and is used to tailor the content to its data object.

Third, the directive has no special knowledge about the data it is working with and no knowledge of the content that is being generated. Angular takes care of providing the directive with the context it needs from the rest of the application, providing the data source through the input property and providing the content for each view through the `TemplateRef` object.

Enabling the directive requires an addition to the Angular module, as shown in Listing 14-9.

Listing 14-9. Adding a Custom Directive in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
```

```
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel, PaStructureDirective,
        PaIteratorDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The result is that the directive iterates through the objects in its data source and uses the ng-template element's content to create a view for each of them, providing rows for the table, as shown in Figure 14-3. You will need to check the box to show the table. (If you don't see the changes, then start the Angular development tools and reload the browser window.)

Figure 14-3. *Creating an iterating structural directive*

Providing Additional Context Data

Structural directives can provide templates with additional values to be assigned to template variables and used in bindings. For example, the ngFor directive provides odd, even, first, and last values. Context values are provided through the same object that defines the $implicit property, and in Listing 14-10, I have re-created the same set of values that ngFor provides.

Listing 14-10. Providing Context Data in the iterator.directive.ts File in the src/app Folder

```
import { Directive, ViewContainerRef, TemplateRef, Input}
    from "@angular/core";

@Directive({
    selector: "[paForOf]"
})
export class PaIteratorDirective {

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>) { }

    @Input("paForOf")
    dataSource: any;

    ngOnInit() {
        this.container.clear();
        for (let i = 0; i < this.dataSource.length; i++) {
            this.container.createEmbeddedView(this.template,
                new PaIteratorContext(this.dataSource[i],
                    i, this.dataSource.length));
        }
    }
}

class PaIteratorContext {
    odd: boolean; even: boolean;
    first: boolean; last: boolean;

    constructor(public $implicit: any,
            public index: number, total: number ) {

        this.odd = index % 2 == 1;
        this.even = !this.odd;
        this.first = index == 0;
        this.last = index == total - 1;
    }
}
```

This listing defines additional properties in the PaIteratorContext class and expands its constructor so that it receives additional parameters, which are used to set the property values.

The effect of these additions is that context object properties can be used to create template variables, which can then be referred to in binding expressions, as shown in Listing 14-11.

Listing 14-11. Using Structural Directive Context Data in the template.html File in the src/app Folder

```
<div class="p-2">

    <div class="form-check m-2">
        <input type="checkbox" class="form-check-input" [(ngModel)]="showTable" />
        <label class="form-check-label">Show Table</label>
```

```
    </div>

    <table *paIf="showTable" class="table table-sm table-bordered table-striped">
        <thead>
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <ng-template [paForOf]="getProducts()" let-item let-i="index"
                    let-odd="odd" let-even="even">
                <tr [class.table-info]="odd" [class.table-warning]="even">
                    <td>{{i + 1}}</td>
                    <td>{{item.name}}</td>
                    <td>{{item.category}}</td>
                    <td>{{item.price}}</td>
                </tr>
            </ng-template>
        </tbody>
    </table>
</div>
```

Template variables are created using the let-<name> attribute syntax and assigned one of the context data values. In this listing, I used the odd and even context values to create template variables of the same name, which are then incorporated into class bindings on the tr element, resulting in striped table rows, as shown in Figure 14-4. The listing also adds table cells to display all the Product properties.

Figure 14-4. *Using directive context data*

Using the Concise Structure Syntax

Iterating structural directives support the concise syntax and omit the `ng-template` element, as shown in Listing 14-12.

Listing 14-12. Using the Concise Syntax in the template.html File in the src/app Folder

```
<div class="p-2">

    <div class="form-check m-2">
        <input type="checkbox" class="form-check-input" [(ngModel)]="showTable" />
        <label class="form-check-label">Show Table</label>
    </div>

    <table *paIf="showTable" class="table table-sm table-bordered table-striped">
        <thead>
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
        </thead>
        <tbody>
            <tr *paFor="let item of getProducts(); let i = index; let odd = odd;
                    let even = even" [class.table-info]="odd"
                        [class.table-warning]="even">
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td>{{item.price}}</td>
            </tr>
        </tbody>
    </table>
</div>
```

This is a more substantial change than the one required for attribute directives. The biggest change is in the attribute used to apply the directive. When using the full syntax, the directive was applied to the `ng-template` element using the attribute specified by its selector, like this:

```
...
<ng-template [paForOf]="getProducts()" let-item let-i="index" let-odd="odd"
    let-even="even">
...
```

When using the concise syntax, the `Of` part of the attribute is omitted, the name is prefixed with an asterisk, and the brackets are omitted.

```
...
<tr *paFor="let item of getProducts(); let i = index; let odd = odd;
    let even = even" [class.table-info]="odd" [class.table-warning]="even">
...
```

The other change is to incorporate all the context values into the directive's expression, replacing the individual let- attributes. The main data value becomes part of the initial expression, with additional context values separated by semicolons.

No changes are required to the directive to support the concise syntax, whose selector and input property still specify an attribute called paForOf. Angular takes care of expanding the concise syntax, and the directive doesn't know or care whether an ng-template element has been used.

Dealing with Property-Level Data Changes

There are two kinds of changes that can occur in the data sources used by iterating structural directives. The first kind happens when the properties of an individual object change. This has a knock-on effect on the data bindings contained within the ng-template element, either directly through a change in the implicit value or indirectly through the additional context values provided by the directive. Angular takes care of these changes automatically, reflecting any changes in the context data in the bindings that depend on them.

To demonstrate, in Listing 14-13 I have added a call to the standard JavaScript setInterval function in the constructor of the context class. The function passed to setInterval alters the odd and even properties and changes the value of the price property of the Product object that is used as the implicit value.

Listing 14-13. Modifying Individual Objects in the iterator.directive.ts File in the src/app Folder

```
...
class PaIteratorContext {
    odd: boolean; even: boolean;
    first: boolean; last: boolean;

    constructor(public $implicit: any,
            public index: number, total: number ) {

        this.odd = index % 2 == 1;
        this.even = !this.odd;
        this.first = index == 0;
        this.last = index == total - 1;

        setInterval(() => {
            this.odd = !this.odd; this.even = !this.even;
            this.$implicit.price++;
        }, 2000);
    }
}
...
```

Once every two seconds, the values of the odd and even properties are inverted, and the price value is incremented. When you save the changes, you will see that the colors of the table rows change and the prices slowly increase, as illustrated in Figure 14-5.

Figure 14-5. *Automatic change detection for individual data source objects*

Dealing with Collection-Level Data Changes

The second type of change occurs when the objects within the collection are added, removed, or replaced. Angular doesn't detect this kind of change automatically, which means the iterating directive's ngOnChanges method won't be invoked.

Receiving notifications about collection-level changes is done by implementing the ngDoCheck method, which is called whenever a data change is detected in the application, regardless of where that change occurs or what kind of change it is. The ngDoCheck method allows a directive to respond to changes even when they are not automatically detected by Angular. Implementing the ngDoCheck method requires caution, however, because it represents a pitfall that can destroy the performance of a web application. To demonstrate the problem, Listing 14-14 implements the ngDoCheck method so that the directive updates the content it displays when there is a change.

Listing 14-14. Implementing the ngDoCheck Methods in the iterator.directive.ts File in the src/app Folder

```
import { Directive, ViewContainerRef, TemplateRef, Input}
    from "@angular/core";

@Directive({
    selector: "[paForOf]"
})
export class PaIteratorDirective {

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>) { }

    @Input("paForOf")
    dataSource: any;
```

```
    ngOnInit() {
        this.updateContent();
    }

    ngDoCheck() {
        console.log("ngDoCheck Called");
        this.updateContent();
    }

    private updateContent() {
        this.container.clear();
        for (let i = 0; i < this.dataSource.length; i++) {
            this.container.createEmbeddedView(this.template,
                new PaIteratorContext(this.dataSource[i],
                    i, this.dataSource.length));
        }
    }
}

class PaIteratorContext {
    odd: boolean; even: boolean;
    first: boolean; last: boolean;

    constructor(public $implicit: any,
            public index: number, total: number ) {

        this.odd = index % 2 == 1;
        this.even = !this.odd;
        this.first = index == 0;
        this.last = index == total - 1;

        // setInterval(() => {
        //     this.odd = !this.odd; this.even = !this.even;
        //     this.$implicit.price++;
        // }, 2000);
    }
}
```

The ngOnInit and ngDoCheck methods both call a new updateContent method that clears the contents of the view container and generates new template content for each object in the data source. I have also commented out the call to the setInterval function in the PaIteratorContext class.

To understand the problem with collection-level changes and the ngDoCheck method, I need to restore the form to the component's template, as shown in Listing 14-15. I also removed the checkbox and removed the directive from the table so that it is always displayed.

Listing 14-15. Restoring the HTML Form in the template.html File in the src/app Folder

```
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4">
            <form class="m-2" (ngSubmit)="submitForm()">
                <div class="form-group">
```

```
                <label>Name</label>
                <input class="form-control" name="name"
                    [(ngModel)]="newProduct.name" />
            </div>
            <div class="form-group">
                <label>Category</label>
                <input class="form-control" name="category"
                    [(ngModel)]="newProduct.category" />
            </div>
            <div class="form-group">
                <label>Price</label>
                <input class="form-control" name="price"
                    [(ngModel)]="newProduct.price" />
            </div>
            <button class="btn btn-primary mt-2" type="submit">Create</button>
        </form>
    </div>

    <div class="col">
        <table class="table table-sm table-bordered table-striped">
            <thead>
                <tr><th></th><th>Name</th><th>Category</th><th>Price</th></tr>
            </thead>
            <tbody>
                <tr *paFor="let item of getProducts(); let i = index;
                    let odd = odd; let even = even" [class.table-info]="odd"
                    [class.table-warning]="even">
                    <td>{{i + 1}}</td>
                    <td>{{item.name}}</td>
                    <td>{{item.category}}</td>
                    <td>{{item.price}}</td>
                </tr>
            </tbody>
        </table>
    </div>
  </div>
</div>
```
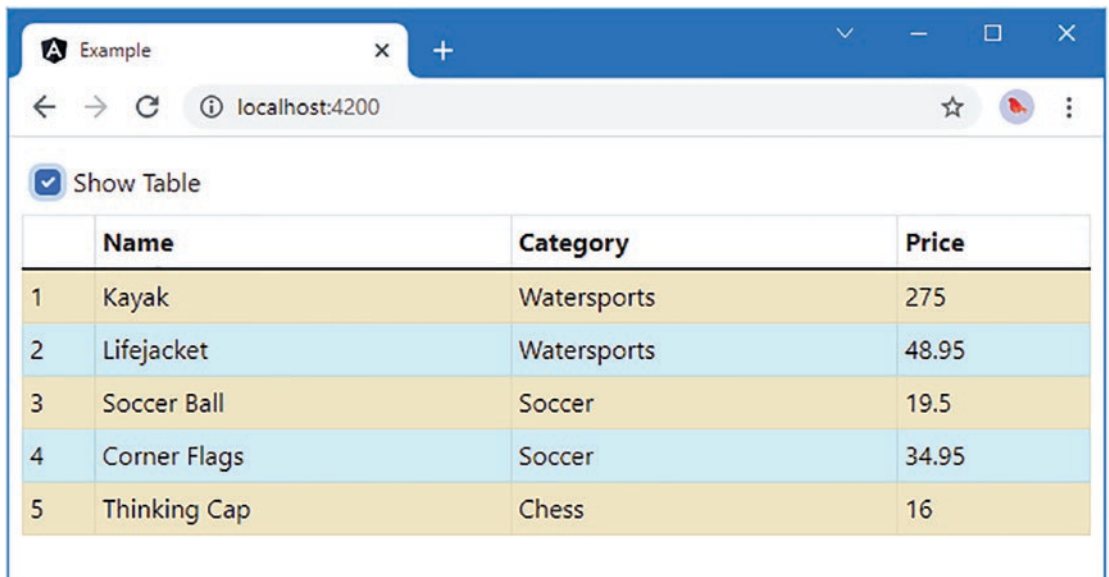

When you save the changes to the template, the HTML form will be displayed alongside the table of products, as shown in Figure 14-6.

Figure 14-6. *Restoring the table in the template*

The problem with the ngDoCheck method is that it is invoked every time Angular detects a change anywhere in the application—and those changes happen more often than you might expect.

To demonstrate how often changes occur, I added a call to the console.log method within the directive's ngDoCheck method in Listing 14-14 so that a message will be displayed in the browser's JavaScript console each time the ngDoCheck method is called. Use the HTML form to create a new product and see how many messages are written out to the browser's JavaScript console, each of which represents a change detected by Angular and which results in a call to the ngDoCheck method.

A new message is displayed each time an input element gets the focus, each time a key event is triggered, each time a validation check is performed, and so on. A quick test adding a Running Shoes product in the Running category with a price of 100 generates 27 messages on my system, although the exact number will vary based on how you navigate between elements, whether you need to correct typos, and so on.

For each of those 27 times, the structural directive destroys and re-creates its content, which means producing new tr and td elements with new directive and binding objects.

There are only a few rows of data in the example application, but these are expensive operations, and a real application can grind to a halt as the content is repeatedly destroyed and re-created. The worst part of this problem is that all the changes except one were unnecessary because the content in the table didn't need to be updated until the new Product object was added to the data model. For all the other changes, the directive destroyed its content and created an identical replacement.

Fortunately, Angular provides some tools for managing updates more efficiently and updating content only when it is required. The ngDoCheck method will still be called for all changes in the application, but the directive can inspect its data to see whether any changes that require new content have occurred, as shown in Listing 14-16.

Listing 14-16. Minimizing Content Changes in the iterator.directive.ts File in the src/app Folder

```
import { Directive, ViewContainerRef, TemplateRef, Input,
    IterableDiffer, IterableDiffers, IterableChangeRecord }
    from "@angular/core";
```

```
@Directive({
    selector: "[paForOf]"
})
export class PaIteratorDirective {
    private differ: IterableDiffer<any> | undefined;

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>,
        private differs: IterableDiffers) { }

    @Input("paForOf")
    dataSource: any;

    ngOnInit() {
        this.differ =
            <IterableDiffer<any>> this.differs.find(this.dataSource).create();
    }

    ngDoCheck() {
        let changes = this.differ?.diff(this.dataSource);
        if (changes != null) {
            console.log("ngDoCheck called, changes detected");
            let arr: IterableChangeRecord<any>[] = [];
            changes.forEachAddedItem(addition => arr.push(addition));
            arr.forEach(addition => {
                if (addition.currentIndex != null) {
                    this.container.createEmbeddedView(this.template,
                        new PaIteratorContext(addition.item, addition.currentIndex,
                            arr.length));
                }
            });
        }
    }

    // private updateContent() {
    //     this.container.clear();
    //     for (let i = 0; i < this.dataSource.length; i++) {
    //         this.container.createEmbeddedView(this.template,
    //             new PaIteratorContext(this.dataSource[i],
    //                 i, this.dataSource.length));
    //     }
    // }
}

class PaIteratorContext {
    odd: boolean; even: boolean;
    first: boolean; last: boolean;
```

```
    constructor(public $implicit: any,
            public index: number, total: number ) {

        this.odd = index % 2 == 1;
        this.even = !this.odd;
        this.first = index == 0;
        this.last = index == total - 1;
    }
}
```

The idea is to work out whether there have been objects added, removed, or moved from the collection. This means the directive has to do some work every time the ngDoCheck method is called to avoid unnecessary and expensive DOM operations when there are no collection changes to process.

The process starts in the constructor, which receives two new arguments whose values will be provided by Angular when a new instance of the directive class is created. The IterableDiffers object is used to set up change detection on the data source collection in the ngOnInit method, like this:

```
...
ngOnInit() {
    this.differ = <IterableDiffer<any>> this.differs.find(this.dataSource).create();
}
...
```

Angular includes built-in classes, known as *differs*, that can detect changes in different types of objects. The IterableDiffers.find method accepts an object and returns an IterableDifferFactory object that is capable of creating a differ class for that object. The IterableDifferFactory class defines a create method that returns a IterableDiffer object that will perform the change detection.

The important part of this incantation is the IterableDiffer object, which was assigned to a property called differ so that it can be used when the ngDoCheck method is called.

```
...
ngDoCheck() {
    let changes = this.differ?.diff(this.dataSource);
    if (changes != null) {
        console.log("ngDoCheck called, changes detected");
        let arr: IterableChangeRecord<any>[] = [];
        changes.forEachAddedItem(addition => arr.push(addition));
        arr.forEach(addition => {
            if (addition.currentIndex != null) {
                this.container.createEmbeddedView(this.template,
                    new PaIteratorContext(addition.item, addition.currentIndex,
                        arr.length));
            }
        });
    }
}
...
```

The IterableDiffer.diff method accepts an object for comparison and returns an IterableChanges object, which contains a list of the changes, or null if there have been no changes. Checking for the null result allows the directive to avoid unnecessary work when the ngDoCheck method is called for changes elsewhere in the application. The IterableChanges object returned by the diff method provides methods described in Table 14-4 for processing changes.

Table 14-4. *The IterableChanges Methods and Properties*

Name	Description
forEachItem(func)	This method invokes the specified function for each object in the collection.
forEachPreviousItem(func)	This method invokes the specified function for each object in the previous version of the collection.
forEachAddedItem(func)	This method invokes the specified function for each new object in the collection.
forEachMovedItem(func)	This method invokes the specified function for each object whose position has changed.
forEachRemovedItem(func)	This method invokes the specified function for each object that was removed from the collection.
forEachIdentityChange(func)	This method invokes the specified function for each object whose identity has changed.

The functions that are passed to the methods described in Table 14-4 will receive an IterableChangeRecord object that describes an item and how it has changed, using the properties shown in Table 14-5.

Table 14-5. *The IterableChangeRecord Properties*

Name	Description
item	This property returns the data item.
trackById	This property returns the identity value if a trackBy function is used.
currentIndex	This property returns the current index of the item in the collection.
previousIndex	This property returns the previous index of the item in the collection.

The code in Listing 14-16 only needs to deal with new objects in the data source since that is the only change that the rest of the application can perform. If the result of the diff method isn't null, then I use the forEachAddedItem method to invoke a fat arrow function for each new object that has been detected. The function is called once for each new object and uses the properties in Table 14-5 to create new views in the view container.

The changes in Listing 14-16 included a new console message that is written to the browser's JavaScript console only when there has been a data change detected by the directive. If you repeat the process of adding a new product, you will see that the message is displayed only when the application first starts and when the Create button is clicked. The ngDoCheck method is still being called, and the directive has to check for data changes every time, so there is still unnecessary work going on. But these operations are much less expensive and time-consuming than destroying and then re-creating HTML elements.

Keeping Track of Views

Handling change detection is simple when you are handling the creation of new data items. Other operations—such as dealing with deletions or modifications—are more complex and require the directive to keep track of which view is associated with which data object.

To demonstrate, I am going to add support for deleting a Product object from the data model. First, Listing 14-17 adds a method to the component to delete a product using its key. This isn't a requirement because the template could access the repository through the component's model property, but it can help make applications easier to understand when all of the data is accessed and used in the same way.

Listing 14-17. Adding a Delete Method in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();
    showTable: boolean = false;

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    newProduct: Product = new Product();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }

    deleteProduct(key: number) {
        this.model.deleteProduct(key);
    }

    submitForm() {
        this.addProduct(this.newProduct);
    }
}
```

Listing 14-18 updates the template so that the content generated by the structural directive contains a column of button elements that will delete the data object associated with the row that contains it.

Listing 14-18. Adding a Delete Button in the template.html File in the src/app Folder

```
...
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index; let odd = odd;
                let even = even" [class.table-info]="odd"
                    [class.table-warning]="even" class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
...
```

The button elements have click event bindings that call the component's deleteProduct method. I also assigned the tr element to the align-middle class so the text in the table cells is aligned with the button text. The final step is to process the data changes in the structural directive so that it responds when an object is removed from the data source, as shown in Listing 14-19.

Listing 14-19. Responding to a Removed Item in the iterator.directive.ts File in the src/app Folder

```
import { Directive, ViewContainerRef, TemplateRef, Input,
    IterableDiffer, IterableDiffers, ChangeDetectorRef, IterableChangeRecord,
    ViewRef } from "@angular/core";

@Directive({
    selector: "[paForOf]"
})
export class PaIteratorDirective {
    private differ: IterableDiffer<any> | undefined;
    private views: Map<any, PaIteratorContext> = new Map<any, PaIteratorContext>();

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>,
        private differs: IterableDiffers,
        private changeDetector: ChangeDetectorRef) { }

    @Input("paForOf")
    dataSource: any;
```

```
    ngOnInit() {
        this.differ =
            <IterableDiffer<any>> this.differs.find(this.dataSource).create();
    }

    ngDoCheck() {
        let changes = this.differ?.diff(this.dataSource);
        if (changes != null) {
            let arr: IterableChangeRecord<any>[] = [];
            changes.forEachAddedItem(addition => arr.push(addition));
            arr.forEach(addition => {
                if (addition.currentIndex != null) {
                    let context = new PaIteratorContext(addition.item,
                        addition.currentIndex, arr.length);
                    context.view = this.container.createEmbeddedView(this.template,
                        context);
                    this.views.set(addition.trackById, context);
                }
            });
            let removals = false;
            changes.forEachRemovedItem(removal => {
                removals = true;
                let context = this.views.get(removal.trackById);
                if (context != null && context.view != null) {
                    this.container.remove(this.container.indexOf(context.view));
                    this.views.delete(removal.trackById);
                }
            });
            if (removals) {
                let index = 0;
                this.views.forEach(context =>
                    context.setData(index++, this.views.size));
            }
        }
    }
}

class PaIteratorContext {
    index: number = 0;
    odd: boolean = false; even: boolean = false;
    first: boolean = false; last: boolean = false;
    view: ViewRef | undefined;

    constructor(public $implicit: any,
            public position: number, total: number ) {
        this.setData(position, total);
    }

    setData(index: number, total: number) {
        this.index = index;
        this.odd = index % 2 == 1;
```

```
        this.even = !this.odd;
        this.first = index == 0;
        this.last = index == total - 1;
    }
}
```

Two tasks are required to handle removed objects. The first task is updating the set of views by removing the ones that correspond to the items provided by the `forEachRemovedItem` method. This means keeping track of the mapping between the data objects and the views that represent them, which I have done by adding a `ViewRef` property to the `PaIteratorContext` class and using a `Map` to collect them, indexed by the value of the `IterableChangeRecord.trackById` property.

When processing the collection changes, the directive handles each removed object by retrieving the corresponding `PaIteratorContext` object from the `Map`, getting its `ViewRef` object, and passing it to the `ViewContainerRef.remove` element to remove the content associated with the object from the view container.

The second task is to update the context data for those objects that remain so that the bindings that rely on a view's position in the view container are updated correctly. The directive calls the `PaIteratorContext.setData` method for each context object left in the `Map` to update the view's position in the container and to update the total number of views that are in use. Without these changes, the properties provided by the context object wouldn't accurately reflect the data model, which means the background colors for the rows wouldn't be striped and the Delete buttons wouldn't target the right objects.

The effect of these changes is that each table row contains a Delete button that removes the corresponding object from the data model, which in turn triggers an update of the table, as shown in Figure 14-7.

Figure 14-7. *Removing objects from the data model*

Querying the Host Element Content

Directives can query the contents of their host element to access the directives it contains, known as the *content children*, which allows directives to coordinate themselves to work together.

■ **Tip** Directives can also work together by sharing services, which I describe in Chapter 17.

To demonstrate how content can be queried, I added a file called cellColor.directive.ts to the src/app folder and used it to define the directive shown in Listing 14-20.

Listing 14-20. The Contents of the cellColor.directive.ts File in the src/app Folder

```
import { Directive, HostBinding } from "@angular/core";

@Directive({
    selector: "td"
})
export class PaCellColor {

    @HostBinding("class")
    bgClass: string = "";

    setColor(dark: Boolean) {
        this.bgClass = dark ? "table-dark" : "";
    }
}
```

The PaCellColor class defines a simple attribute directive that operates on td elements and that binds to the class property of the host element. The setColor method accepts a Boolean parameter that, when the value is true, sets the class property to table-dark, which is the Bootstrap class for a dark background.

The PaCellColor class will be the directive that is embedded in the host element's content in this example. The goal is to write another directive that will query its host element to locate the embedded directive and invoke its setColor method. To that end, I added a file called cellColorSwitcher.directive.ts to the src/app folder and used it to define the directive shown in Listing 14-21.

Listing 14-21. The Contents of the cellColorSwitcher.directive.ts File in the src/app Folder

```
import { Directive, Input, SimpleChanges, ContentChild } from "@angular/core";
import { PaCellColor } from "./cellColor.directive";

@Directive({
    selector: "table"
})
export class PaCellColorSwitcher {

    @Input("paCellDarkColor")
    modelProperty: Boolean | undefined;

    @ContentChild(PaCellColor)
    contentChild: PaCellColor | undefined;
```

```
    ngOnChanges(changes:  SimpleChanges ) {
        if (this.contentChild != null) {
            this.contentChild.setColor(changes["modelProperty"].currentValue);
        }
    }
}
```

The PaCellColorSwitcher class defines a directive that operates on table elements and that defines an input property called paCellDarkColor. The important part of this directive is the contentChild property.

```
...
@ContentChild(PaCellColor)
contentChild: PaCellColor | undefined;
...
```

The @ContentChild decorator tells Angular that the directive needs to query the host element's content and assign the first result of the query to the property. The argument to the @ContentChild director is one or more directive classes. In this case, the argument to the @ContentChild decorator is PaCellColor, which tells Angular to locate the first PaCellColor object contained within the host element's content and assign it to the decorated property.

■ **Tip**   You can also query using template variable names, such that @ContentChild("myVariable") will find the first directive that has been assigned to myVariable.

The query result provides the PaCellColorSwitcher directive with access to the child component and allows it to call the setColor method in response to changes to the input property.

■ **Tip**   If you want to include the descendants of children in the results, then you can configure the query, like this: @ContentChild(PaCellColor, { descendants: true}).

In Listing 14-22, I altered the checkbox in the template so it uses the ngModel directive to set a variable that is bound to the PaCellColorSwitcher directive's input property.

Listing 14-22. Applying the Directives in the template.html File in the src/app Folder

```
...
<div class="col">

    <div class="form-check">
        <label class="form-check-label">Dark Cell Color</label>
        <input type="checkbox" class="form-check-input" [(ngModel)]="darkColor" />
    </div>

    <table class="table table-sm table-bordered table-striped"
            [paCellDarkColor]="darkColor">
        <thead>
            <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
        </thead>
```

```
        <tbody>
            <tr *paFor="let item of getProducts(); let i = index; let odd = odd;
                    let even = even" [class.table-info]="odd"
                        [class.table-warning]="even" class="align-middle">
                <td>{{i + 1}}</td>
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td>{{item.price}}</td>
                <td class="text-center">
                    <button class="btn btn-danger btn-sm"
                            (click)="deleteProduct(item.id)">
                        Delete
                    </button>
                </td>
            </tr>
        </tbody>
    </table>
</div>
...
```

Listing 14-23 adds the darkColor property to the component.

Listing 14-23. Defining a Property in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();
    showTable: boolean = false;
    darkColor: boolean = false;

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    newProduct: Product = new Product();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
```

```
    deleteProduct(key: number) {
        this.model.deleteProduct(key);
    }

    submitForm() {
        this.addProduct(this.newProduct);
    }
}
```

The final step is to register the new directives with the Angular module's declarations property, as shown in Listing 14-24.

Listing 14-24. Registering New Directives in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

When you save the changes, you will see a new checkbox above the table. When you check the box, the ngModel directive will cause the PaCellColorSwitcher directive's input property to be updated, which will call the setColor method of the PaCellColor directive object that was found using the @ContentChild decorator. The visual effect is small because only the first PaCellColor directive is affected, which is the cell that displays the number 1, at the top-left corner of the table, as shown in Figure 14-8. (If you don't see the color change, then restart the Angular development tools and reload the browser.)

Figure 14-8. *Operating on a content child*

Querying Multiple Content Children

The `@ContentChild` decorator finds the first directive object that matches the argument and assigns it to the decorated property. If you want to receive all the directive objects that match the argument, then you can use the `@ContentChildren` decorator instead, as shown in Listing 14-25.

Listing 14-25. Querying Multiple Children in the cellColorSwitcher.directive.ts File in the src/app Folder

```
import { Directive, Input, SimpleChanges, ContentChildren, QueryList }
    from "@angular/core";
import { PaCellColor } from "./cellColor.directive";

@Directive({
    selector: "table"
})
export class PaCellColorSwitcher {

    @Input("paCellDarkColor")
    modelProperty: Boolean | undefined;

    @ContentChildren(PaCellColor, {descendants: true})
    contentChildren: QueryList<PaCellColor> | undefined;
```

```
    ngOnChanges(changes: SimpleChanges) {
        this.updateContentChildren(changes["modelProperty"].currentValue);
    }

    private updateContentChildren(dark: Boolean) {
        if (this.contentChildren != null && dark != undefined) {
            this.contentChildren.forEach((child, index) => {
                child.setColor(index % 2 ? dark : !dark);
            });
        }
    }
}
```

When you use the @ContentChildren decorator, the results of the query are provided through a
QueryList, which provides access to the directive objects using the methods and properties described in
Table 14-6. The descendants configuration property is used to select descendant elements, and without this
value, only direct children are selected.

Table 14-6. *The QueryList Members*

Name	Description
length	This property returns the number of matched directive objects.
first	This property returns the first matched directive object.
last	This property returns the last matched directive object.
map(function)	This method calls a function for each matched directive object to create a new array, equivalent to the Array.map method.
filter(function)	This method calls a function for each matched directive object to create an array containing the objects for which the function returns true, equivalent to the Array.filter method.
reduce(function)	This method calls a function for each matched directive object to create a single value, equivalent to the Array.reduce method.
forEach(function)	This method calls a function for each matched directive object, equivalent to the Array.forEach method.
some(function)	This method calls a function for each matched directive object and returns true if the function returns true at least once, equivalent to the Array.some method.
changes	This property is used to monitor the results for changes, as described in the upcoming "Receiving Query Change Notifications" section.

In the listing, the directive responds to changes in the input property value by calling the
updateContentChildren method, which in turn uses the forEach method on the QueryList and invokes the
setColor method on every second directive that has matched the query. Figure 14-9 shows the effect when
the checkbox is selected.

Figure 14-9. *Operating on multiple content children*

Receiving Query Change Notifications

The results of content queries are live, meaning that they are automatically updated to reflect additions, changes, or deletions in the host element's content. Receiving a notification when there is a change in the query results requires using the Observable interface, which is provided by the Reactive Extensions package, as described in Chapter 4.

In Listing 14-26, I have updated the PaCellColorSwitcher directive so that it receives notifications when the set of content children in the QueryList changes.

Listing 14-26. Receiving Notifications in the cellColorSwitcher.directive.ts File in the src/app Folder

```
import { Directive, Input, SimpleChanges, ContentChildren, QueryList } from "@angular/core";
import { PaCellColor } from "./cellColor.directive";

@Directive({
    selector: "table"
})
export class PaCellColorSwitcher {

    @Input("paCellDarkColor")
    modelProperty: Boolean | undefined;

    @ContentChildren(PaCellColor, {descendants: true})
    contentChildren: QueryList<PaCellColor> | undefined;

    ngOnChanges(changes: SimpleChanges) {
        this.updateContentChildren(changes["modelProperty"].currentValue);
    }
```

```
    ngAfterContentInit() {
        if (this.modelProperty != undefined) {
            this.contentChildren?.changes.subscribe(() => {
                this.updateContentChildren(this.modelProperty as Boolean);
            });
        }
    }

    private updateContentChildren(dark: Boolean) {
        if (this.contentChildren != null && dark != undefined) {
            this.contentChildren.forEach((child, index) => {
                child.setColor(index % 2 ? dark : !dark);
            });
        }
    }
}
```

The value of a content child query property isn't set until the ngAfterContentInit lifecycle method is invoked, so I use this method to set up the change notification. The QueryList class defines a changes method that returns a Reactive Extensions Observable object, which defines a subscribe method. This method accepts a function that is called when the contents of the QueryList change, meaning that there is some change in the set of directives matched by the argument to the @ContentChildren decorator. The function that I passed to the subscribe method calls the updateContentChildren method to set the colors.

The result of these changes is that the dark coloring is automatically applied to new table cells that are created when the HTML form is used, as shown in Figure 14-10.

Figure 14-10. *Acting on content query change notifications*

Summary

In this chapter, I explained how structural directives work by re-creating the functionality of the built-in `ngIf` and `ngFor` directives. I explained the use of view containers and templates, described the full and concise syntax for applying structural directives, and showed you how to create a directive that iterates over a collection of data objects and how directives can query the content of their host element. In the next chapter, I introduce components and explain how they differ from directives.

CHAPTER 15

■ ■ ■

Understanding Components

Components are directives that have their own templates, rather than relying on content provided from elsewhere. Components have access to all the directive features described in earlier chapters and still have a host element, can still define input and output properties, and so on. But they also define their own content using templates.

It can be easy to underestimate the importance of the template, but attribute and structural directives have limitations. Directives can do useful and powerful work, but they don't have much insight into the elements they are applied to. Directives are most useful when they are general-purpose tools, such the `ngModel` directive, which can be applied to any data model property and any form element, without regard to what the data or the element is being used for.

Components, by contrast, are closely tied to the contents of their templates. Components provide the data and logic that will be used by the data bindings that are applied to the HTML elements in the template, which provide the context used to evaluate data binding expressions and act as the glue between the directives and the rest of the application. Components are also a useful tool in allowing large Angular projects to be broken up into manageable chunks.

In this chapter, I explain how components work and explain how to restructure an application by introducing some additional components. Table 15-1 puts components in context.

Table 15-1. *Putting Components in Context*

Question	Answer
What are they?	Components are directives that define their own HTML content and, optionally, CSS styles.
Why are they useful?	Components make it possible to define self-contained blocks of functionality, which makes projects more manageable and allows for functionality to be more readily reused.
How are they used?	The `@Component` decorator is applied to a class, which is registered in the application's Angular module.
Are there any pitfalls or limitations?	No. Components provide all the functionality of directives, with the addition of providing their own templates.
Are there any alternatives?	An Angular application must contain at least one component, which is used in the bootstrap process. Aside from this, you don't have to add additional components, although the resulting application becomes unwieldy and difficult to manage.

Table 15-2 summarizes the chapter.

Table 15-2. *Chapter Summary*

Problem	Solution	Listing
Creating a component	Apply the @Component directive to a class	1–5
Defining the content displayed by a component	Create an inline or external template	6–8
Including data in a template	Use a data binding in the component's template	9
Coordinating between components	Use input or output properties	10–16
Displaying content in an element to which a component has been applied	Project the host element's content	17–21
Styling component content	Create component styles	22–31
Querying the content in the component's template	Use the @ViewChildren decorator	32

Preparing the Example Project

In this chapter, I continue using the example project that I created in Chapter 9 and have been modifying since. No changes are required to prepare for this chapter.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Run the following command in the example folder to start the Angular development tools:

```
ng serve
```

Open a new browser and navigate to `http://localhost:4200` to see the content in Figure 15-1.

Figure 15-1. *Running the example project*

Structuring an Application with Components

At the moment, the example project contains only one component and one template. Angular applications require at least one component, known as the *root component*, which is the entry point specified in the Angular module.

The problem with having only one component is that it ends up containing the logic required for all the application's features, with its template containing all the markup required to expose those features to the user. The result is that a single component and its template are responsible for handling a lot of tasks. The component in the example application is responsible for the following:

- Providing Angular with an entry point into the application, as the root component

- Providing access to the application's data model so that it can be used in data bindings

- Defining the HTML form used to create new products

- Defining the HTML table used to display products

- Defining the layout that contains the form and the table

- Maintaining state information used to prevent invalid data from being used to create data

- Maintaining state information about whether the table should be displayed

There is a lot going on for such a simple application, and not all of these tasks are related. This effect tends to creep up gradually as development proceeds, but it means that the application is harder to test because individual features can't be isolated effectively, and it is harder to enhance and maintain because the code and markup become increasingly complex.

Adding components to the application allows features to be separated into building blocks that can be used repeatedly in different parts of the application and tested in isolation. In the sections that follow, I create components that break up the functionality contained in the example application into manageable, reusable, and self-contained units. Along the way, I'll explain the different features that components provide beyond those available to directives. To prepare for these changes, I have simplified the existing component's template, as shown in Listing 15-1.

Listing 15-1. Simplifying the Content of the template.html File in the src/app Folder

```
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4 p-2 bg-success text-white">
            Form will go here
        </div>
        <div class="col p-2 bg-primary text-white">
            Table will go here
        </div>
    </div>
</div>
```

When you save the changes to the template, you will see the content in Figure 15-2. The placeholders will be replaced with application functionality as I develop the new components and add them to the application.

Figure 15-2. Simplifying the existing template

Creating New Components

To create a new component, I added a file called productTable.component.ts to the src/app folder and used it to define the component shown in Listing 15-2.

Listing 15-2. The Contents of the productTable.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paProductTable",
    template: "<div>This is the table component</div>"
})
export class ProductTableComponent {

}
```

A component is a class to which the @Component decorator has been applied. This is as simple as a component can get, and it provides just enough functionality to count as a component without doing anything useful.

The naming convention for the files that define components is to use a descriptive name that suggests the purpose of the component, followed by a period and then component.ts. For this component, which will be used to generate the table of products, the filename is productTable.component.ts. The name of the class should be equally descriptive. This component's class is named ProductTableComponent.

The @Component decorator describes and configures the component. The most useful decorator properties are described in Table 15-3, which also includes details of where they are described (not all of them are covered in this chapter).

Table 15-3. *Useful Component Decorator Properties*

Name	Description
animations	This property is used to configure animations, as described in Chapter 27.
encapsulation	This property is used to change the view encapsulation settings, which control how component styles are isolated from the rest of the HTML document. See the "Setting View Encapsulation" section for details.
selector	This property is used to specify the CSS selector used to match host elements, as described after the table.
styles	This property is used to define CSS styles that are applied only to the component's template. The styles are defined inline, as part of the TypeScript file. See the "Using Component Styles" section for details.
styleUrls	This property is used to define CSS styles that are applied only to the component's template. The styles are defined in separate CSS files. See the "Using Component Styles" section for details.
template	This property is used to specify an inline template, as described in the "Defining Templates" section.
templateUrl	This property is used to specify an external template, as described in the "Defining Templates" section.
providers	This property is used to create local providers for services, as described in Chapter 17.
viewProviders	This property is used to create local providers for services that are available only to view children, as described in Chapter 18.

For the second component, I created a file called `productForm.component.ts` in the `src/app` folder and added the code shown in Listing 15-3.

Listing 15-3. The Contents of the productForm.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paProductForm",
    template: "<div>This is the form component</div>"
})
export class ProductFormComponent {

}
```

This component is equally simple and is just a placeholder for the moment. Later in the chapter, I'll add some more useful features. To enable the components, they must be declared in the application's Angular module, as shown in Listing 15-4.

Listing 15-4. Enabling New Components in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The component class is brought into scope using an import statement and is added to the NgModule decorator's declarations array. The final step is to add an HTML element that matches the component's selector property, as shown in Listing 15-5, which will provide the component with its host element.

Listing 15-5. Adding a Host Element in the template.html File in the src/app Folder

```
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4 p-2 bg-success text-white">
            <paProductForm></paProductForm>
        </div>
        <div class="col p-2 bg-primary text-white">
            <paProductTable></paProductTable>
        </div>
    </div>
</div>
```

When all the changes have been saved, the browser will display the content shown in Figure 15-3, which shows that parts of the HTML document are now under the management of the new components.

Figure 15-3. *Adding new components*

Understanding the New Application Structure

The new components have changed the structure of the application. Previously, the root component was responsible for all the HTML content displayed by the application. Now, however, there are three components, and responsibility for some of the HTML content has been delegated to the new additions, as illustrated in Figure 15-4.

Figure 15-4. *The new application structure*

When the browser loads the index.html file, the Angular bootstrap process starts, and Angular processes the application's module, which provides a list of the components that the application requires. Angular inspects the decorator for each component in its configuration, including the value of the selector property, which is used to identify which elements will be hosts.

Angular then begins processing the body of the index.html file and finds the app element, which is specified by the selector property of the ProductComponent component. Angular populates the app element with the component's template, which is contained in the template.html file. Angular inspects the contents of the template.html file and finds the paProductForm and paProductTable elements, which match the selector properties of the newly added components. Angular populates these elements with each component's template, producing the placeholder content shown in Figure 15-3.

There are some important new relationships to understand. First, the HTML content that is displayed in the browser window is now composed of several templates, each of which is managed by a component. Second, the ProductComponent is now the parent component to the ProductFormComponent and ProductTableComponent objects, a relationship that is formed by the fact that the host elements for the new components are defined in the template.html file, which is the ProductComponent template. Equally, the new components are children of the ProductComponent. The parent-child relationship is an important one when it comes to Angular components, as you will see as I describe how components work in later sections.

Defining Templates

Although there are new components in the application, they don't have much impact at the moment because they display only placeholder content. Each component has its own template, which defines the content that will be used to replace its host element in the HTML document. There are two different ways to define templates: inline within the @Component decorator or externally in an HTML file.

The new components that I added use templates, where a fragment of HTML is assigned to the template property of the @Component decorator, like this:

```
...
template: "<div>This is the form component</div>"
...
```

The advantage of this approach is simplicity: the component and the template are defined in a single file, and there is no way that the relationship between them can be confused. The drawback of inline templates is that they can get out of control and be hard to read if they contain more than a few HTML elements.

■ **Note** Another problem is that editors that highlight syntax errors as you type usually rely on the file extension to figure out what type of checking should be performed and won't realize that the value of the template property is HTML and will simply treat it as a string.

If you are using TypeScript, then you can use multiline strings to make inline templates more readable. Multiline strings are denoted with the backtick character (the ` character, which is also known as the *grave accent*), and they allow strings to spread over multiple lines, as shown in Listing 15-6.

Listing 15-6. Using a Multiline String in the productTable.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paProductTable",
    template: `<div class='bg-info p-2'>
                    This is a multiline template
               </div>`
})
export class ProductTableComponent {

}
```

Multiline strings allow the structure of the HTML elements in a template to be preserved, which makes it easier to read and increase the size of the template that can be practically included inline before it becomes too unwieldy to manage. Figure 15-5 shows the effect of the template in Listing 15-6.

Figure 15-5. *Using a multiline inline template*

My advice is to use external templates (explained in the next section) for any template that contains more than two or three simple elements, largely to take advantage of the HTML editing and syntax highlighting features provided by modern editors, which can go a long way to reduce the number of errors you discover when running the application.

Defining External Templates

External templates are defined in a different file from the rest of the component. The advantage of this approach is that the code and HTML are not mixed together, which makes both easier to read and unit test, and it also means that code editors will know they are working with HTML content when you are working on a template file, which can help reduce coding-time errors by highlighting errors.

The drawback of external templates is that you have to manage more files in the project and ensure that each component is associated with the correct template file. The best way to do this is to follow a consistent filenaming strategy so that it is immediately obvious that a file contains a template for a given component. The convention for Angular is to create pairs of files using the convention <componentname>. component.<type> so that when you see a file called productTable.component.ts, you know it contains a component called Products written in TypeScript, and when you see a file called productTable.component. html, you know that it contains an external template for the Products component.

■ **Tip** The syntax and features for both types of template are the same, and the only difference is where the content is stored, either in the same file as the component code or in a separate file.

To define an external template using the naming convention, I created a file called productTable. component.html in the src/app folder and added the markup shown in Listing 15-7.

Listing 15-7. The Contents of the productTable.component.html File in the src/app Folder

```
<div class="bg-info p-2">
    This is an external template
</div>
```

This is the kind of template that I have been using for the root component since Chapter 9. To specify an external template, the templateURL property is used in the @Component decorator, as shown in Listing 15-8.

Listing 15-8. Using an External Template in the productTable.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paProductTable",
    // template: `<div class='bg-info p-2'>
    //                This is a multiline template
    //            </div>`
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {

}
```

Notice that different properties are used: `template` is for inline templates, and `templateUrl` is for external templates. Figure 15-6 shows the effect of using an external template.

Figure 15-6. Using an external template

Using Data Bindings in Component Templates

A component's template can contain the full range of data bindings and target any of the built-in directives or custom directives that have been registered in the application's Angular module. Each component class provides the context for evaluating the data binding expressions in its template, and by default, each component is isolated from the others. This means the component doesn't have to worry about using the same property and method names that other components use and can rely on Angular to keep everything separate. As an example, Listing 15-9 shows the addition of a property called `model` to the form child component, which would conflict with the property of the same name in the root component were they not kept separate.

Listing 15-9. Adding a Property in the productForm.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paProductForm",
    template: "<div>{{model}}</div>"
})
export class ProductFormComponent {

    model: string = "This is the model";
}
```

The component class uses the `model` property to store a message that is displayed in the template using a string interpolation binding. Figure 15-7 shows the result.

Figure 15-7. *Using a data binding in a child component*

Using Input Properties to Coordinate Between Components

Few components exist in isolation and need to share data with other parts of the application. Components can define input properties to receive the value of data binding expressions on their host elements. The expression will be evaluated in the context of the parent component, but the result will be passed to the child component's property.

To demonstrate, Listing 15-10 adds an input property to the table component, which it will use to receive the model data that it should display.

Listing 15-10. Defining an Input Property in the productTable.component.ts File in the src/app Folder

```
import { Component, Input } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {

    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }
```

```
    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    showTable: boolean = true;
}
```

The component now defines an input property that will be assigned the value expression assigned to the model attribute on the host element. The getProduct, getProducts, and deleteProduct methods use the input property to provide access to the data model to bindings in the component's template, which is modified in Listing 15-11. The showTable property is used when I enhance the template in Listing 15-14 later in the chapter.

Listing 15-11. Adding a Data Binding in the productTable.component.html File in the src/app Folder

```
There are {{getProducts()?.length}} items in the model
```

Providing the child component with the data that it requires means adding a binding to its host element, which is defined in the template of the parent component, as shown in Listing 15-12.

Listing 15-12. Adding a Data Binding in the template.html File in the src/app Folder

```html
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4 p-2 bg-success text-white">
            <paProductForm></paProductForm>
        </div>
        <div class="col p-2 bg-primary text-white">
            <paProductTable [model]="model"></paProductTable>
        </div>
    </div>
</div>
```

The effect of this binding is to provide the child component with access to the parent component's model property. This can be a confusing feature because it relies on the fact that the host element is defined in the parent component's template but that the input property is defined by the child component, as illustrated by Figure 15-8.

Figure 15-8. *Sharing data between parent and child components*

The child component's host element acts as the bridge between the parent and child components, and the input property allows the component to provide the child with the data it needs, producing the result shown in Figure 15-9.

Figure 15-9. *Sharing data from a parent to a child component*

Using Directives in a Child Component Template

Once the input property has been defined, the child component can use the full range of data bindings and directives, either by using the data provided through the parent component or by defining its own. In Listing 15-13, I have restored the original table functionality from earlier chapters that displays a list of the Product objects in the data model, along with a checkbox that determines whether the table is displayed. This functionality was previously managed by the root component and its template.

Listing 15-13. Restoring the Table in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price}}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                    (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

The same HTML elements, data bindings, and directives (including custom directives like paIf and paFor) are used, producing the result shown in Figure 15-10. The key difference is not in the appearance of the table but in the way that it is now managed by a dedicated component.

Figure 15-10. *Restoring the table display*

Using Output Properties to Coordinate Between Components

Child components can use output properties that define custom events that signal important changes and that allow the parent component to respond when they occur. Listing 15-14 changes the form component, adding an external template and an output property that will be triggered when the user creates a new Product object when invoking the submitForm method.

Listing 15-14. Defining an Output Property in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter } from "@angular/core";
import { Product } from "./product.model";

@Component({
    selector: "paProductForm",
    templateUrl: "productForm.component.html"
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    @Output("paNewProduct")
    newProductEvent = new EventEmitter<Product>();

    submitForm(form: any) {
        this.newProductEvent.emit(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The output property is called newProductEvent, and the component triggers it when the submitForm method is called. Aside from the output property, the additions in the listing are based on the logic in the root controller, which previously managed the form. I also removed the inline template and created a file called productForm.component.html in the src/app folder, with the content shown in Listing 15-15.

Listing 15-15. The Contents of the productForm.component.html File in the src/app Folder

```
<form #form="ngForm" (ngSubmit)="submitForm(form)">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control"
            name="name" [(ngModel)]="newProduct.name" />
    </div>
    <div class="form-group">
        <label>Category</label>
        <input class="form-control"
            name="category" [(ngModel)]="newProduct.category" />
    </div>
    <div class="form-group">
        <label>Price</label>
        <input class="form-control"
            name="name" [(ngModel)]="newProduct.price" />
    </div>
```

```
    <button class="btn btn-primary mt-2" type="submit">
            Create
    </button>
</form>
```

The form contains standard elements, configured using two-way bindings. The child component's host element acts as the bridge to the parent component, which can register interest in the custom event, as shown in Listing 15-16.

Listing 15-16. Registering for the Custom Event in the template.html File in the src/app Folder

```
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
            <paProductForm (paNewProduct)="addProduct($event)"></paProductForm>
        </div>
        <div class="col p-2">
            <paProductTable [model]="model"></paProductTable>
        </div>
    </div>
</div>
```

The new binding handles the custom event by passing the event object to the addProduct method. The child component is responsible for managing the form elements and validating their contents. When the data passes validation, the custom event is triggered, and the data binding expression is evaluated in the context of the parent component, whose addProduct method adds the new object to the model. Since the model has been shared with the table child component through its input property, the new data is displayed to the user, as shown in Figure 15-11. (You may need to restart the Angular development tools to include the new template file in the build process.)

Figure 15-11. *Using a custom event in a child component*

Projecting Host Element Content

If the host element for a component contains content, it can be included in the template using the special ng-content element. This is known as *content projection*, and it allows components to be created that combine the content in their template with the content in the host element. To demonstrate, I added a file called toggleView.component.ts to the src/app folder and used it to define the component shown in Listing 15-17.

Listing 15-17. The Contents of the toggleView.component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paToggleView",
    templateUrl: "toggleView.component.html"
})
export class PaToggleView {

    showContent: boolean = true;
}
```

This component defines a showContent property that will be used to determine whether the host element's content will be displayed within the template. To provide the template, I added a file called toggleView.component.html to the src/app folder and added the elements shown in Listing 15-18.

Listing 15-18. The Contents of the toggleView.component.html File in the src/app Folder

```
<div class="form-check">
    <label class="form-check-label">Show Content</label>
    <input class="form-check-input" type="checkbox" [(ngModel)]="showContent" />
</div>
<ng-content *ngIf="showContent"></ng-content>
```

The important element is ng-content, which Angular will replace with the content of the host element. The ngIf directive has been applied to the ng-content element so that it will be visible only if the checkbox in the template is checked. Listing 15-19 registers the component with the Angular module.

Listing 15-19. Registering the Component in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
```

```
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The final step is to apply the new component to a host element that contains content, as shown in Listing 15-20.

Listing 15-20. Adding a Host Element with Content in the template.html File in the src/app Folder

```
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
            <paProductForm (paNewProduct)="addProduct($event)"></paProductForm>
        </div>
        <div class="col p-2">
            <paToggleView>
                <paProductTable [model]="model"></paProductTable>
            </paToggleView>
        </div>
    </div>
</div>
```

The paToggleView element is the host for the new component, and it contains the paProductTable element, which applies the component that creates the product table. The result is that there is a checkbox that controls the visibility of the table, as shown in Figure 15-12. The new component has no knowledge of the content of its host element, and its inclusion in the template is possible only through the ng-content element.

Figure 15-12. *Including host element content in the template*

SELECTING COMPONENTS DYNAMICALLY

The `ViewContainerRef` class, introduced in Chapter 14, defines the `createComponent` method, which can be used to select a component programmatically, without having to specify a fixed element in a template. I have not demonstrated this feature because it has serious limitations and causes more problems than it addresses, at least in my experience. If you want to explore this feature, see the Angular documentation at `https://angular.io/guide/dynamic-component-loader`, but proceed with caution.

Completing the Component Restructure

The functionality that was previously contained in the root component has been distributed to the new child components. All that remains is to tidy up the root component to remove the code that is no longer required, as shown in Listing 15-21.

Listing 15-21. Removing Obsolete Code in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
```

```
@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {
    model: Model = new Model();
    // showTable: boolean = false;
    // darkColor: boolean = false;

    // getProduct(key: number): Product | undefined {
    //     return this.model.getProduct(key);
    // }

    // getProducts(): Product[] {
    //     return this.model.getProducts();
    // }

    // newProduct: Product = new Product();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }

    // deleteProduct(key: number) {
    //     this.model.deleteProduct(key);
    // }

    // submitForm() {
    //     this.addProduct(this.newProduct);
    // }
}
```

Many of the responsibilities of the root component have been moved elsewhere in the application. Of the original list from the start of the chapter, only the following remain the responsibility of the root component:

- Providing Angular with an entry point into the application, as the root component

- Providing access to the application's data model so that it can be used in data bindings

The child components have assumed the rest of the responsibilities, providing self-contained blocks of functionality that are simpler, easier to develop, and easier to maintain and that can be reused as required.

Using Component Styles

Components can define styles that apply only to the content in their templates, which allows content to be styled by a component without it being affected by the styles defined by its parents or other antecedents and without affecting the content in its child and other descendant components. Styles can be defined inline using the styles property of the @Component decorator, as shown in Listing 15-22.

Listing 15-22. Defining Inline Styles in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter } from "@angular/core";
import { Product } from "./product.model";

@Component({
    selector: "paProductForm",
    templateUrl: "productForm.component.html",
    styles: ["div { background-color: lightgreen }"]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    @Output("paNewProduct")
    newProductEvent = new EventEmitter<Product>();

    submitForm(form: any) {
        this.newProductEvent.emit(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The styles property is set to an array, where each item contains a CSS selector and one or more properties. In the listing, I have specified styles that set the background color of div elements to lightgreen. Even though there are div elements throughout the combined HTML document, this style will affect only the elements in the template of the component that defines them, which is the form component in this case, as shown in Figure 15-13.

Figure 15-13. *Defining inline component styles*

■ **Tip** The styles included in the bundles created by the development tools are still applied, which is why the elements are still styled using Bootstrap.

Defining External Component Styles

Inline styles offer the same benefits and drawbacks as inline templates: they are simple and keep everything in one file, but they can be hard to read, can be hard to manage, and can confuse code editors.

The alternative is to define styles in a separate file and associate them with a component using the styleUrls property in its decorator. External style files follow the same naming convention as templates and code files. I added a file called productForm.component.css to the src/app folder and used it to define the styles shown in Listing 15-23.

Listing 15-23. The Contents of the productForm.component.css File in the src/app Folder

```
div {
    background-color: lightcoral;
}
```

This is the same style that was defined inline but with a different color value to confirm that this is the CSS being used by the component. In Listing 15-24, the component's decorator has been updated to specify the styles file.

Listing 15-24. Using External Styles in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter } from "@angular/core";
import { Product } from "./product.model";

@Component({
    selector: "paProductForm",
    templateUrl: "productForm.component.html",
    //styles: ["div { background-color: lightgreen }"],
    styleUrls: ["productForm.component.css"]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    @Output("paNewProduct")
    newProductEvent = new EventEmitter<Product>();

    submitForm(form: any) {
        this.newProductEvent.emit(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The styleUrls property is set to an array of strings, each of which specifies a CSS file. Figure 15-14 shows the effect of adding the external styles file.

427

Figure 15-14. *Defining external component styles*

Using Advanced Style Features

Defining styles in components is a useful feature, but you won't always get the results you expect. Some advanced features allow you to take control of how component styles work.

Setting View Encapsulation

By default, component-specific styles are implemented by writing the CSS that has been applied to the component so that it targets special attributes, which Angular then adds to all of the top-level elements contained in the component's template. If you inspect the DOM using the browser's F12 developer tools, you will see that the contents of the external CSS file in Listing 15-23 have been rewritten like this:

```
...
<style>
    div[_ngcontent-oni-c43] {
        background-color: lightcoral;
    }
</style>
...
```

The selector has been modified so that it matches div elements with an attribute called _ngcontent-oni-c43 (although you may see a different name in your browser since the name of the attribute is generated dynamically by Angular).

To ensure that the CSS in the style element affects only the HTML elements managed by the component, the elements in the template are modified so they have the same dynamically generated attribute, like this:

```
...
<div _ngcontent-oni-c43="" class="form-group">
    <label _ngcontent-oni-c43="">Name</label>
    <input _ngcontent-oni-c43="" name="name" class="form-control ng-untouched
        ng-pristine ng-valid" ng-reflect-name="name">
</div>

<div _ngcontent-jwe-c40="" class="form-group">
    <label _ngcontent-jwe-c40="">Name</label>
    <input _ngcontent-jwe-c40="" name="name" class="form-control ng-untouched
        ng-pristine ng-valid" ng-reflect-name="name">
</div>
...
```

This is known as the component's *view encapsulation* behavior, and what Angular is doing is emulating a feature known as the *shadow DOM*, which allows sections of the Domain Object Model to be isolated so they have their own scope, meaning that JavaScript, styles, and templates can be applied to part of the HTML document.

The shadow DOM feature is supported by most modern browsers, but its path to adoption has been messy, and Angular emulates the feature to ensure consistency. There are two other encapsulation options in addition to emulation, which are set using the encapsulation property in the @Component decorator.

■ **Tip** You can learn more about the shadow DOM at http://developer.mozilla.org/en-US/docs/Web/Web_Components/Shadow_DOM. You can see which browsers support the shadow DOM feature at https://caniuse.com/shadowdomv1.

The encapsulation property is assigned a value from the ViewEncapsulation enumeration, which is defined in the @angular/core module, and it defines the values described in Table 15-4.

Table 15-4. The ViewEncapsulation Values

Name	Description
Emulated	When this value is specified, Angular emulates the shadow DOM by writing content and styles to add attributes, as described earlier. This is the default behavior if no encapsulation value is specified in the @Component decorator.
ShadowDom	When this value is specified, Angular uses the browser's shadow DOM feature. This will work only if the browser implements the shadow DOM.
None	When this value is specified, Angular simply adds the unmodified CSS styles to the head section of the HTML document and lets the browser figure out how to apply the styles using the normal CSS precedence rules.

The ShadowDom and None values should be used with caution. Browser support for the shadow DOM feature is improving but has been patchy and was made more complex because there was an earlier version of the shadow DOM feature that was abandoned in favor of the current approach.

The None option adds all the styles defined by components to the head section of the HTML document and lets the browser figure out how to apply them. This has the benefit of working in all browsers, but the results are unpredictable, and there is no isolation between the styles defined by different components.

One important consideration is that the Emulated setting doesn't produce the same results as enabling native shadow DOM support with the ShadowDom setting. The Emulated setting ensures that styles defined for a specific component are not applied to elements generated by other components, but it still allows elements to be styled by the global CSS styles, such as those defined by the Bootstrap CSS package. When the ShadowDom setting is used, the browser completely isolated an element, which prevents elements from being affected by global CSS styles. To demonstrate, Listing 15-25 enables the ShadowDom mode.

Listing 15-25. Setting View Encapsulation in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation } from "@angular/core";
import { Product } from "./product.model";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    styleUrls: ["productForm.component.css"],
    encapsulation: ViewEncapsulation.ShadowDom
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    @Output("paNewProduct")
    newProductEvent = new EventEmitter<Product>();

    submitForm(form: any) {
        this.newProductEvent.emit(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The selectors for components that use the ShadowDom setting must be all lowercase and contain a hyphen, which is why I changed the selector to pa-productform. Listing 15-26 updates the template to match the new selector.

Listing 15-26. Updating an Element in the template.html File in the src/app Folder

```
<div class="container-fluid">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
            <pa-productform (paNewProduct)="addProduct($event)"></pa-productform>
        </div>
        <div class="col p-2">
            <paToggleView>
                <paProductTable [model]="model"></paProductTable>
            </paToggleView>
```

```
        </div>
    </div>
</div>
```

Figure 15-15 shows how the styles defined in the `productForm.component.css` file are applied to the HTML elements generated by the component, but the globally defined Bootstrap styles, added to the project in Chapter 9, are not.

Figure 15-15. *Enabling the native shadow DOM feature*

Using the Shadow DOM CSS Selectors

Using the shadow DOM means that there are boundaries that regular CSS selectors do not operate across. To help address this, there are special CSS selectors that are useful when using styles that rely on the shadow DOM (even when it is being emulated), as described in Table 15-5 and demonstrated in the sections that follow.

Table 15-5. *The Shadow DOM CSS Selectors*

Name	Description
`:host`	This selector is used to match the component's host element.
`:host-context(classSelector)`	This selector is used to match the ancestors of the host element that are members of a specific class.
`/deep/`, `>>>`, or `::ng-deep`	These selectors are used by a parent component to define styles that affect the elements in child component templates. This selector should be used only when the `@Component` decorator's `encapsulation` property is set to `emulated`, as described in the "Setting View Encapsulation" section.

Selecting the Host Element

A component's host element appears outside of its template, which means that the selectors in its styles apply only to elements that the host element contains and not the element itself. This can be addressed by using the `:host` selector, which matches the host element. Listing 15-27 defines a style that is applied only when the mouse pointer is hovering over the host element, which is specified by combining the `:host` and `:hover` selectors.

Listing 15-27. Matching the Host Element in the productForm.component.css File in the src/app Folder

```
div {
    background-color: lightcoral;
}
:host :hover {
    font-size: 25px;
}
```

When the mouse pointer is over the host element, its `font-size` property will be set to `25px`, which increases the text size to 25 points for all the elements in the form, as shown in Figure 15-16.

Figure 15-16. *Selecting the host element in a component style*

Selecting the Host Element's Ancestors

The `:host-context` selector is used to style elements within the component's template based on the class membership of the host element's ancestors (which are outside the template). This is a more limited selector than `:host` and cannot be used to specify anything other than a class selector, without support for matching tag types, attributes, or any other selector. Listing 15-28 shows the use of the `:host-context` selector.

Listing 15-28. Selecting Ancestors in the productForm.component.css File in the src/app Folder

```
div {
    background-color: lightcoral;
}
```

432

```
:host:hover {
    font-size: 25px;
}
:host-context(.angularApp) input {
    background-color: lightgray;
}
```

The selector in the listing sets the background-color property of input elements within the component's template to lightgrey only if one of the host element's ancestor elements is a member of a class called angularApp. In Listing 15-29, I have added a div element in the template.html file to the angularApp class.

Listing 15-29. Adding the Host Element to a Class in the template.html File in the src/app Folder

```
<div class="container-fluid angularApp">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
            <pa-productform (paNewProduct)="addProduct($event)"></pa-productform>
        </div>
        <div class="col p-2">
            <paToggleView>
                <paProductTable [model]="model"></paProductTable>
            </paToggleView>
        </div>
    </div>
</div>
```

Figure 15-17 shows the effect of the selector before and after the changes in Listing 15-29.

Figure 15-17. *Selecting the host element's ancestors*

Pushing a Style into the Child Component's Template

Styles defined by a component are not automatically applied to the elements in the child component's templates. As a demonstration, Listing 15-30 adds a style to the @Component decorator of the root component.

Listing 15-30. Defining Styles in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html",
    styles: ["div { border: 2px black solid;  font-style:italic }"]
})
export class ProductComponent {
    model: Model = new Model();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
}
```

The selector matches all div elements and applies a border and changes the font style. Figure 15-18 shows the result.

Figure 15-18. Applying regular CSS styles

Some CSS style properties, such as `font-style`, are inherited by default, which means that setting such a property in a parent component will affect the elements in child component templates because the browser automatically applies the style.

Other properties, such as `border`, are not inherited by default, and setting such a property in a parent component does not affect child component templates unless the `/deep/` or `>>>` selector is used, as shown in Listing 15-31. (These selectors are aliases of one another and have the same effect.)

Listing 15-31. Pushing a Style into Child Templates in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html",
    styles: ["/deep/ div { border: 2px black solid;  font-style:italic }"]
})
export class ProductComponent {
    model: Model = new Model();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
}
```

The selector for the style uses `/deep/` to push the styles into the child components' templates, which means that all the `div` elements are given a border, as shown in Figure 15-19.

Figure 15-19. *Pushing a style into child component templates*

Querying Template Content

Components can query the content of their templates to locate instances of directives or components, which are known as *view children*. These are similar to the directive content children queries that were described in Chapter 14 but with some important differences.

In Listing 15-32, I have added some code to the component that manages the table that queries for the PaCellColor directive that was created to demonstrate directive content queries. This directive is still registered in the Angular module and selects td elements, so Angular will have applied it to the cells in the table component's content.

Listing 15-32. Selecting View Children in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
import { PaCellColor } from "./cellColor.directive";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {

    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    showTable: boolean = true;

    @ViewChildren(PaCellColor)
    viewChildren: QueryList<PaCellColor> | undefined;

    ngAfterViewInit() {
        this.viewChildren?.changes.subscribe(() => {
            this.updateViewChildren();
        });
        this.updateViewChildren();
    }

    private updateViewChildren() {
```

```
        setTimeout(() => {
            this.viewChildren?.forEach((child, index) => {
                child.setColor(index % 2 ? true : false);
            })
        }, 0);
    }
}
```

Two property decorators are used to query for directives or components defined in the template, as described in Table 15-6.

Table 15-6. *The View Children Query Property Decorators*

Name	Description
@ViewChild(class)	This decorator tells Angular to query for the first directive or component object of the specified type and assign it to the property. The class name can be replaced with a template variable. Multiple classes or variable names can be separated by commas.
@ViewChildren(class)	This decorator assigns all the directive and component objects of the specified type to the property. Template variables can be used instead of classes, and multiple values can be separated by commas. The results are provided in a QueryList object, described in Chapter 14.

In the listing, I used the @ViewChildren decorator to select all the PaCellColor objects from the component's template. Aside from the different property decorators, components have two different lifecycle methods that are used to provide information about how the template has been processed, as described in Table 15-7.

Table 15-7. *The Additional Component Lifecycle Methods*

Name	Description
ngAfterViewInit	This method is called when the component's view has been initialized. The results of the view queries are set before this method is invoked.
ngAfterViewChecked	This method is called after the component's view has been checked as part of the change detection process.

In the listing, I implement the ngAfterViewInit method to ensure that Angular has processed the component's template and set the result of the query. Within the method I perform the initial call to the updateViewChildren method, which operates on the PaCellColor objects, and I set up the function that will be called when the query results change, using the QueryList.changes property, as described in Chapter 14. The view children are updated within a call to the setTimeout function, which ensures that the changes are applied without triggering the change detection guard. The result is that the color of every second table cell is changed, as shown in Figure 15-20.

Figure 15-20. *Querying for view children*

■ **Tip**   You may need to combine view child and content child queries if you have used the `ng-content` element. The content defined in the template is queried using the technique shown in Listing 15-32, but the project content—which replaces the `ng-content` element—is queried using the child queries described in Chapter 14.

Summary

In this chapter, I revisited the topic of components and explained how to combine all the features of directives with the ability to provide their own templates. I explained how to structure an application to create small module components and how components can coordinate between themselves using input and output properties. I also showed how components can define CSS styles that are applied only to their templates and no other parts of the application. In the next chapter, I introduce pipes, which are used to prepare data for display in templates.

CHAPTER 16

▪ ▪ ▪

Using and Creating Pipes

Pipes are small fragments of code that transform data values so they can be displayed to the user in templates. Pipes allow transformation logic to be defined in self-contained classes so that it can be applied consistently throughout an application. Table 16-1 puts pipes in context.

Table 16-1. *Putting Pipes in Context*

Question	Answer
What are they?	Pipes are classes that are used to prepare data for display to the user.
Why are they useful?	Pipes allow preparation logic to be defined in a single class that can be used throughout an application, ensuring that data is presented consistently.
How are they used?	The @Pipe decorator is applied to a class and used to specify a name by which the pipe can be used in a template.
Are there any pitfalls or limitations?	Pipes should be simple and focused on preparing data. It can be tempting to let the functionality creep into areas that are the responsibility of other building blocks, such as directives or components.
Are there any alternatives?	You can implement data preparation code in components or directives, but that makes it harder to reuse in other parts of the application.

Table 16-2 summarizes the chapter.

Table 16-2. *Chapter Summary*

Problem	Solution	Listing
Formatting a data value for inclusion in a template	Use a pipe in a data binding expression	1–6
Creating a custom pipe	Apply the @Pipe decorator to a class	7–9
Formatting a data value using multiple pipes	Chain the pipe names together using the bar character	10
Specifying when Angular should reevaluate the output from a pipe	Use the pure property of the @Pipe decorator	11–14
Formatting numerical values	Use the number pipe	15, 16

(*continued*)

Table 16-2. (*continued*)

Problem	Solution	Listing
Formatting currency values	Use the `currency` pipe	17, 18
Formatting percentage values	Use the `percent` pipe	19
Formatting dates	Use the `date` pipe	20–22
Changing the case of strings	Use the `uppercase` or `lowercase` pipe	23, 24
Serializing objects into the JSON format	Use the `json` pipe	25
Selecting elements from an array	Use the `slice` pipe	26
Formatting an object or map as key-value pairs	Use the `keyvalue` pipe	27
Selecting a value to display for a string or number value	Use the `i18nSelect` or `i18nPlural` pipe	28–31
Display events from an observable	Use the `async` pipe	32–34

Preparing the Example Project

I am going to continue working with the example project that was first created in Chapter 9 and that has been expanded and modified in the chapters since. In the final examples in the previous chapter, component styles and view children queries left the application with a strikingly garish appearance that I am going to tone down for this chapter. In Listing 16-1, I have disabled the inline component styles applied to the form elements.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 16-1. Disabling CSS Styles in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation } from "@angular/core";
import { Product } from "./product.model";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    // styleUrls: ["productForm.component.css"],
    // encapsulation: ViewEncapsulation.ShadowDom
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    @Output("paNewProduct")
    newProductEvent = new EventEmitter<Product>();
```

```
    submitForm(form: any) {
        this.newProductEvent.emit(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

To disable the checkerboard coloring of the table cells, I changed the selector for the PaCellColor directive so that it matches an attribute that is not currently applied to the HTML elements, as shown in Listing 16-2.

Listing 16-2. Changing the Selector in the cellColor.directive.ts File in the src/app Folder

```
import { Directive, HostBinding } from "@angular/core";

@Directive({
    selector: "td[paApplyColor]"
})
export class PaCellColor {

    @HostBinding("class")
    bgClass: string = "";

    setColor(dark: Boolean) {
        this.bgClass = dark ? "table-dark" : "";
    }
}
```

Listing 16-3 disables the deep styles defined by the root component.

Listing 16-3. Disabling CSS Styles in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html",
    //styles: ["/deep/ div { border: 2px black solid;  font-style:italic }"]
})
export class ProductComponent {
    model: Model = new Model();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
}
```

The next change is to simplify the ProductTableComponent class to remove methods and properties that are no longer required and add new properties that will be used in later examples, as shown in Listing 16-4.

Listing 16-4. Simplifying the Code in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
//import { PaCellColor } from "./cellColor.directive";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {

    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    // showTable: boolean = true;

    // @ViewChildren(PaCellColor)
    // viewChildren: QueryList<PaCellColor> | undefined;

    // ngAfterViewInit() {
    //     this.viewChildren?.changes.subscribe(() => {
    //         this.updateViewChildren();
    //     });
    //     this.updateViewChildren();
    // }

    // private updateViewChildren() {
    //     setTimeout(() => {
    //         this.viewChildren?.forEach((child, index) => {
    //             child.setColor(index % 2 ? true : false);
    //         })
    //     }, 0);
    // }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;
}
```

Finally, I have removed one of the component elements from the root component's template to disable the checkbox that shows and hides the table, as shown in Listing 16-5.

Listing 16-5. Simplifying the Elements in the template.html File in the src/app Folder

```
<div class="container-fluid angularApp">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
            <pa-productform (paNewProduct)="addProduct($event)"></pa-productform>
        </div>
        <div class="col p-2">
            <!-- <paToggleView> -->
                <paProductTable [model]="model"></paProductTable>
            <!-- </paToggleView> -->
        </div>
    </div>
</div>
```

Run the following command in the example folder to start the Angular development tools:

```
ng serve
```

Open a new browser tab and navigate to http://localhost:4200 to see the content shown in Figure 16-1.

Figure 16-1. *Running the example application*

Understanding Pipes

Pipes are classes that transform data before it is received by a directive or component. That may not sound like an important job, but pipes can be used to perform some of the most commonly required development tasks easily and consistently.

As a quick example to demonstrate how pipes are used, Listing 16-6 applies one of the built-in pipes to transform the values in the Price column of the table displayed by the application.

Listing 16-6. Using a Pipe in the productTable.component.html File in the src/app Folder

```html
<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | currency:"USD":"symbol" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

The syntax for applying a pipe is similar to the style used by command prompts, where a value is "piped" for transformation using the vertical bar symbol (the | character). Figure 16-2 shows the structure of the data binding that contains the pipe.

Figure 16-2. *The anatomy of data binding with a pipe*

The name of the pipe used in Listing 16-6 is currency, and it formats numbers into currency values. Arguments to the pipe are separated by colons (the : character). The first pipe argument specifies the currency code that should be used, which is USD in this case, representing U.S. dollars. The second pipe argument, which is symbol, specifies whether the currency symbol, rather than its code, should be displayed.

When Angular processes the expression, it obtains the data value and passes it to the pipe for transformation. The result produced by the pipe is then used as the expression result for the data binding. In the example, the bindings are string interpolations, and Figure 16-3 shows the results.

Figure 16-3. *The effect of using the currency pipe*

Creating a Custom Pipe

I will return to the built-in pipes that Angular provides later in the chapter, but the best way to understand how pipes work and what they are capable of is to create a custom pipe. I added a file called addTax.pipe.ts in the src/app folder and defined the class shown in Listing 16-7.

Listing 16-7. The Contents of the addTax.pipe.ts File in the src/app Folder

```
import { Pipe } from "@angular/core";

@Pipe({
    name: "addTax"
})
export class PaAddTaxPipe {

    defaultRate: number = 10;

    transform(value: any, rate?: any): number {
        let valueNumber = Number.parseFloat(value);
        let rateNumber = rate == undefined ?
```

```
            this.defaultRate : Number.parseInt(rate);
        return valueNumber + (valueNumber * (rateNumber / 100));
    }
}
```

Pipes are classes to which the `Pipe` decorator has been applied and that implement a method called `transform`. The `Pipe` decorator defines two properties, which are used to configure pipes, as described in Table 16-3.

Table 16-3. *The Pipe Decorator Properties*

Name	Description
name	This property specifies the name by which the pipe is applied in templates.
pure	When `true`, this pipe is reevaluated only when its input value or its arguments are changed. This is the default value. See the "Creating Impure Pipes" section for details.

The example pipe is defined in a class called `PaAddTaxPipe`, and its decorator `name` property specifies that the pipe will be applied using `addTax` in templates. The `transform` method must accept at least one argument, which Angular uses to provide the data value that the pipe formats. The pipe does its work in the `transform` method, and its result is used by Angular in the binding expression. In this example, the `transform` method accepts a number value, and its result is the received value plus sales tax.

The transform method can also define additional arguments that are used to configure the pipe. In the example, the optional `rate` argument can be used to specify the sales tax rate, which defaults to 10 percent.

■ **Caution**   Be careful when dealing with the arguments received by the `transform` method and make sure that you parse or convert them to the types you need. The TypeScript type annotations are not enforced at runtime, and Angular will pass you whatever data values it is working with.

Registering a Custom Pipe

Pipes are registered using the `declarations` property of the Angular module, as shown in Listing 16-8.

Listing 16-8.   Registering a Custom Pipe in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
```

```
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Applying a Custom Pipe

Once a custom pipe has been registered, it can be used in data binding expressions. In Listing 16-9, I have applied the pipe to the price value in the tables and added a select element that allows the tax rate to be specified.

Listing 16-9. Applying the Custom Pipe in the productTable.component.html File in the src/app Folder

```html
<div class="my-2">
    <label>Tax Rate:</label>
    <select class="form-select" [value]="taxRate || 0"
            (change)="taxRate=$any($event).target.value">
        <option value="0">None</option>
        <option value="10">10%</option>
        <option value="20">20%</option>
        <option value="50">50%</option>
    </select>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
```

```
        <td>{{item.category}}</td>
        <td>{{item.price | addTax:(taxRate || 0) }}</td>
        <td class="text-center">
            <button class="btn btn-danger btn-sm"
                (click)="deleteProduct(item.id)">
                Delete
            </button>
        </td>
    </tr>
</tbody>
</table>
```

Just for variety, I defined the tax rate entirely within the template. The `select` element has a binding that sets its `value` property to a component variable called `taxRate` or defaults to 0 if the property has not been defined. The `event` binding handles the `change` event and sets the value of the `taxRate` property. You cannot specify a fallback value when using the `ngModel` directive, which is why I have split up the bindings.

In applying the custom pipe, I have used the vertical bar character, followed by the value specified by the `name` property in the pipe's decorator. The name of the pipe is followed by a colon, which is followed by an expression that is evaluated to provide the pipe with its argument. In this case, the `taxRate` property will be used if it has been defined, with a fallback value of zero.

Pipes are part of the dynamic nature of Angular data bindings, and the pipe's `transform` method will be called to get an updated value if the underlying data value changes or if the expression used for the arguments changes. The dynamic nature of pipes can be seen by changing the value displayed by the select element, which will define or change the `taxRate` property, which will, in turn, update the amount added to the `price` property by the custom pipe, as shown in Figure 16-4.

Figure 16-4. *Using a custom pipe*

Combining Pipes

The `addTax` pipe is applying the tax rate, but the fractional amounts that are produced by the calculation are unsightly—and unhelpful since few tax authorities insist on accuracy to 15 fractional digits.

I could fix this by adding support to the custom pipe to format the number values as currencies, but that would require duplicating the functionality of the built-in `currency` pipe that I used earlier in the chapter. A better approach is to combine the functionality of both pipes so that the output from the custom `addTax` pipe is fed into the built-in `currency` pipe, which is then used to produce the value displayed to the user.

Pipes are chained together in this way using the vertical bar character, and the names of the pipes are specified in the order that data should flow, as shown in Listing 16-10.

Listing 16-10. Combining Pipes in the productTable.component.html File in the src/app Folder

```
...
<td>{{item.price | addTax:(taxRate || 0) | currency:"USD":"symbol"  }}</td>
...
```

The value of the `item.price` property is passed to the `addTax` pipe, which adds the sales tax, and then to the `currency` pipe, which formats the number value into a currency amount, as shown in Figure 16-5.

Figure 16-5. *Combining the functionality of pipes*

Creating Impure Pipes

The `pure` decorator property is used to tell Angular when to call the pipe's `transform` method. The default value for the `pure` property is `true`, which tells Angular that the pipe's transform method will generate a new value only if the input data value—the data value before the vertical bar character in the template—changes or when one or more of its arguments is modified. This is known as a *pure* pipe because it has no independent internal state and all its dependencies can be managed using the Angular change detection process.

449

Setting the pure decorator property to false creates an *impure pipe* and tells Angular that the pipe has its own state data or that it depends on data that may not be picked up in the change detection process when there is a new value.

When Angular performs its change detection process, it treats impure pipes as sources of data values in their own right and invokes the transform methods even when there has been no data value or argument changes.

The most common need for impure pipes is when they process the contents of arrays and the elements in the array change. As you saw in Chapter 14, Angular doesn't automatically detect changes that occur within arrays and won't invoke a pure pipe's transform method when an array element is added, edited, or deleted because it just sees the same array object being used as the input data value.

■ **Caution**   Impure pipes should be used sparingly because Angular has to call the transform method whenever there is any data change or user interaction in the application, just in case it might result in a different result from the pipe. If you do create an impure pipe, then keep it as simple as possible. Performing complex operations, such as sorting an array, can devastate the performance of an Angular application.

As a demonstration, I added a file called categoryFilter.pipe.ts in the src/app folder and used it to define the pipe shown in Listing 16-11.

Listing 16-11. The Contents of the categoryFilter.pipe.ts File in the src/app Folder

```
import { Pipe } from "@angular/core";
import { Product } from "./product.model";

@Pipe({
    name: "filter",
    pure: true
})
export class PaCategoryFilterPipe {

    transform(products: Product[] | undefined, category: string | undefined):
            Product[] {
        if (products == undefined) {
            return [];
        }
        return category == undefined ?
            products : products.filter(p => p.category == category);
    }
}
```

This is a pure filter that receives an array of Product objects and returns only the ones whose category property matches the category argument. Listing 16-12 shows the new pipe registered in the Angular module.

Listing 16-12. Registering a Pipe in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';
```

```
import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Listing 16-13 shows the application of the new pipe to the binding expression that targets the ngFor directive as well as a new select element that allows the filter category to be selected.

Listing 16-13. Applying a Pipe in the productTable.component.html File in the src/app Folder

```
<div class="my-2">
    <label>Tax Rate:</label>
    <select class="form-select" [value]="taxRate || 0"
            (change)="taxRate=$any($event).target.value">
        <option value="0">None</option>
        <option value="10">10%</option>
        <option value="20">20%</option>
        <option value="50">50%</option>
    </select>
</div>

<div class="my-2">
    <label>Category Filter:</label>
    <select class="form-select" [(ngModel)]="categoryFilter">
        <option>Watersports</option>
        <option>Soccer</option>
        <option>Chess</option>
```

```
    </select>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>
                {{item.price | addTax:(taxRate || 0) | currency:"USD":"symbol"  }}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                    (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

To see the problem, use the select element to filter the products in the table so that only those in the Soccer category are shown. Then use the form elements to create a new product in that category. Clicking the Create button will add the product to the data model, but the new product won't be shown in the table, as illustrated in Figure 16-6.

Figure 16-6. *A problem caused by a pure pipe*

452

The table isn't updated because, as far as Angular is concerned, none of the inputs to the `filter` pipe has changed. The component's `getProducts` method returns the same array object, and the `categoryFilter` property is still set to `Soccer`. The fact that there is a new object inside the array returned by the `getProducts` method isn't recognized by Angular.

The solution is to set the pipe's `pure` property to `false`, as shown in Listing 16-14.

Listing 16-14. Marking a Pipe as Impure in the categoryFilter.pipe.ts File in the src/app Folder

```
import { Pipe } from "@angular/core";
import { Product } from "./product.model";

@Pipe({
    name: "filter",
    pure: false
})
export class PaCategoryFilterPipe {

    transform(products: Product[] | undefined, category: string | undefined): Product[] {
        if (products == undefined) {
            return [];
        }
        return category == undefined ?
            products : products.filter(p => p.category == category);
    }
}
```

If you repeat the test, you will see that the new product is now correctly displayed in the table, as shown in Figure 16-7.

Figure 16-7. *Using an impure pipe*

Using the Built-in Pipes

Angular includes a set of built-in pipes that perform commonly required tasks. These pipes are described in Table 16-4 and demonstrated in the sections that follow.

Table 16-4. *The Built-in Pipes*

Name	Description
number	This pipe performs location-sensitive formatting of number values. See the "Formatting Numbers" section for details.
currency	This pipe performs location-sensitive formatting of currency amounts. See the "Formatting Currency Values" section for details.
percent	This pipe performs location-sensitive formatting of percentage values. See the "Formatting Percentages" section for details.
date	This pipe performs location-sensitive formatting of dates. See the "Formatting Dates" section for details.
uppercase	This pipe transforms all the characters in a string to uppercase. See the "Changing String Case" section for details.
Lowercase	This pipe transforms all the characters in a string to lowercase. See the "Changing String Case" section for details.
titlecase	This pipe transforms all the characters in a string to title case. See the "Changing String Case" section for details.
json	This pipe transforms an object into a JSON string. See the "Serializing Data as JSON" section for details.
slice	This pipe selects items from an array or characters from a string, as described in the "Slicing Data Arrays" section.
keyvalue	This pipe transforms an object or map into a series of key-value pairs, as described in the "Formatting Key-Value Pairs" section.
i18nSelect	This pipe selects a text value to display for a set of values, as described in the "Selecting Values" section.
i18nPlural	This pipe selects a pluralized string for a value, as described in the "Pluralizing Values" section.
async	This pipe subscribes to an observable or a promise and displays the most recent value it produces.

Formatting Numbers

The number pipe formats number values using locale-sensitive rules. Listing 16-15 shows the use of the number pipe, along with the argument that specifies the formatting that will be used. I have removed the custom pipes and the associated select elements from the template.

Listing 16-15. Using the number Pipe in the productTable.component.html File in the src/app Folder

```html
<!-- <div class="my-2">
    <label>Tax Rate:</label>
    <select class="form-select" [value]="taxRate || 0"
            (change)="taxRate=$any($event).target.value">
        <option value="0">None</option>
        <option value="10">10%</option>
        <option value="20">20%</option>
        <option value="50">50%</option>
    </select>
</div>

<div class="my-2">
    <label>Category Filter:</label>
    <select class="form-select" [(ngModel)]="categoryFilter">
        <option>Watersports</option>
        <option>Soccer</option>
        <option>Chess</option>
    </select>
</div> -->

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | number:"3.2-2" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

The number pipe accepts a single argument that specifies the number of digits that are included in the formatted result. The argument is in the following format (note the period and hyphen that separate the values and that the entire argument is quoted as a string):

```
"<minIntegerDigits>.<minFactionDigits>-<maxFractionDigits>"
```

Table 16-5 describes each element of the formatting argument.

Table 16-5. *The Elements of the number Pipe Argument*

Name	Description
minIntegerDigits	This value specifies the minimum number of digits. The default value is 1.
minFractionDigits	This value specifies the minimum number of fractional digits. The default value is 0.
maxFractionDigits	This value specifies the maximum number of fractional digits. The default value is 3.

The argument used in the listing is "3.2-2", which specifies that at least three digits should be used to display the integer portion of the number and that two fractional digits should always be used. This produces the result shown in Figure 16-8.

Figure 16-8. *Formatting number values*

The number pipe is location-sensitive, which means that the same format argument will produce differently formatted results based on the user's locale setting. Angular applications default to the en-US locale by default and require other locales to be loaded explicitly, as shown in Listing 16-16.

Listing 16-16. Setting the Locale in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
```

```
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [{ provide: LOCALE_ID, useValue: "fr-FR" }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Setting the locale consists of importing the locale you require from the modules that contain each region's data and registering it by calling the registerLocaleData function, which is imported from the @angular/common module. In the listing, I have imported the fr-FR locale, which is for French as it is spoken in France. The final step is to configure the providers property, which I describe in Chapter 17, but the effect of the configuration in Listing 16-16 is to enable the fr-FR locale, which changes the formatting of the numerical values, as shown in Figure 16-9.

Figure 16-9. *Locale-sensitive formatting*

You can override the application's locale setting by specifying a locale as a configuration option for the pipe, like this:

```
...
<td>{{item.price | number:"3.2-2":"en-US" }}</td>
...
```

Formatting Currency Values

The `currency` pipe formats `number` values that represent monetary amounts. Listing 16-6 used this pipe to introduce the topic, and Listing 16-17 shows another application of the same pipe but with the addition of number format specifiers.

Listing 16-17. Using the currency Pipe in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | currency:"USD":"symbol":"2.2-2" }}</td>
            <td class="text-center">
```

```
            <button class="btn btn-danger btn-sm"
                  (click)="deleteProduct(item.id)">
                Delete
            </button>
        </td>
    </tr>
    </tbody>
</table>
```

The currency pipe can be configured using four arguments, which are described in Table 16-6.

Table 16-6. *The Types of Web Forms Code Nuggets*

Name	Description
currencyCode	This string argument specifies the currency using an ISO 4217 code. The default value is USD if this argument is omitted. You can see a list of currency codes at `http://en.wikipedia.org/wiki/ISO_4217`.
display	This string indicates whether the currency symbol or code should be displayed. The supported values are code (use the currency code), symbol (use the currency symbol), and symbol-narrow (which shows the concise form when a currency has narrow and wide symbols). You can also specify a string to use. The default value is symbol.
digitInfo	This string argument specifies the formatting for the number, using the same formatting instructions supported by the number pipe, as described in the "Formatting Numbers" section.
locale	This string argument specifies the locale for the currency. This defaults to the LOCALE_ID value, the configuration of which is shown in Listing 16-16.

The arguments specified in Listing 16-17 tell the pipe to use the U.S. dollar as the currency (which has the ISO code USD), to display the symbol rather than the code in the output, and to format the number so that it has at least two integer digits and exactly two fraction digits.

This pipe relies on the Internationalization API to get details of the currency—especially its symbol—but doesn't select the currency automatically to reflect the user's locale setting.

This means that the formatting of the number and the position of the currency symbol are affected by the application's locale setting, regardless of the currency that has been specified by the pipe. The example application is still configured to use the fr-FR locale, which produces the results shown in Figure 16-10.

Figure 16-10. *Location-sensitive currency formatting*

To revert to the default locale, Listing 16-18 removes the fr-FR setting from the application's root module.

Listing 16-18. Removing the locale Setting in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

registerLocaleData(localeFr);
```

```
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    //providers: [{ provide: LOCALE_ID, useValue: "fr-FR" }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Figure 16-11 shows the result.

Figure 16-11. *Formatting currency values*

Formatting Percentages

The percent pipe formats number values as percentages, where values between 0 and 1 are formatted to represent 0 to 100 percent. This pipe has optional arguments that are used to specify the number formatting options, using the same format as the number pipe, and override the default locale. Listing 16-19 re-introduces the custom sales tax filter and populates the associated select element with option elements whose content is formatted with the percent filter.

Listing 16-19. Formatting Percentages in the productTable.component.html File in the src/app Folder

```html
<div class="my-2">
    <label>Tax Rate:</label>
    <select class="form-select" [value]="taxRate || 0"
            (change)="taxRate=$any($event).target.value">
        <option value="0">None</option>
        <option value="10">{{ 0.1 | percent }}</option>
        <option value="20">{{ 0.2 | percent }}</option>
        <option value="50">{{ 0.5 | percent }}</option>
        <option value="150">{{ 1.5 | percent }}</option>
    </select>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

Values that are greater than 1 are formatted into percentages greater than 100 percent. You can see this in the last item shown in Figure 16-12, where the value 1.5 produces a formatted value of 150 percent.

Figure 16-12. *Formatting percentage values*

The formatting of percentage values is location-sensitive, although the differences between locales can be subtle. As an example, while the en-US locale produces a result such as 10 percent, with the numerals and the percent sign next to one another, many locales, including fr-FR, will produce a result such as 10 %, with a space between the numerals and the percent sign.

Formatting Dates

The date pipe performs location-sensitive formatting of dates. Dates can be expressed using JavaScript Date objects, as a number value representing milliseconds since the beginning of 1970 or as a well-formatted string. Listing 16-20 adds three properties to the ProductTableComponent class, each of which encodes a date in one of the formats supported by the date pipe.

Listing 16-20. Defining Dates in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {
```

```
    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;

    dateObject: Date = new Date(2020, 1, 20);
    dateString: string = "2020-02-20T00:00:00.000Z";
    dateNumber: number = 1582156800000;
}
```

All three properties describe the same date, which is February 20, 2020. No time has been specified, which means that these values will represent midnight, with no time specified. In Listing 16-21, I have used the date pipe to format all three properties.

Listing 16-21. Formatting Dates in the productTable.component.html File in the src/app Folder

```
<div class="bg-info p-2 text-white">
    <div>Date formatted from object: {{ dateObject | date }}</div>
    <div>Date formatted from string: {{ dateString | date }}</div>
    <div>Date formatted from number: {{ dateNumber | date }}</div>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
            let i = index; let odd = odd;
            let even = even" [class.table-info]="odd" [class.table-warning]="even"
            class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
```

```
                (click)="deleteProduct(item.id)">
                Delete
            </button>
        </td>
    </tr>
</tbody>
</table>
```

The pipe works out which data type it is working with, parses the value to get a date, and then formats it, as shown in Figure 16-13.

Figure 16-13. *Formatting dates*

If you are in a time zone that is to the left of GMT, then you will see Feb 19, 2020, for two of the dates. The first date is expressed relative to the application's time zone, but the others are expressed in the UTC time zone, which means that the dates will be adjusted, as shown in Figure 16-14.

Figure 16-14. *The effect of a different time zone*

The date pipe accepts an argument that specifies the date format that should be used. Individual date components can be selected for the output using the symbols described in Table 16-7. A complete set of supported symbols can be found in the Angular API documentation at https://angular.io/api/common/DatePipe.

Table 16-7. *Useful Date Pipe Format Symbols*

Name	Description
y, yy, yyyy	These symbols select the year.
M, MMM, MMMM	These symbols select the month.
d, dd	These symbols select the day (as a number).
E, EE, EEE, EEEE, EEEEE	These symbols select the day (as a name).
h, hh, H, HH	These symbols select the hour in 12- and 24-hour forms.
m, mm	These symbols select the minutes.
s, ss	These symbols select the seconds.
Z	This symbol selects the time zone.

The symbols in Table 16-7 provide access to the date components in differing levels of brevity so that M will return 2 if the month is February, MM will return 02, MMM will return Feb, and MMMM will return February, assuming that you are using the en-US locale. The date pipe also supports predefined date formats for commonly used combinations, the most useful of which are described in Table 16-8.

Table 16-8. *Useful Predefined date Pipe Formats*

Name	Description
short	This format is equivalent to the component string M/d/yy, h:mm a. It presents the date in a concise format, including the time component.
medium	This format is equivalent to the component string MMM d, y, h:mm:ss a. It presents the date as a more expansive format, including the time component.
shortDate	This format is equivalent to the component string M/d/yy. It presents the date in a concise format and excludes the time component.
mediumDate	This format is equivalent to the component string MMM d, y. It presents the date in a more expansive format and excludes the time component.
longDate	This format is equivalent to the component string MMMM d, y. It presents the date and excludes the time component.
fullDate	This format is equivalent to the component string EEEE, MMMM d, y. It presents the date fully and excludes the date format.
shortTime	This format is equivalent to the component string h:mm a.
mediumTime	This format is equivalent to the component string h:mm:ss a.

The date pipe also accepts arguments that specify a time zone and a locale. Listing 16-22 shows the use of the predefined formats as arguments to the date pipe, rendering the same date in different ways and with different locale settings.

■ **Tip** The time zone argument has to be specified in order to set the locale. Use the empty string ("") as the time zone if you want to use the application's default time zone.

Listing 16-22. Formatting Dates in the productTable.component.html File in the src/app Folder

```html
<div class="bg-info p-2 text-white">
    <div>Date formatted from object: {{ dateObject | date:"shortDate" }}</div>
    <div>Date formatted from string: {{ dateString | date:"mediumDate" }}</div>
    <div>Date formatted from number: {{ dateNumber | date:"longDate" }}</div>
</div>

<div class="bg-info p-2 text-white">
    <div>
        Date formatted from object: {{ dateObject | date:"shortDate":"UTC":"fr-FR" }}
    </div>
    <div>
        Date formatted from string: {{ dateString | date:"mediumDate":"UTC":"fr-FR" }}
    </div>
    <div>
        Date formatted from number: {{ dateNumber | date:"longDate":"UTC":"fr-FR" }}
    </div>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                    (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

Formatting arguments are specified as literal strings. Take care to capitalize the format string correctly because shortDate will be interpreted as one of the predefined formats from Table 16-8, but shortdate (with a lowercase letter d) will be interpreted as a series of characters from Table 16-7 and produce nonsensical output.

■ **Caution**   Date parsing/formatting is a complex and time-consuming process. As a consequence, the pure property for the date pipe is true; as a result, changes to individual components of a Date object won't trigger an update. If you need to reflect changes in the way that a date is displayed, then you must change the reference to the Date object that the binding containing the date pipe refers to.

Figure 16-15 shows the formatted dates, in the en-US and fr-FR locales.

Figure 16-15. *Location-sensitive date formatting*

UNDERSTANDING THE IMPACT OF LAZY LOCALIZATION

Localizing a product takes time, effort, and resources, and it needs to be done by someone who understands the linguistic, cultural, and monetary conventions of the target country or region. If you don't localize properly, then the result can be worse than not localizing at all.

It is for this reason that I don't describe localization features in detail in this book—or any of my books. Describing features outside of the context in which they will be used feels like setting up readers for a self-inflicted disaster. At least if a product isn't localized, the user knows where they stand and doesn't have to try to figure out whether you just forgot to change the currency code or whether those prices are really in U.S. dollars. (This is an issue that I see all the time living in the United Kingdom.)

You *should* localize your products. Your users *should* be able to do business or perform other operations in a way that makes sense to them. But you *must* take it seriously and allocate the time and effort required to do it properly.

Changing String Case

The uppercase, lowercase, and titlecase pipes convert all the characters in a string to uppercase or lowercase, respectively. Listing 16-23 shows the first two pipes applied to cells in the product table. This listing also removes the dates used in the previous section.

Listing 16-23. Changing Character Case in the productTable.component.html File in the src/app Folder

```
<!-- <div class="bg-info p-2 text-white">
    <div>Date formatted from object: {{ dateObject | date:"shortDate" }}</div>
    <div>Date formatted from string: {{ dateString | date:"mediumDate" }}</div>
    <div>Date formatted from number: {{ dateNumber | date:"longDate" }}</div>
</div>

<div class="bg-info p-2 text-white">
    <div>Date formatted from object: {{ dateObject | date:"shortDate":"UTC":"fr-FR" }}</div>
    <div>Date formatted from string: {{ dateString | date:"mediumDate":"UTC":"fr-FR"
}}</div>
    <div>Date formatted from number: {{ dateNumber | date:"longDate":"":"fr-FR" }}</div>
</div> -->

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name | uppercase }}</td>
            <td>{{item.category | lowercase }}</td>
            <td>
                {{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                    (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

These pipes use the standard JavaScript string methods toUpperCase and toLowerCase, which are not sensitive to locale settings, as shown in Figure 16-16.

Figure 16-16. *Changing character case*

The `titlecase` pipe capitalizes the first character of each word and uses lowercase for the remaining characters. Listing 16-24 applies the `titlecase` pipe to the table cells.

Listing 16-24. Applying the Pipe in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name | titlecase }}</td>
            <td>{{item.category | lowercase }}</td>
            <td>
                {{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

Figure 16-17 shows the effect of the pipe.

Figure 16-17. *Using the titlecase pipe*

Serializing Data as JSON

The json pipe creates a JSON representation of a data value. No arguments are accepted by this pipe, which uses the browser's JSON.stringify method to create the JSON string. Listing 16-25 applies this pipe to create a JSON representation of the objects in the data model.

Listing 16-25. Creating a JSON String in the productTable.component.html File in the src/app Folder

```html
<div class="bg-info p-2 text-white">
    <div>{{ getProducts() | json }}</div>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | filter:categoryFilter;
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name | titlecase }}</td>
            <td>{{item.category | lowercase }}</td>
            <td>{{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}
            </td>
```

471

```
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                    (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

This pipe is useful during debugging, and its decorator's pure property is false so that any change in the application will cause the pipe's transform method to be invoked, ensuring that even collection-level changes are shown. Figure 16-18 shows the JSON generated from the objects in the example application's data model.

Figure 16-18. *Generating JSON strings for debugging*

Slicing Data Arrays

The slice pipe operates on an array or string and returns a subset of the elements or characters it contains. This is an impure pipe, which means it will reflect any changes that occur within the data object it is operating on but also means that the slice operation will be performed after any change in the application, even if that change was not related to the source data.

The objects or characters selected by the slice pipe are specified using two arguments, which are described in Table 16-9.

Table 16-9. *The Slice Pipe Arguments*

Name	Description
start	This argument must be specified. If the value is positive, the start index for items to be included in the result counts from the first position in the array. If the value is negative, then the pipe counts back from the end of the array.
end	This optional argument is used to specify how many items from the start index should be included in the result. If this value is omitted, all the items after the start index (or before in the case of negative values) will be included.

Listing 16-26 demonstrates the use of the slice pipe in combination with a select element that specifies how many items should be displayed in the product table.

Listing 16-26. Using the slice Pipe in the productTable.component.html File in the src/app Folder

```html
<div class="form-group my-2">
    <label>Number of items:</label>
    <select class="form-select" [value]="itemCount ?? 1"
            (change)="itemCount=$any($event).target.value">
        <option *ngFor="let item of getProducts(); let i = index" [value]="i + 1"
                [selected]="(i + 1) === itemCount">
            {{i + 1}}
        </option>
    </select>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead class="table-light">
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts() | slice:0:(itemCount ?? 1);
                let i = index; let odd = odd;
                let even = even" [class.table-info]="odd" [class.table-warning]="even"
                class="align-middle">
            <td>{{i + 1}}</td>
            <td>{{item.name | titlecase }}</td>
            <td>{{item.category | lowercase }}</td>
            <td>{{item.price | addTax:(taxRate ?? 0)
                    | currency:"USD":"symbol":"2.2-2" }}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

The `select` element is populated with `option` elements created with the `ngFor` directive. This directive doesn't directly support iterating a specific number of times, so I have used the `index` variable to generate the values that are required. The `select` element sets a property called `itemCount`, which is used as the second argument of the `slice` pipe, like this:

```
...
<tr *paFor="let item of getProducts() | slice:0:(itemCount ?? 1);
    let i = index; let odd = odd;
    let even = even" [class.table-info]="odd" [class.table-warning]="even"
    class="align-middle">
...
```

The effect is that changing the value displayed by the `select` element changes the number of items displayed in the product table, as shown in Figure 16-19.

Figure 16-19. *Using the slice pipe*

Formatting Key-Value Pairs

The `keyvalue` pipe operates on an object or a map and returns a sequence of key-value pairs. Each object in the sequence is represented as an object with key and value properties, and Listing 16-27 replaces the contents of the `productTable.component.html` file to demonstrate the use of the pipe to enumerate the contents of the array returned by the `getProducts` method.

Listing 16-27. Using the keyvalue Pipe in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead><tr><th>Key</th><th>Value</th></tr></thead>
    <tbody>
        <tr *paFor="let item of getProducts() | keyvalue">
            <td>{{ item.key }}</td>
```

```
                <td>{{ item.value | json }}</td>
            </tr>
        </tbody>
</table>
```

When used on an array, the keys are the array indexes, and the values are the objects in the array. The objects in the array are formatted using the json filter, producing the results shown in Figure 16-20.

Figure 16-20. *Using the keyvalue pipe*

Selecting Values

The i18nSelect pipe selects a string based on a value, allowing context-sensitive values to be displayed to the user. The mapping between values and strings is defined as a simple map, as shown in Listing 16-28.

Listing 16-28. Mapping Values to Strings in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {

    @Input("model")
    dataModel: Model | undefined;
```

```
    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;

    // dateObject: Date = new Date(2020, 1, 20);
    // dateString: string = "2020-02-20T00:00:00.000Z";
    // dateNumber: number = 1582156800000;

    selectMap = {
        "Watersports": "stay dry",
        "Soccer": "score goals",
        "other": "have fun"
    }
}
```

The other mapping is used as a fallback when there is no match with the other values. In Listing 16-29, I have applied the pipe to select a message to display to the user.

Listing 16-29. Using the Pipe in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead><tr><th>Name</th><th>Category</th><th>Message</th></tr></thead>
    <tbody>
        <tr *paFor="let item of getProducts()">
            <td>{{ item.name }}</td>
            <td>{{ item.category }}</td>
            <td>Helps you {{ item.category | i18nSelect:selectMap }} </td>
        </tr>
    </tbody>
</table>
```

The pipe is provided with the map as an argument and produces the response shown in Figure 16-21.

Figure 16-21. *Selecting values using the i18nSelect pipe*

Pluralizing Values

The `i18nPlural` pipe is used to select an expression that describes a numeric value. The mapping between values and expressions is expressed as a simple map, as shown in Listing 16-30.

Listing 16-30. Mapping Numbers to Strings in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {

    // ...other statments omitted for brevity...

    selectMap = {
        "Watersports": "stay dry",
        "Soccer": "score goals",
        "other": "have fun"
    }

    numberMap = {
        "=1": "one product",
```

477

```
        "=2": "two products",
        "other": "# products"
    }
}
```

Each mapping is expressed with an equals sign followed by the number. The other value is a fallback, and the result it produces can refer to the number value using the # placeholder character. Listing 16-31 shows the results that can be produced using the example mappings.

Listing 16-31. Using the Pipe in the productTable.component.html File in the src/app Folder

```html
<table class="table table-sm table-bordered table-striped">
    <thead>    <tr><th>Name</th><th>Category</th><th>Message</th></tr></thead>
    <tbody>
        <tr *paFor="let item of getProducts()">
            <td>{{ item.name }}</td>
            <td>{{ item.category }}</td>
            <td>Helps you {{ item.category | i18nSelect:selectMap }} </td>
        </tr>
    </tbody>
</table>

<div class="bg-info text-white p-2">
    <div>There are {{ 1 | i18nPlural:numberMap }} </div>
    <div>There are {{ 2 | i18nPlural:numberMap }} </div>
    <div>There are {{ 100 | i18nPlural:numberMap }} </div>
</div>
```

The mapping is specified as the argument to the pipe, and the values in Listing 16-31 produce the result shown in Figure 16-22.

Figure 16-22. *Selecting values using the i18nPlural pipe*

Using the Async Pipe

Angular includes the async pipe, which can be used to consume Observable objects directly in a view, selecting the last object received from the event sequence. This is an impure pipe because its changes are driven from outside of the view in which it is used, meaning that its transform method will be called often, even if a new event has not been received from the Observable.

You can see this pipe used in later chapters to receive events from observables provided by the Angular API, but for this chapter, I am going to generate test events. Listing 16-32 adds a Subject<number> property to the ProductTableComponent class and uses it to generate a sequence of events.

Listing 16-32. Adding a Subject in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
import { Subject } from "rxjs";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
```

```
export class ProductTableComponent {

    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;

    selectMap = {
        "Watersports": "stay dry",
        "Soccer": "score goals",
        "other": "have fun"
    }

    numberMap = {
        "=1": "one product",
        "=2": "two products",
        "other": "# products"
    }

    numbers: Subject<number> = new Subject<number>();

    ngOnInit() {
        let counter = 100;
        setInterval(() => {
            this.numbers.next(counter += 10)
        }, 1000);
    }
}
```

Listing 16-33 applies the async pipe to display the values received from the observable.

Listing 16-33. Using the Async Pipe in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>    <tr><th>Name</th><th>Category</th><th>Message</th></tr></thead>
    <tbody>
        <tr *paFor="let item of getProducts()">
            <td>{{ item.name }}</td>
```
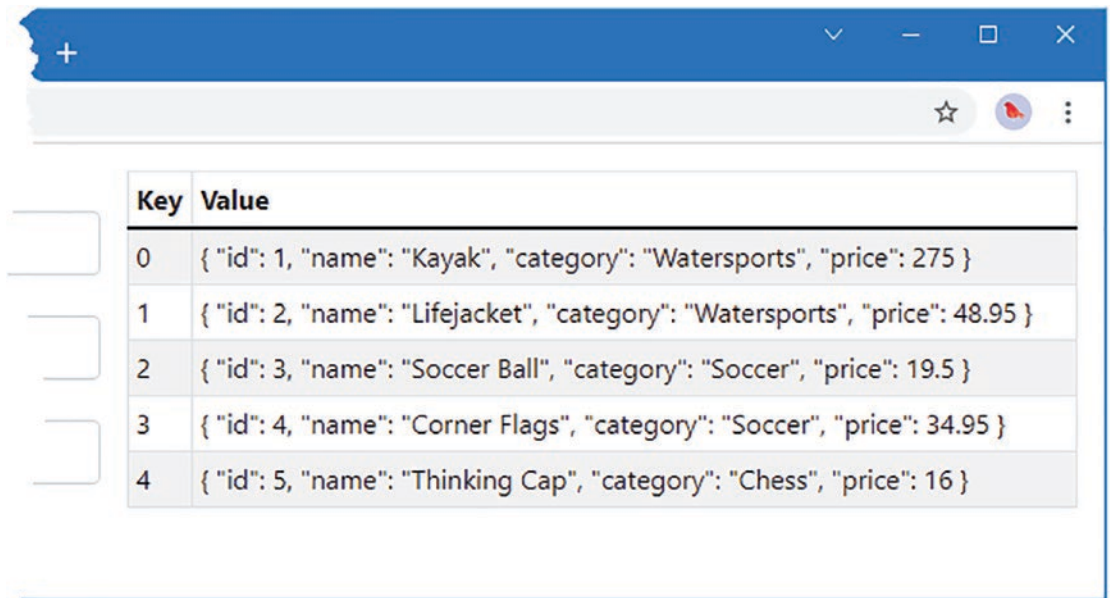

```
            <td>{{ item.category }}</td>
            <td>Helps you {{ item.category | i18nSelect:selectMap }} </td>
        </tr>
    </tbody>
</table>

<div class="bg-info text-white p-2">
    <div> Counter: {{ numbers | async }} </div>
</div>
```

The string interpolation binding expression gets the numbers property from the component and passes it to the async pipe, which keeps track of the most recent event that has been received, as shown in Figure 16-23.

Figure 16-23. *Using the async pipe*

The async pipe can be used with other pipes, such as the currency pipe shown in Listing 16-34.

Listing 16-34. Combining Pipes in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>    <tr><th>Name</th><th>Category</th><th>Message</th></tr></thead>
    <tbody>
        <tr *paFor="let item of getProducts()">
            <td>{{ item.name }}</td>
            <td>{{ item.category }}</td>
```

```
            <td>Helps you {{ item.category | i18nSelect:selectMap }} </td>
        </tr>
    </tbody>
</table>

<div class="bg-info text-white p-2">
    <div> Counter: {{ numbers | async | currency:"USD":"symbol":"2.2-2" }} </div>
</div>
```

As each event is received, it is passed from the async pipe to the currency pipe, producing the result shown in Figure 16-24.

Figure 16-24. *Combining pipes*

Summary

In this chapter, I introduced pipes and explained how they are used to transform data values so they can be presented to the user in the template. I demonstrated the process for creating custom pipes, explained how some pipes are pure and others are not, and demonstrated the built-in pipes that Angular provides for handling common tasks. In the next chapter, I introduce services, which can be used to simplify the design of Angular applications and allow building blocks to easily collaborate.

■ ■ ■

Using Services

Services are objects that provide common functionality to support other building blocks in an application, such as directives, components, and pipes. What's important about services is the way that they are used, which is through a process called *dependency injection*. Using services can increase the flexibility and scalability of an Angular application, but dependency injection can be a difficult topic to understand. To that end, I start this chapter slowly and explain the problems that services and dependency injection can be used to solve, how dependency injection works, and why you should consider using services in your own projects. In Chapter 18, I introduce some more advanced features that Angular provides for service. Table 17-1 puts services in context.

Table 17-1. *Putting Services in Context*

Question	Answer
What are they?	Services are objects that define the functionality required by other building blocks such as components or directives. What separates services from regular objects is that they are provided to building blocks by an external provider, rather than being created directly using the `new` keyword or received by an input property.
Why are they useful?	Services simplify the structure of applications, make it easier to move or reuse functionality, and make it easier to isolate building blocks for effective unit testing.
How are they used?	Classes declare dependencies on services using constructor parameters, which are then resolved using the set of services for which the application has been configured. Services are classes to which the `@Injectable` decorator has been applied.
Are there any pitfalls or limitations?	Dependency injection is a contentious topic, and not all developers like using it. If you don't perform unit tests or if your applications are relatively simple, the extra work required to implement dependency injection is unlikely to pay any long-term dividends.
Are there any alternatives?	Services and dependency injection are hard to avoid because Angular uses them to provide access to built-in functionality. But you are not required to define services for your own custom functionality if that is your preference.

Table 17-2 summarizes the chapter.

Table 17-2. *Chapter Summary*

Problem	Solution	Listing
Avoiding the need to distribute shared objects manually	Use services	1–14, 21–28
Declaring a dependency on a service	Add a constructor parameter with the type of the service you require	15–20

Preparing the Example Project

I continue using the example project in this chapter that I have been working with since Chapter 9. To prepare for this chapter, I have replaced the contents of the template for the ProductTable component with the elements shown in Listing 17-1.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 17-1. Replacing the Contents of the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | currency:"USD":"symbol" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>
```

Run the following command in the example folder to start the TypeScript compiler and the development HTTP server:

```
ng serve
```

Open a new browser window and navigate to `http://localhost:4200` to see the content shown in Figure 17-1.

Figure 17-1. *Running the example application*

Understanding the Object Distribution Problem

In Chapter 15, I added components to the project to help break up the monolithic structure of the application. In doing this, I used input and output properties to connect components, using host elements to bridge the isolation that Angular enforces between a parent component and its children. I also showed you how to query the contents of the template for view children, which complements the content children feature described in Chapter 14.

These techniques for coordinating between directives and components can be powerful and useful if applied carefully. But they can also end up as a general tool for distributing shared objects throughout an application, where the result is to increase the complexity of the application and to tightly bind components together.

Demonstrating the Problem

To help demonstrate the problem, I am going to add a shared object to the project and two components that rely on it. I created a file called `discount.service.ts` to the `src/app` folder and defined the class shown in Listing 17-2. I'll explain the significance of the `service` part of the filename later in the chapter.

Listing 17-2. The Contents of the discount.service.ts File in the src/app Folder

```
export class DiscountService {
    private discountValue: number = 10;

    public get discount(): number {
        return this.discountValue;
    }
}
```

```
    public set discount(newValue: number) {
        this.discountValue = newValue ?? 0;
    }

    public applyDiscount(price: number) {
        return Math.max(price - this.discountValue, 5);
    }
}
```

The `DiscountService` class defines a private property called `discountValue` that is used to store a number that will be used to reduce the product prices in the data model. This value is exposed through getters and setters called `discount`, and there is a convenience method called `applyDiscount` that reduces a price while ensuring that a price is never less than $5.

For the first component that makes use of the `DiscountService` class, I added a file called `discountDisplay.component.ts` to the `src/app` folder and added the code shown in Listing 17-3.

Listing 17-3. The Contents of the discountDisplay.component.ts File in the src/app Folder

```
import { Component, Input } from "@angular/core";
import { DiscountService } from "./discount.service";

@Component({
    selector: "paDiscountDisplay",
    template: `<div class="bg-info text-white p-2 my-2">
                The discount is {{discounter?.discount }}
              </div>`
})
export class PaDiscountDisplayComponent {

    @Input("discounter")
    discounter?: DiscountService;
}
```

The `DiscountDisplayComponent` uses an inline template to display the discount amount, which is obtained from a `DiscountService` object received through an `input` property.

For the second component that makes use of the `DiscountService` class, I added a file called `discountEditor.component.ts` to the `src/app` folder and added the code shown in Listing 17-4.

Listing 17-4. The Contents of the discountEditor.component.ts File in the src/app Folder

```
import { Component, Input } from "@angular/core";
import { DiscountService } from "./discount.service";

@Component({
    selector: "paDiscountEditor",
    template: `<div class="form-group">
                <label>Discount</label>
                <ng-template [ngIf]="discounter?.discount ?? false">
                    <input [(ngModel)]="discounter!.discount"
                        class="form-control" type="number" />
                </ng-template>
```

```
            </div>`
})
export class PaDiscountEditorComponent {

    @Input("discounter")
    discounter?: DiscountService;
}
```

The `DiscountEditorComponent` uses an inline template with an `input` element that allows the discount amount to be edited. The `input` element has a two-way binding on the `DiscountService.discount` property that targets the `ngModel` directive. Listing 17-5 shows the new components being enabled in the Angular module.

Listing 17-5. Enabling the Components in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent],
```

487

```
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    // providers: [{ provide: LOCALE_ID, useValue: "fr-FR" }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

To get the new components working, I added them to the parent component's template, positioning the new content underneath the table that lists the products, which means that I need to edit the productTable. component.html file, as shown in Listing 17-6.

Listing 17-6. Adding Component Elements in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | currency:"USD":"symbol" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>

<paDiscountEditor [discounter]="discounter"></paDiscountEditor>
<paDiscountDisplay [discounter]="discounter"></paDiscountDisplay>
```
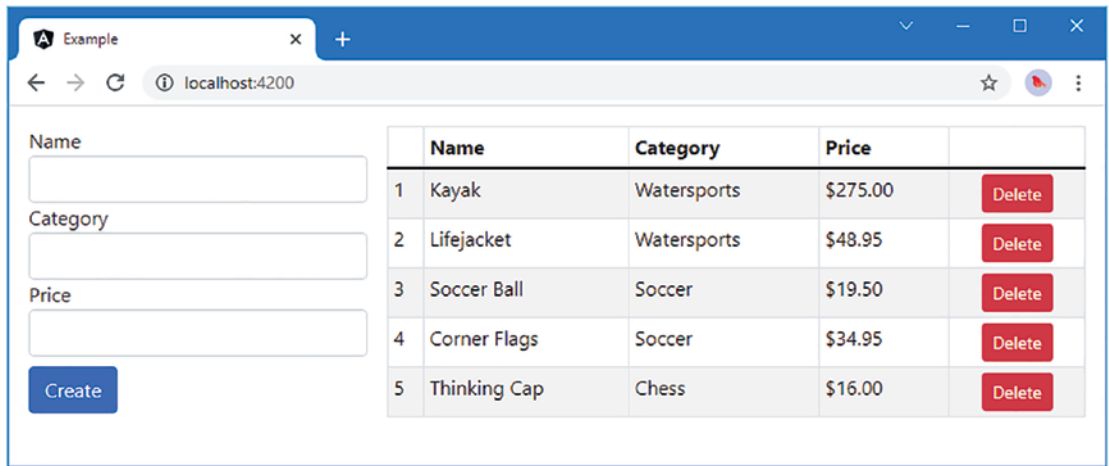

These elements correspond to the components' selector properties in Listing 17-3 and Listing 17-4 and use data bindings to set the value of the input properties. The final step is to create an object in the parent component that will provide the value for the data binding expressions, as shown in Listing 17-7.

Listing 17-7. Creating the Shared Object in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
//import { Subject } from "rxjs";
import { DiscountService } from "./discount.service";
```

```
@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {
    discounter: DiscountService = new DiscountService();

    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;

    // selectMap = {
    //     "Watersports": "stay dry",
    //     "Soccer": "score goals",
    //     "other": "have fun"
    // }

    // numberMap = {
    //     "=1": "one product",
    //     "=2": "two products",
    //     "other": "# products"
    // }

    // numbers: Subject<number> = new Subject<number>();

    // ngOnInit() {
    //     let counter = 100;
    //     setInterval(() => {
    //         this.numbers.next(counter += 10)
    //     }, 1000);
    // }
}
```

Figure 17-2 shows the content from the new components. Changes to the value in the input element provided by one of the components will be reflected in the content presented by the other component, reflecting the use of the shared DiscountService object and its discount property.

Figure 17-2. *Adding components to the example application*

The process for adding the new components and the shared object was straightforward and logical, until the final stage. The problem arises in the way that I had to create and distribute the shared object: the instance of the `DiscountService` class.

Because Angular isolates components from one another, I had no way to share the `DiscountService` object directly between the `DiscountEditorComponent` and `DiscountDisplayComponent`. Each component could have created its own `DiscountService` object, but that means changes from the editor component wouldn't be shown in the display component.

That is what led me to create the `DiscountService` object in the product table component, which is the first shared ancestor of the discount editor and display components. This allowed me to distribute the `DiscountService` object through the product table component's template, ensuring that a single object was shared with both of the components that need it.

But there are a couple of problems. The first is that the `ProductTableComponent` class doesn't actually need or use a `DiscountService` object to deliver its own functionality. It just happens to be the first common ancestor of the components that do need the object. And creating the shared object in the `ProductTableComponent` class makes that class slightly more complex and slightly more difficult to test effectively. This is a modest increment of complexity, but it will occur for every shared object that the application requires—and a complex application can depend on a lot of shared objects, each of which ends up being created by components that just happen to be the first common ancestor of the classes that depend on them.

The second problem is hinted at by the term *first common ancestor*. The `ProductTableComponent` class happens to be the parent of both of the classes that depend on the `DiscountService` object, but think about what would happen if I wanted to move the `DiscountEditorComponent` so that it was displayed under the form rather than the table. In this situation, I have to work my way up the tree of components until I find a common ancestor, which would end up being the root component. Then I would have to work my way down the component tree adding input properties and modifying templates so that each intermediate component could receive the `DiscountService` object from its parent and pass it on to any children that have

descendants that need it. The same applies to any directives that depend on receiving a `DiscountService` object, where any component whose template contains data bindings that target that directive must make sure they are part of the distribution chain, too.

The result is that the components and directives in the application become tightly bound together. A major refactoring is required if you need to move or reuse a component in a different part of the application and the management of the input properties and data bindings becomes unmanageable.

Distributing Objects as Services Using Dependency Injection

There is a better way to distribute objects to the classes that depend on them, which is to use *dependency injection*, where objects are provided to classes from an external source. Angular includes a built-in dependency injection system and supplies the external source of objects, known as *providers*. In the sections that follow, I rework the example application to provide the `DiscountService` object without needing to use the component hierarchy as a distribution mechanism.

Preparing the Service

Any object that is managed and distributed through dependency injection is called a *service*, which is why I selected the name `DiscountService` for the class that defines the shared object and why that class is defined in a file called discount.service.ts. Angular denotes service classes using the `@Injectable` decorator, as shown in Listing 17-8. The `@Injectable` decorator doesn't define any configuration properties.

Listing 17-8. Preparing a Class as a Service in the discount.service.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";

@Injectable()
export class DiscountService {
    private discountValue: number = 10;

    public get discount(): number {
        return this.discountValue;
    }

    public set discount(newValue: number) {
        this.discountValue = newValue || 0;
    }

    public applyDiscount(price: number) {
        return Math.max(price - this.discountValue, 5);
    }
}
```

■ **Tip** Strictly speaking, the `@Injectable` decorator is required only when a class has its own constructor arguments to resolve, but it is a good idea to apply it anyway because it serves as a signal that the class is intended for use as a service.

Preparing the Dependent Components

A class declares dependencies using its constructor. When Angular needs to create an instance of the class—such as when it finds an element that matches the selector property defined by a component—its constructor is inspected, and the type of each argument is examined. Angular then uses the services that have been defined to try to satisfy the dependencies. The term *dependency injection* arises because each dependency is *injected* into the constructor to create the new instance.

For the example application, it means that the components that depend on a DiscountService object no longer require input properties and can declare a constructor dependency instead. Listing 17-9 shows the changes to the DiscountDisplayComponent class.

Listing 17-9. Declaring a Dependency in the discountDisplay.component.ts File in the src/app Folder

```typescript
import { Component, Input } from "@angular/core";
import { DiscountService } from "./discount.service";

@Component({
    selector: "paDiscountDisplay",
    template: `<div class="bg-info text-white p-2 my-2">
                 The discount is {{discounter?.discount }}
               </div>`
})
export class PaDiscountDisplayComponent {

    constructor(public discounter: DiscountService) { }

    // @Input("discounter")
    // discounter?: DiscountService;
}
```

The same change can be applied to the DiscountEditorComponent class, replacing the input property with a dependency declared through the constructor, as shown in Listing 17-10.

Listing 17-10. Declaring a Dependency in the discountEditor.component.ts File in the src/app Folder

```typescript
import { Component, Input } from "@angular/core";
import { DiscountService } from "./discount.service";

@Component({
    selector: "paDiscountEditor",
    template: `<div class="form-group">
                   <label>Discount</label>
                   <input [(ngModel)]="discounter.discount"
                       class="form-control" type="number" />
               </div>`
})
export class PaDiscountEditorComponent {

    constructor(public discounter: DiscountService) { }

    // @Input("discounter")
    // discounter?: DiscountService;
}
```

These are small changes, but they avoid the need to distribute objects using templates and input properties and produce a more flexible application. And, since the value of the discounter property is set in the constructor, I can simplify the template so that it doesn't need to deal with undefined values.

I can now remove the DiscountService object from the product table component, as shown in Listing 17-11.

Listing 17-11. Removing the Shared Object in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
//import { Subject } from "rxjs";
import { DiscountService } from "./discount.service";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {
    //discounter: DiscountService = new DiscountService();

    @Input("model")
    dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;
}
```

Since the parent component is no longer providing the shared object through data bindings, I can remove them from the template, as shown in Listing 17-12.

Listing 17-12. Removing the Data Bindings in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index">
```

493

```
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | currency:"USD":"symbol" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>

<paDiscountEditor></paDiscountEditor>
<paDiscountDisplay></paDiscountDisplay>
```

Registering the Service

The final change is to configure the dependency injection feature so that it can provide DiscountService objects to the components that require them. To make the service available throughout the application, it is registered in the Angular module, as shown in Listing 17-13.

Listing 17-13. Registering a Service in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';
```

```
import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The `NgModule` decorator's `providers` property is set to an array of the classes that will be used as services. There is only one service at the moment, which is provided by the `DiscountService` class.

When you save the changes to the application, there won't be any visual changes, but the dependency injection feature will be used to provide the components with the `DiscountService` object they require.

Reviewing the Dependency Injection Changes

Angular seamlessly integrates dependency injection into its feature set. Each time that Angular encounters an element that requires a new building block, such as a component or a pipe, it examines the class constructor to check what dependencies have been declared and uses its services to try to resolve them. The set of services used to resolve dependencies includes the custom services defined by the application, such as the `DiscountService` service that was registered in Listing 17-13, and a set of built-in services provided by Angular that will be described in later chapters.

The changes to introduce dependency injection in the previous section didn't result in a big-bang change in the way that the application works—or any visible change at all. But there is a profound difference in the way that the application is put together that makes it more flexible and fluid. The best demonstration of this is to add the components that require the `DiscountService` to a different part of the application, as shown in Listing 17-14.

Listing 17-14. Adding Components in the productForm.component.html File in the src/app Folder

```
<form #form="ngForm" (ngSubmit)="submitForm(form)">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control"
            name="name" [(ngModel)]="newProduct.name" />
    </div>
```

495

```
    <div class="form-group">
        <label>Category</label>
        <input class="form-control"
            name="category" [(ngModel)]="newProduct.category" />
    </div>
    <div class="form-group">
        <label>Price</label>
        <input class="form-control"
            name="name" [(ngModel)]="newProduct.price" />
    </div>
    <button class="btn btn-primary mt-2" type="submit">
            Create
    </button>
</form>
```

```
<paDiscountEditor></paDiscountEditor>
<paDiscountDisplay></paDiscountDisplay>
```

These new elements duplicate the discount display and editor components so they appear below the form used to create new products, as shown in Figure 17-3.

Figure 17-3. *Duplicating components with dependencies*

There are two points of note. First, using dependency injection made this a simple process of adding elements to a template, without needing to modify the ancestor components to provide a DiscountService object using input properties.

The second point of note is that all the components in the application that have declared a dependency on DiscountService have received the same object. If you edit the value in either of the input elements, the changes will be reflected in the other input element and in the string interpolation bindings, as shown in Figure 17-4.

Figure 17-4. *Checking that the dependency is resolved using a shared object*

Declaring Dependencies in Other Building Blocks

It isn't just components that can declare constructor dependencies. Once you have defined a service, you can use it more widely, including other building blocks in the application, such as pipes and directives, as demonstrated in the sections that follow.

Declaring a Dependency in a Pipe

Pipes can declare dependencies on services by defining a constructor with arguments for each required service. To demonstrate, I added a file called discount.pipe.ts to the src/app folder and used it to define the pipe shown in Listing 17-15.

Listing 17-15. The Contents of the discount.pipe.ts File in the src/app Folder

```
import { Pipe } from "@angular/core";
import { DiscountService } from "./discount.service";

@Pipe({
    name: "discount",
    pure: false
})
export class PaDiscountPipe {

    constructor(private discount: DiscountService) { }

    transform(price: number): number {
        return this.discount.applyDiscount(price);
    }
}
```

The PaDiscountPipe class is a pipe that receives a price and generates a result by calling the DiscountService.applyDiscount method, where the service is received through the constructor. The pure property in the Pipe decorator is false, which means that the pipe will be asked to update its result when the value stored by the DiscountService changes, which won't be recognized by the Angular change-detection process.

■ **Tip** This feature should be used with caution because it means that the `transform` method will be called after every change in the application, not just when the service is changed.

Listing 17-16 shows the new pipe being registered in the application's Angular module.

Listing 17-16. Registering a Pipe in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe],
```

```
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Listing 17-17 shows the new pipe applied to the Price column in the product table.

Listing 17-17. Applying a Pipe in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td>{{item.price | discount | currency:"USD":"symbol" }}</td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>

<paDiscountEditor></paDiscountEditor>
<paDiscountDisplay></paDiscountDisplay>
```

The discount pipe processes the price to apply the discount and then passes on the value to the currency pipe for formatting. You can see the effect of using the service in the pipe by changing the value in one of the discount input elements, as shown in Figure 17-5.

Figure 17-5. *Using a service in a pipe*

Declaring Dependencies in Directives

Directives can also use services. As I explained in Chapter 15, components are just directives with templates, so anything that works in a component will also work in a directive.

To demonstrate using a service in a directive, I added a file called `discountAmount.directive.ts` to the src/app folder and used it to define the directive shown in Listing 17-18.

Listing 17-18. The Contents of the discountAmount.directive.ts File in the src/app Folder

```
import { Directive, Input,SimpleChange, KeyValueDiffer,
    KeyValueDiffers } from "@angular/core";
import { DiscountService } from "./discount.service";

@Directive({
    selector: "td[pa-price]",
    exportAs: "discount"
})
export class PaDiscountAmountDirective {
    private differ?: KeyValueDiffer<any, any>;

    constructor(private keyValueDiffers: KeyValueDiffers,
        private discount: DiscountService) { }

    @Input("pa-price")
    originalPrice?: number;

    discountAmount?: number;
```

```
    ngOnInit() {
        this.differ =
            this.keyValueDiffers.find(this.discount).create();
    }

    ngOnChanges(changes: { [property: string]: SimpleChange }) {
        if (changes["originalPrice"] != null) {
            this.updateValue();
        }
    }

    ngOnCheck() {
        if (this.differ?.diff(this.discount) != null) {
            this.updateValue();
        }
    }

    private updateValue() {
        this.discountAmount = this.discount.applyDiscount(this.originalPrice ?? 0);
    }
}
```

Directives don't have an equivalent to the pure property used by pipes and must take direct responsibility for responding to changes propagated through services. This directive displays the discounted amount for a product. The selector property matches td elements that have a pa-price attribute, which is also used as an input property to receive the price that will be discounted. The directive exports its functionality using the exportAs property and provides a property called discountAmount whose value is set to the discount that has been applied to the product.

There are two other points to note about this directive. The first is that the DiscountService object isn't the only constructor parameter in the directive's class.

```
...
constructor(private keyValueDiffers: KeyValueDiffers,
    private discount: DiscountService) { }
...
```

The KeyValueDiffers parameter is also a dependency that Angular will have to resolve when it creates a new instance of the directive class. This is an example of the built-in services that Angular provides that deliver commonly required functionality.

The second point of note is what the directive does with the services it receives. The components and the pipe that use the DiscountService service don't have to worry about tracking updates, either because Angular automatically evaluates the expressions of the data bindings and updates them when the discount rate change (for the components) or because any change in the application triggers an update (for the impure pipe). The data binding for this directive is on the price property, which will trigger a change if is altered. But there is also a dependency on the discount property defined by the DiscountService class. Changes in the discount property are detected using the service received through the constructor, which tracks changes as described in Chapter 14. When Angular invokes the ngDoCheck method, the directive uses the key-value pair differ to see whether there has been a change. (This change direction could also have been handled by keeping track of the previous update in the directive class, but I wanted to provide an example of using the key-value differ feature.)

501

The directive also implements the ngOnChanges method so that it can respond to changes in the value of the input property. For both types of update, the updateValue method is called, which calculates the discounted price and assigns it to the discountAmount property.

Listing 17-19 registers the new directive in the application's Angular module.

Listing 17-19. Registering a Directive in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
```

```
    providers: [DiscountService],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

To apply the new directive, Listing 17-20 adds a new column to the table, using a string interpolation binding to access the property provided by the directive and to pass it to the currency pipe.

Listing 17-20. Creating a New Column in the productTable.component.html File in the src/app Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td [pa-price]="item.price" #discount="discount">
                {{ discount.discountAmount | currency:"USD":"symbol"}}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>

<paDiscountEditor></paDiscountEditor>
<paDiscountDisplay></paDiscountDisplay>
```

The directive could have created a host binding on the textContent property to set the contents of its host element, but that would have prevented the currency pipe from being used. Instead, the directive is assigned to the discount template variable, which is then used in the string interpolation binding to access and then format the discountAmount value. Figure 17-6 shows the results. Changes to the discount amount in either of the discount editor input elements will be reflected in the new table column.

Figure 17-6. *Using a service in a directive*

Understanding the Test Isolation Problem

The example application contains a related problem that services and dependency injection can be used to solve. Consider how the Model class is used in the root component:

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html",
})
export class ProductComponent {
    model: Model = new Model();

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
}
```

The root component is defined as the ProductComponent class, and it sets up a value for its model property by creating a new instance of the Model class. This works—and is a legitimate way to create an object—but it makes it harder to perform unit testing effectively.

Unit testing works best when you can isolate one small part of the application and focus on it to perform tests. But when you create an instance of the ProductComponent class, you are implicitly creating an instance of the Model class as well. If you were to run tests on the root component's addProduct method and find a problem, you would have no indication of whether the problem was in the ProductComponent or Model class.

Isolating Components Using Services and Dependency Injection

The underlying problem is that the ProductComponent class is tightly bound to the Model class, which is, in turn, tightly bound to the SimpleDataSource class. Dependency injection can be used to tease apart the building blocks in an application so that each class can be isolated and tested on its own. In the sections that follow, I walk through the process of breaking up these tightly coupled classes, following essentially the same process as in the previous section but delving deeper into the example application.

Preparing the Services

The @Injectable decorator is used to denote services, just as in the previous example. Listing 17-21 shows the decorator applied to the SimpleDataSource class.

Listing 17-21. Denoting a Service in the datasource.model.ts File in the src/app Folder

```
import { Product } from "./product.model";
import { Injectable } from "@angular/core";

@Injectable()
export class SimpleDataSource {
    private data: Product[];

    constructor() {
        this.data = new Array<Product>(
            new Product(1, "Kayak", "Watersports", 275),
            new Product(2, "Lifejacket", "Watersports", 48.95),
            new Product(3, "Soccer Ball", "Soccer", 19.50),
            new Product(4, "Corner Flags", "Soccer", 34.95),
            new Product(5, "Thinking Cap", "Chess", 16));
    }

    getData(): Product[] {
        return this.data;
    }
}
```

No other changes are required. Listing 17-22 shows the same decorator being applied to the data repository, and since this class has a dependency on the SimpleDataSource class, it declares it as a constructor dependency rather than creating an instance directly.

505

Listing 17-22. Denoting a Service and Dependency in the repository.model.ts File in the src/app Folder

```
import { Product } from "./product.model";
import { SimpleDataSource } from "./datasource.model";
import { Injectable } from "@angular/core";

@Injectable()
export class Model {
    //private dataSource: SimpleDataSource;
    private products: Product[];
    private locator = (p: Product, id: number | any) => p.id == id;

    constructor(private dataSource: SimpleDataSource) {
        //this.dataSource = new SimpleDataSource();
        this.products = new Array<Product>();
        this.dataSource.getData().forEach(p => this.products.push(p));
    }

    // ...other members omitted for brevity...
}
```

The important point to note in this listing is that services can declare dependencies on other services. When Angular comes to create a new instance of a service class, it inspects the constructor and tries to resolve the services in the same way as when dealing with a component or directive.

Registering the Services

These services must be registered so that Angular knows how to resolve dependencies on them, as shown in Listing 17-23.

Listing 17-23. Registering the Services in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";
```

```
import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Preparing the Dependent Component

Rather than create a Model object directly, the root component can declare a constructor dependency that Angular will resolve using dependency injection when the application starts, as shown in Listing 17-24.

Listing 17-24. Declaring a Service Dependency in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html",
})
export class ProductComponent {
    //model: Model = new Model();
```

```
    constructor(public model: Model) { }

    addProduct(p: Product) {
        this.model.saveProduct(p);
    }
}
```

There is now a chain of dependencies that Angular has to resolve. When the application starts, the Angular module specifies that the ProductComponent class needs a Model object. Angular inspects the Model class and finds that it needs a SimpleDataSource object. Angular inspects the SimpleDataSource object and finds that there are no declared dependencies and therefore knows that this is the end of the chain. It creates a SimpleDataSource object and passes it as an argument to the Model constructor to create a Model object, which can then be passed to the ProductComponent class constructor to create the object that will be used as the root component. All of this happens automatically, based on the constructors defined by each class and the use of the @Injectable decorator.

These changes don't create any visible changes in the way that the application works, but they do allow a completely different way of performing unit tests. The ProductComponent class requires that a Model object is provided as a constructor argument, which allows for a mock object to be used.

Breaking up the direct dependencies between the classes in the application means that each of them can be isolated for the purposes of unit testing and provided with mock objects through their constructor, allowing the effect of a method or some other feature to be consistently and independently assessed.

Completing the Adoption of Services

Once you start using services in an application, the process generally takes on a life of its own, and you start to examine the relationships between the building blocks you have created. The extent to which you introduce services is—at least in part—a matter of personal preference.

A good example is the use of the Model class in the root component. Although the component does implement a method that uses the Model object, it does so because it needs to handle a custom event from one of its child components. The only other reason that the root component has for needing a Model object is to pass it on via its template to the other child component using an input property.

This situation isn't an enormous problem, and your preference may be to have these kinds of relationships in a project. After all, each of the components can be isolated for unit testing, and there is some purpose, however limited, to the relationships between them. This kind of relationship between components can help make sense of the functionality that an application provides.

On the other hand, the more you use services, the more the building blocks in your project become self-contained and reusable blocks of functionality, which can ease the process of adding or changing functionality as the project matures.

There is no absolute right or wrong, and you must find the balance that suits you, your team, and, ultimately, your users and customers. Not everyone likes using dependency injection, and not everyone performs unit testing.

My preference is to use dependency injection as widely as possible. I find that the final structure of my applications can differ significantly from what I expect when I start a new project and that the flexibility offered by dependency injection helps me avoid repeated periods of refactoring. So, to complete this chapter, I am going to push the use of the Model service into the rest of the application, breaking the coupling between the root component and its immediate children.

Updating the Root Component and Template

The first changes I will make are to remove the Model object from the root component, along with the method that uses it and the input property in the template that distributes the model to one of the child components. Listing 17-25 shows the changes to the component class.

Listing 17-25. Removing the Model Object from the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";
// import { Model } from "./repository.model";
// import { Product } from "./product.model";

@Component({
    selector: "app",
    templateUrl: "template.html",
})
export class ProductComponent {
    // constructor(public model: Model) { }

    // addProduct(p: Product) {
    //     this.model.saveProduct(p);
    // }
}
```

The revised root component class doesn't define any functionality and now exists only to provide the top-level application content in its template. Listing 17-26 shows the corresponding changes in the root template to remove the custom event binding and the input property.

Listing 17-26. Removing the Data Bindings in the template.html File in the src/app Folder

```
<div class="container-fluid angularApp">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
            <pa-productform></pa-productform>
        </div>
        <div class="col p-2">
            <paProductTable></paProductTable>
        </div>
    </div>
</div>
```

Updating the Child Components

The component that provides the form for creating new Product objects relied on the root component to handle its custom event and update the model. Without this support, the component must now declare a Model dependency and perform the update itself, as shown in Listing 17-27.

Listing 17-27. Working with the Model in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation } from "@angular/core";
import { Product } from "./product.model";
import { Model } from "./repository.model";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    // styleUrls: ["productForm.component.css"],
    // encapsulation: ViewEncapsulation.ShadowDom
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model) { }

    // @Output("paNewProduct")
    // newProductEvent = new EventEmitter<Product>();

    submitForm(form: any) {
        // this.newProductEvent.emit(this.newProduct);
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The component that manages the table of product objects used an input property to receive a Model object from its parent but must now obtain it directly by declaring a constructor dependency, as shown in Listing 17-28.

Listing 17-28. Declaring a Model Dependency in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
//import { Subject } from "rxjs";
import { DiscountService } from "./discount.service";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html"
})
export class ProductTableComponent {
    //discounter: DiscountService = new DiscountService();

    constructor(private dataModel: Model) { }

    // @Input("model")
    // dataModel: Model | undefined;
```

```
    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;
}
```

You will see the same functionality displayed in the browser window when all the changes have been saved and the browser reloads the Angular application—but the way that the functionality is wired up has changed substantially, with each component obtaining the share objects it needs through the dependency injection feature, rather than relying on its parent component to provide it.

Summary

In this chapter, I explained the problems that dependency injection can be used to address and demonstrated the process of defining and consuming services. I described how services can be used to increase the flexibility in the structure of an application and how dependency injection makes it possible to isolate building blocks so they can be unit tested effectively. In the next chapter, I describe the advanced features that Angular provides for working with services.

CHAPTER 18

■ ■ ■

Using Service Providers

In the previous chapter, I introduced services and explained how they are distributed using dependency injection. When using dependency injection, the objects that are used to resolve dependencies are created by *service providers*, known more commonly as *providers*. In this chapter, I explain how providers work, describe the different types of providers available, and demonstrate how providers can be created in different parts of the application to change the way that services behave. Table 18-1 puts providers in context.

<div style="border:1px solid black; padding:10px;">

WHY YOU SHOULD CONSIDER SKIPPING THIS CHAPTER

Dependency injection provokes strong reactions in developers and polarizes opinion. If you are new to dependency injection and have yet to form your own opinion, then you might want to skip this chapter and just use the features that I described in Chapter 17. That's because features like the ones I describe in this chapter are exactly why many developers dread using dependency injection and form a strong preference against its use.

The basic Angular dependency injection features are easy to understand and have an immediate and obvious benefit in making applications easier to write and maintain. The features described in this chapter provide fine-grained control over how dependency injection works, but they also make it possible to sharply increase the complexity of an Angular application and, ultimately, undermine many of the benefits that the basic features offer.

If you decide that you want all of the gritty details, then read on. But if you are new to the world of dependency injection, you may prefer to skip this chapter until you find that the basic features from Chapter 17 don't deliver the functionality you require.

</div>

Table 18-1. *Putting Service Providers in Context*

Question	Answer
What are they?	Providers are classes that create service objects the first time that Angular needs to resolve a dependency.
Why are they useful?	Providers allow the creation of service objects to be tailored to the needs of the application. The simplest provider just creates an instance of a specified class, but there are other providers that can be used to tailor the way that service objects are created and configured.
How are they used?	Providers are defined in the providers property of the Angular module's decorator. They can also be defined by components and directives to provide services to their children, as described in the "Using Local Providers" section.
Are there any pitfalls or limitations?	It is easy to create unexpected behavior, especially when working with local providers. If you encounter problems, check the scope of the local providers you have created and make sure that your dependencies and providers are using the same tokens.
Are there any alternatives?	Many applications will require only the basic dependency injection features described in Chapter 17. You should use the features in this chapter only if you cannot build your application using the basic features and only if you have a solid understanding of dependency injection.

Table 18-2 summarizes the chapter.

Table 18-2. *Chapter Summary*

Problem	Solution	Listing
Changing the way that services are created	Use a service provider	1–3
Specifying a service using a class	Use the class provider	4–6, 10–13
Defining arbitrary tokens for services	Use the InjectionToken class	7–9
Specifying a service using an object	Use the value provider	14–15
Specifying a service using a function	Use the factory provider	16–18
Specifying one service using another	Use the existing service provider	19
Changing the scope of a service	Use a local service provider	20–28
Controlling the resolution of dependencies	Use the @Host, @Optional, or @SkipSelf decorator	29–30

Preparing the Example Project

As with the other chapters in this part of the book, I am going to continue working with the project created in Chapter 11 and most recently modified in Chapter 19. To prepare for this chapter, I added a file called log. service.ts to the src/app folder and used it to define the service shown in Listing 18-1.

Listing 18-1. The Contents of the log.service.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";

export enum LogLevel {
    DEBUG, INFO, ERROR
}

@Injectable()
export class LogService {
    minimumLevel: LogLevel = LogLevel.INFO;

    logInfoMessage(message: string) {
        this.logMessage(LogLevel.INFO, message);
    }

    logDebugMessage(message: string) {
        this.logMessage(LogLevel.DEBUG, message);
    }

    logErrorMessage(message: string) {
        this.logMessage(LogLevel.ERROR, message);
    }

    logMessage(level: LogLevel, message: string) {
        if (level >= this.minimumLevel) {
            console.log(`Message (${LogLevel[level]}): ${message}`);
        }
    }
}
```

This service writes out log messages, with differing levels of severity, to the browser's JavaScript console. I will register and use this service later in the chapter.

When you have created the service and saved the changes, run the following command in the example folder to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the application, as shown in Figure 18-1.

515

Figure 18-1. *Running the example application*

Using Service Providers

As I explained in the previous chapters, classes declare dependencies on services using their constructor arguments. When Angular needs to create a new instance of the class, it inspects the constructor and uses a combination of built-in and custom services to resolve each argument. Listing 18-2 updates the DiscountService class so that it depends on the LogService class created in the previous section.

Listing 18-2. Creating a Dependency in the discount.service.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";
import { LogService } from "./log.service";

@Injectable()
export class DiscountService {
    private discountValue: number = 10;

    constructor(private logger: LogService) { }

    public get discount(): number {
        return this.discountValue;
    }

    public set discount(newValue: number) {
        this.discountValue = newValue ?? 0;
    }
```

```
    public applyDiscount(price: number) {
        this.logger.logInfoMessage(`Discount ${this.discount}`
            + ` applied to price: ${price}`);
        return Math.max(price - this.discountValue, 5);
    }
}
```

The changes in Listing 18-2 prevent the application from running. Angular processes the HTML document and starts creating the hierarchy of components, each with their templates that require directives and data bindings, and it encounters the classes that depend on the DiscountService class. But it can't create an instance of DiscountService because its constructor requires a LogService object, and it doesn't know how to handle this class.

When you save the changes in Listing 18-2, you will see an error like this one in the browser's JavaScript console:

```
NullInjectorError: No provider for LogService!
```

Angular delegates responsibility for creating the objects needed for dependency injection to *providers*, each of which managed a single type of dependency. When it needs to create an instance of the DiscountService class, it looks for a suitable provider to resolve the LogService dependency. Since there is no such provider, Angular can't create the objects it needs to start the application and reports the error.

The simplest way to create a provider is to add the service class to the array assigned to the Angular module's providers property, as shown in Listing 18-3. (I have taken the opportunity to remove some of the statements that are no longer required in the module.)

Listing 18-3. Creating a Provider in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';
```

```
import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService } from "./log.service";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model, LogService],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

When you save the changes, you will have defined the provider that Angular requires to handle the LogService dependency, and you will see messages like this one shown in the browser's JavaScript console:

```
Message (INFO): Discount 10 applied to price: 16
```

You might wonder why the configuration step in Listing 18-3 is required. After all, Angular could just assume that it should create a new LogService object the first time it needs one.

In fact, Angular provides a range of different providers, each of which creates objects in a different way to let you take control of the service creation process. Table 18-3 describes the set of available providers, which are described in the sections that follow.

Table 18-3. The Angular Providers

Name	Description
Class provider	This provider is configured using a class. Dependencies on the service are resolved by an instance of the class, which Angular creates.
Value provider	This provider is configured using an object, which is used to resolve dependencies on the service.
Factory provider	This provider is configured using a function. Dependencies on the service are resolved using an object that is created by invoking the function.
Existing service provider	This provider is configured using the name of another service and allows aliases for services to be created.

Using the Class Provider

This provider is the most commonly used and is the one I applied by adding the class names to the module's
providers property in Listing 18-3. This listing shows the shorthand syntax, and there is also a literal syntax
that achieves the same result, as shown in Listing 18-4.

Listing 18-4. Using the Class Provider Literal Syntax in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LogService, useClass: LogService }],
    bootstrap: [ProductComponent]
})
...
```

Providers are defined as classes, but they can be specified and configured using the JavaScript object
literal format, like this:

```
...
{ provide: LogService, useClass: LogService }
...
```

The class provider supports three properties, which are described in Table 18-4 and explained in the
sections that follow.

519

Table 18-4. *The Class Provider's Properties*

Name	Description
provide	This property is used to specify the token, which is used to identify the provider and the dependency that will be resolved. See the "Understanding the Token" section.
useClass	This property is used to specify the class that will be instantiated to resolve the dependency by the provider. See the "Understanding the useClass Property" section.
multi	This property can be used to deliver an array of service objects to resolve dependencies. See the "Resolving a Dependency with Multiple Objects" section.

Understanding the Token

All providers rely on a token, which Angular uses to identify the dependency that the provider can resolve. The simplest approach is to use a class as the token, which is what I did in Listing 18-4. However, you can use any object as the token, which allows the dependency and the type of the object to be separated. This has the effect of increasing the flexibility of the dependency injection configuration because it allows a provider to supply objects of different types, which can be useful with some of the more advanced providers described later in the chapter. As a simple example, Listing 18-5 uses the class provider to register the log service created at the start of the chapter using a string as a token, rather than a class.

Listing 18-5. Registering a Service with a Token in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: "logger", useClass: LogService }],
    bootstrap: [ProductComponent]
})
...
```

In the listing, the provide property of the new provider is set to logger. Angular will automatically match providers whose token is a class, but it needs some additional help for other token types. Listing 18-6 shows the DiscountService class updated with a dependency on the logging service, accessed using the logger token.

Listing 18-6. Using a String Provider Token in the discount.service.ts File in the src/app Folder

```
import { Injectable, Inject } from "@angular/core";
import { LogService } from "./log.service";

@Injectable()
export class DiscountService {
    private discountValue: number = 10;

    constructor(@Inject("logger") private logger: LogService) { }

    public get discount(): number {
        return this.discountValue;
    }

    public set discount(newValue: number) {
        this.discountValue = newValue ?? O;
    }

    public applyDiscount(price: number) {
        this.logger.logInfoMessage(`Discount ${this.discount}`
            + ` applied to price: ${price}`);
        return Math.max(price - this.discountValue, 5);
    }
}
```

The @Inject decorator is applied to the constructor argument and used to specify the token that should be used to resolve the dependency. When Angular needs to create an instance of the DiscountService class, it will inspect the constructor and use the @Inject decorator argument to select the provider that will be used to resolve the dependency, resolving the dependency on the LogService class.

Using Opaque Tokens

When using simple types as provider tokens, there is a chance that two different parts of the application will try to use the same token to identify different services, which means that the wrong type of object may be used to resolve dependencies and cause errors.

To help work around this, Angular provides the InjectionToken class, which provides an object wrapper around a string value and can be used to create unique token values. In Listing 18-7, I have used the InjectionToken class to create a token that will be used to identify dependencies on the LogService class.

Listing 18-7. Using the InjectionToken Class in the log.service.ts File in the src/app Folder

```
import { Injectable, InjectionToken } from "@angular/core";

export const LOG_SERVICE = new InjectionToken("logger");

export enum LogLevel {
    DEBUG, INFO, ERROR
}
```

```
@Injectable()
export class LogService {
    minimumLevel: LogLevel = LogLevel.INFO;

    // ...methods omitted for brevity...
}
```

The constructor for the `InjectionToken` class accepts a `string` value that describes the service, but it is the `InjectionToken` object that will be the token. Dependencies must be declared on the same `InjectionToken` that is used to create the provider in the module; this is why the token has been created using the `const` keyword, which prevents the object from being modified. Listing 18-8 shows the provider configuration using the new token.

Listing 18-8. Creating a Provider Using an InjectionToken in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE } from "./log.service";

registerLocaleData(localeFr);
```

```
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LOG_SERVICE, useClass: LogService }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

Finally, Listing 18-9 shows the DiscountService class updated to declare a dependency using the InjectionToken instead of a string.

Listing 18-9. Declaring a Dependency in the discount.service.ts File in the src/app Folder

```
import { Injectable, Inject } from "@angular/core";
import { LogService, LOG_SERVICE } from "./log.service";

@Injectable()
export class DiscountService {
    private discountValue: number = 10;

    constructor( @Inject(LOG_SERVICE) private logger: LogService) { }

    public get discount(): number {
        return this.discountValue;
    }

    public set discount(newValue: number) {
        this.discountValue = newValue || 0;
    }

    public applyDiscount(price: number) {
        this.logger.logInfoMessage(`Discount ${this.discount}`
            + ` applied to price: ${price}`);
        return Math.max(price - this.discountValue, 5);
    }
}
```

There is no difference in the functionality offered by the application, but using the InjectionToken means that there will be no confusion between services.

Understanding the useClass Property

The class provider's useClass property specifies the class that will be instantiated to resolve dependencies. The provider can be configured with any class, which means you can change the implementation of a service by changing the provider configuration. This feature should be used with caution because the recipients of the service object will be expecting a specific type and a mismatch won't result in an error until the application is running in the browser. (TypeScript type enforcement has no effect on dependency injection because it occurs at runtime after the type annotations have been processed by the TypeScript compiler.)

The most common way to change classes is to use different subclasses. In Listing 18-10, I extended the LogService class to create a service that writes a different format of message in the browser's JavaScript console.

Listing 18-10. Creating a Subclassed Service in the log.service.ts File in the src/app Folder

```
import { Injectable, InjectionToken } from "@angular/core";

export const LOG_SERVICE = new InjectionToken("logger");

export enum LogLevel {
    DEBUG, INFO, ERROR
}

@Injectable()
export class LogService {
    minimumLevel: LogLevel = LogLevel.INFO;

    logInfoMessage(message: string) {
        this.logMessage(LogLevel.INFO, message);
    }

    logDebugMessage(message: string) {
        this.logMessage(LogLevel.DEBUG, message);
    }

    logErrorMessage(message: string) {
        this.logMessage(LogLevel.ERROR, message);
    }

    logMessage(level: LogLevel, message: string) {
        if (level >= this.minimumLevel) {
            console.log(`Message (${LogLevel[level]}): ${message}`);
        }
    }
}

@Injectable()
export class SpecialLogService extends LogService {

    constructor() {
        super()
        this.minimumLevel = LogLevel.DEBUG;
    }
```

```
    override logMessage(level: LogLevel, message: string) {
        if (level >= this.minimumLevel) {
            console.log(`Special Message (${LogLevel[level]}): ${message}`);
        }
    }
}
```

The SpecialLogService class extends LogService and provides its own implementation of the logMessage method. Listing 18-11 updates the provider configuration so that the useClass property specifies the new service.

Listing 18-11. Configuring the Provider in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService } from "./log.service";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
```

```
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LOG_SERVICE, useClass: SpecialLogService }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The combination of token and class means that dependencies on the LOG_SERVICE opaque token will be resolved using a SpecialLogService object. When you save the changes, you will see messages like this one displayed in the browser's JavaScript console, indicating that the derived service has been used:

```
Special Message (INFO): Discount 10 applied to price: 275
```

Care must be taken when setting the useClass property to specify a type that the dependent classes are expecting. Specifying a subclass is the safest option because the functionality of the base class is guaranteed to be available.

Resolving a Dependency with Multiple Objects

The class provider can be configured to deliver an array of objects to resolve a dependency, which can be useful if you want to provide a set of related services that differ in how they are configured. To provide an array, multiple class providers are configured using the same token and with the multi property set as true, as shown in Listing 18-12.

Listing 18-12. Configuring Multiple Service Objects in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
```

```
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LOG_SERVICE, useClass: LogService, multi: true },
        { provide: LOG_SERVICE, useClass: SpecialLogService, multi: true }],
    bootstrap: [ProductComponent]
})
...
```

The Angular dependency injection system will resolve dependencies on the LOG_SERVICE token by creating LogService and SpecialLogService objects, placing them in an array, and passing them to the dependent class's constructor. The class that receives the services must be expecting an array, as shown in Listing 18-13.

Listing 18-13. Receiving Multiple Services in the discount.service.ts File in the src/app Folder

```
import { Injectable, Inject } from "@angular/core";
import { LogService, LOG_SERVICE, LogLevel } from "./log.service";

@Injectable()
export class DiscountService {
    private discountValue: number = 10;
    private logger?: LogService;

    constructor( @Inject(LOG_SERVICE) loggers: LogService[]) {
        this.logger = loggers.find(l => l.minimumLevel == LogLevel.DEBUG);
    }

    public get discount(): number {
        return this.discountValue;
    }

    public set discount(newValue: number) {
        this.discountValue = newValue ?? 0;
    }

    public applyDiscount(price: number) {
        this.logger?.logInfoMessage(`Discount ${this.discount}`
            + ` applied to price: ${price}`);
        return Math.max(price - this.discountValue, 5);
    }
}
```

The services are received as an array by the constructor, which uses the array's find method to locate the first logger whose minimumLevel property is LogLevel.Debug and assign it to the logger property. The applyDiscount method calls the service's logDebugMessage method, which results in messages like this one being displayed in the browser's JavaScript console:

```
Special Message (INFO): Discount 10 applied to price: 275
```

Using the Value Provider

The value provider is used when you want to take responsibility for creating the service objects yourself, rather than leaving it to the class provider. This can also be useful when services are simple types, such as string or number values, which can be a useful way of providing access to common configuration settings. The value provider can be applied using a literal object and supports the properties described in Table 18-5.

Table 18-5. *The Value Provider Properties*

Name	Description
provide	This property defines the service token, as described in the "Understanding the Token" section earlier in the chapter.
useValue	This property specifies the object that will be used to resolve the dependency.
multi	This property is used to allow multiple providers to be combined to provide an array of objects that will be used to resolve a dependency on the token. See the "Resolving a Dependency with Multiple Objects" section earlier in the chapter for an example.

The value provider works in the same way as the class provider except that it is configured with an object rather than a type. Listing 18-14 shows the use of the value provider to create an instance of the LogService class that is configured with a specific property value.

Listing 18-14. Using the Value Provider in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
```

```
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService, LogLevel } from "./log.service";

let logger = new LogService();
logger.minimumLevel = LogLevel.DEBUG;

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LogService, useValue: logger }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

This value provider is configured to resolve dependencies on the LogService token with a specific object that has been created and configured outside of the module class.

The value provider—and, in fact, all of the providers—can use any object as the token, as described in the previous section, but I have returned to using types as tokens because it is the most commonly used technique and because it works so nicely with TypeScript constructor parameter typing. Listing 18-15 shows the corresponding change to the DiscountService, which declares a dependency using a typed constructor argument.

Listing 18-15. Declaring a Dependency Using a Type in the discount.service.ts File in the src/app Folder

```
import { Injectable, Inject } from "@angular/core";
import { LogService, LOG_SERVICE, LogLevel } from "./log.service";

@Injectable()
export class DiscountService {
    private discountValue: number = 10;
    //private logger?: LogService;

    constructor(private logger: LogService) { }

    public get discount(): number {
        return this.discountValue;
    }
```

```
    public set discount(newValue: number) {
        this.discountValue = newValue ?? 0;
    }

    public applyDiscount(price: number) {
        this.logger?.logInfoMessage(`Discount ${this.discount}`
            + ` applied to price: ${price}`);
        return Math.max(price - this.discountValue, 5);
    }
}
```

Using the Factory Provider

The factory provider uses a function to create the object required to resolve a dependency. This provider supports the properties described in Table 18-6.

Table 18-6. *The Factory Provider Properties*

Name	Description
provide	This property defines the service token, as described in the "Understanding the Token" section earlier in the chapter.
deps	This property specifies an array of provider tokens that will be resolved and passed to the function specified by the useFactory property.
useFactory	This property specifies the function that will create the service object. The objects produced by resolving the tokens specified by the deps property will be passed to the function as arguments. The result returned by the function will be used as the service object.
multi	This property is used to allow multiple providers to be combined to provide an array of objects that will be used to resolve a dependency on the token. See the "Resolving a Dependency with Multiple Objects" section earlier in the chapter for an example.

This is the provider that gives the most flexibility in how service objects are created because you can define functions that are tailored to your application's requirements. Listing 18-16 shows a factory function that creates LogService objects.

Listing 18-16. Using the Factory Provider in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
```

```
    providers: [DiscountService, SimpleDataSource, Model,
        {
            provide: LogService, useFactory: () => {
                let logger = new LogService();
                logger.minimumLevel = LogLevel.DEBUG;
                return logger;
            }
        }],
    bootstrap: [ProductComponent]
})
...
```

The function in this example is simple: it receives no arguments and just creates a new `LogService` object. The real flexibility of this provider comes when the deps property is used, which allows for dependencies to be created on other services. In Listing 18-17, I have defined a token that specifies a debugging level.

Listing 18-17. Defining a Logging-Level Service in the log.service.ts File in the src/app Folder

```
import { Injectable, InjectionToken } from "@angular/core";

export const LOG_SERVICE = new InjectionToken("logger");
export const LOG_LEVEL = new InjectionToken("log_level");

export enum LogLevel {
    DEBUG, INFO, ERROR
}

@Injectable()
export class LogService {
    minimumLevel: LogLevel = LogLevel.INFO;

    // ...methods omitted for brevity...
}

@Injectable()
export class SpecialLogService extends LogService {

    // ...methods omitted for brevity...
}
```

In Listing 18-18, I have defined a value provider that creates a service using the `LOG_LEVEL` token and used that service in the factory function that creates the `LogService` object.

Listing 18-18. Using Factory Dependencies in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';
```

531

```
import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService,
    LogLevel, LOG_LEVEL} from "./log.service";

let logger = new LogService();
logger.minimumLevel = LogLevel.DEBUG;

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LOG_LEVEL, useValue: LogLevel.DEBUG },
        { provide: LogService,
          deps: [LOG_LEVEL],
          useFactory: (level: LogLevel) => {
            let logger = new LogService();
```

```
            logger.minimumLevel = level;
            return logger;
        }}],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The LOG_LEVEL token is used by a value provider to define a simple value as a service. The factory provider specifies this token in its deps array, which the dependency injection system resolves and provides as an argument to the factory function, which uses it to set the minimumLevel property of a new LogService object.

Using the Existing Service Provider

This provider is used to create aliases for services so they can be targeted using more than one token, using the properties described in Table 18-7.

Table 18-7. *The Existing Provider Properties*

Name	Description
provide	This property defines the service token, as described in the "Understanding the Token" section earlier in the chapter.
useExisting	This property is used to specify the token of another provider, whose service object will be used to resolve dependencies on this service.
multi	This property is used to allow multiple providers to be combined to provide an array of objects that will be used to resolve a dependency on the token. See the "Resolving a Dependency with Multiple Objects" section earlier in the chapter for an example.

This provider can be useful when you want to refactor the set of providers but don't want to eliminate all the obsolete tokens to avoid refactoring the rest of the application. Listing 18-19 shows the use of this provider.

Listing 18-19. Creating a Service Alias in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
```

```
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LOG_LEVEL, useValue: LogLevel.DEBUG },
        { provide: "debugLevel", useExisting: LOG_LEVEL },
        { provide: LogService,
          deps: ["debugLevel"],
          useFactory: (level: LogLevel) => {
            let logger = new LogService();
            logger.minimumLevel = level;
            return logger;
        }}],
    bootstrap: [ProductComponent]
})
...
```

The token for the new service is the string debugLevel, and it is aliased to the provider with the LOG_
LEVEL token. Using either token will result in the dependency being resolved with the same value.

Using Local Providers

When Angular creates a new instance of a class, it resolves any dependencies using an *injector*. It is an injector that is responsible for inspecting the constructors of classes to determine what dependencies have been declared and resolving them using the available providers.

So far, all the dependency injection examples have relied on providers configured in the application's Angular module. But the Angular dependency injection system is more complex: there is a hierarchy of injectors corresponding to the application's tree of components and directives. Each component and directive can have its own injector, and each injector can be configured with its own set of providers, known as *local providers*.

When there is a dependency to resolve, Angular uses the injector for the nearest component or directive. The injector first tries to resolve the dependency using its own set of local providers. If no local providers have been set up or there are no providers that can be used to resolve this specific dependency, then the injector consults the parent component's injector. The process is repeated—the parent component's injector tries to resolve the dependency using its own set of local providers. If a suitable provider is available, then it is used to provide the service object required to resolve the dependency. If there is no suitable provider, then the request is passed up to the next level in the hierarchy to the grandparent of the original injector. At the top of the hierarchy is the root Angular module, whose providers are the last resort before reporting an error.

Defining providers in the Angular module means that all dependencies for a token within the application will be resolved using the same object. As I explain in the following sections, registering providers further down the injector hierarchy can change this behavior and alter the way that services are created and used.

Understanding the Limitations of Single Service Objects

Using a single service object can be a powerful tool, allowing building blocks in different parts of the application to share data and respond to user interactions. But some services don't lend themselves to being shared so widely. As a simple example, Listing 18-20 adds a dependency on LogService to one of the pipes created in Chapter 16.

Listing 18-20. Adding a Service Dependency in the discount.pipe.ts File in the src/app Folder

```
import { Pipe, Injectable } from "@angular/core";
import { DiscountService } from "./discount.service";
import { LogService } from "./log.service";

@Pipe({
    name: "discount",
    pure: false
})
export class PaDiscountPipe {

    constructor(private discount: DiscountService,
                private logger: LogService) { }

    transform(price: number): number {
        if (price > 100) {
            this.logger.logInfoMessage(`Large price discounted: ${price}`);
        }
        return this.discount.applyDiscount(price);
    }
}
```

The pipe's transform method uses the LogService object, which is received as a constructor argument, to generate logging messages when the price value it transforms is greater than 100.

The problem is that these log messages are drowned out by the messages generated by the DiscountService object, which creates a message every time a discount is applied. The obvious thing to do is to change the minimum level in the LogService object when it is created by the module provider's factory function, as shown in Listing 18-21.

Listing 18-21. Changing the Logging Level in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model,
        { provide: LOG_LEVEL, useValue: LogLevel.ERROR },
        { provide: "debugLevel", useExisting: LOG_LEVEL },
        { provide: LogService,
            deps: ["debugLevel"],
          useFactory: (level: LogLevel) => {
            let logger = new LogService();
```

```
            logger.minimumLevel = level;
            return logger;
        }}],
    bootstrap: [ProductComponent]
})
...
```

Of course, this doesn't have the desired effect because the same LogService object is used throughout the application and filtering the DiscountService messages means that the pipe messages are filtered too.

I could enhance the LogService class so there are different filters for each source of logging messages, but that quickly becomes complicated. Instead, I am going to solve the problem by creating a local provider so that there are multiple LogService objects in the application, each of which can then be configured separately.

Creating Local Providers in a Component

Components can define local providers, which allow separate servers to be created and used by part of the application. Components support two decorator properties for creating local providers, as described in Table 18-8.

Table 18-8. *The Component Decorator Properties for Local Providers*

Name	Description
providers	This property is used to create a provider used to resolve dependencies of view and content children.
viewProviders	This property is used to create a provider used to resolve dependencies of view children.

The simplest way to address my LogService issue is to use the providers property to set up a local provider, as shown in Listing 18-22.

Listing 18-22. Creating a Local Provider in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./repository.model";
import { Product } from "./product.model";
//import { Subject } from "rxjs";
import { DiscountService } from "./discount.service";
import { LogService } from "./log.service";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html",
    providers:[LogService]
})
export class ProductTableComponent {

    constructor(private dataModel: Model) { }

    // @Input("model")
```

```
    // dataModel: Model | undefined;

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;
}
```

When Angular needs to create a new pipe object, it detects the dependency on `LogService` and starts working its way up the application hierarchy, examining each component it finds to determine whether they have a provider that can be used to resolve the dependency. The `ProductTableComponent` does have a `LogService` provider, which is used to create the service used to resolve the pipe's dependency. This means there are now two `LogService` objects in the application, each of which can be configured separately, as shown in Figure 18-2.

Figure 18-2. *Creating a local provider*

The `LogService` object created by the component's provider uses the default value for its `minimumLevel` property and will display `LogLevel.INFO` messages. The `LogService` object created by the module, which will be used to resolve all other dependencies in the application, including the one declared by the `DiscountService` class, is configured so that it will display only `LogLevel.ERROR` messages. When you

save the changes, you will see the logging messages from the pipe (which receives the service from the component) but not from `DiscountService` (which receives the service from the module).

Understanding the Provider Alternatives

As described in Table 18-8, there are two properties that can be used to create local providers. To demonstrate how these properties differ, I added a file called `valueDisplay.directive.ts` to the `src/app` folder and used it to define the directive shown in Listing 18-23.

Listing 18-23. The Contents of the valueDisplay.directive.ts File in the src/app Folder

```
import { Directive, InjectionToken, Inject, HostBinding} from "@angular/core";

export const VALUE_SERVICE = new InjectionToken("value_service");

@Directive({
    selector: "[paDisplayValue]"
})
export class PaDisplayValueDirective {

    constructor( @Inject(VALUE_SERVICE) serviceValue: string) {
        this.elementContent = serviceValue;
    }

    @HostBinding("textContent")
    elementContent: string;
}
```

The VALUE_SERVICE opaque token will be used to define a value-based service, on which the directive in this listing declares a dependency so that it can be displayed in the host element's content. Listing 18-24 shows the service being defined and the directive being registered in the Angular module. I have also simplified the `LogService` provider in the module for brevity.

Listing 18-24. Registering the Directive and Service in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
```

```
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService,
    LogLevel, LOG_LEVEL} from "./log.service";
import { VALUE_SERVICE, PaDisplayValueDirective} from "./valueDisplay.directive";

let logger = new LogService();
logger.minimumLevel = LogLevel.DEBUG;

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective, PaDisplayValueDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model, LogService,
        { provide: VALUE_SERVICE, useValue: "Apples" }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

The provider sets up a value of Apples for the VALUE_SERVICE service. The next step is to apply the new directive so there is an instance that is a view child of a component and another that is a content child. Listing 18-25 sets up the content child instance.

Listing 18-25. Applying a Content Child Directive in the template.html File in the src/app Folder

```
<div class="container-fluid angularApp">
    <div class="row p-2">
        <div class="col-4 p-2 text-dark">
```

```
            <pa-productform>
                <span paDisplayValue></span>
            </pa-productform>
        </div>
        <div class="col p-2">
            <paProductTable></paProductTable>
        </div>
    </div>
</div>
```

Listing 18-26 projects the host element's content and adds a view child instance of the new directive.

Listing 18-26. Adding Directives in the productForm.component.html File in the src/app Folder

```
<form #form="ngForm" (ngSubmit)="submitForm(form)">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control"
            name="name" [(ngModel)]="newProduct.name" />
    </div>
    <div class="form-group">
        <label>Category</label>
        <input class="form-control"
            name="category" [(ngModel)]="newProduct.category" />
    </div>
    <div class="form-group">
        <label>Price</label>
        <input class="form-control"
            name="name" [(ngModel)]="newProduct.price" />
    </div>
    <button class="btn btn-primary mt-2" type="submit">
            Create
    </button>
</form>

<div class="bg-info text-white m-2 p-2">
    View Child Value: <span paDisplayValue></span>
</div>
<div class="bg-info text-white m-2 p-2">
    Content Child Value: <ng-content></ng-content>
</div>
```

When you save the changes, you will see the new elements, as shown in Figure 18-3, both of which show the same value because the only provider for VALUE_SERVICE is defined in the module.

Figure 18-3. *View and content child directives*

Creating a Local Provider for All Children

The @Component decorator's providers property is used to define providers that will be used to resolve service dependencies for all children, regardless of whether they are defined in the template (view children) or projected from the host element (content children). Listing 18-27 defines a VALUE_SERVICE provider in the parent component for two new directive instances.

Listing 18-27. Defining a Provider in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation } from "@angular/core";
import { Product } from "./product.model";
import { Model } from "./repository.model";
import { VALUE_SERVICE } from "./valueDisplay.directive";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    providers: [{ provide: VALUE_SERVICE, useValue: "Oranges" }]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model) { }

    submitForm(form: any) {
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The new provider changes the service value. When Angular comes to create the instances of the new directive, it begins its search for providers by working its way up the application hierarchy and finds the VALUE_SERVICE provider defined in Listing 18-27. The service value is used by both instances of the directive, as shown in Figure 18-4.

Figure 18-4. *Defining a provider for all children in a component*

Creating a Provider for View Children

The viewProviders property defines providers that are used to resolve dependencies for view children but not content children. Listing 18-28 uses the viewProviders property to define a provider for VALUE_SERVICE.

Listing 18-28. Defining a View Child Provider in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation } from "@angular/core";
import { Product } from "./product.model";
import { Model } from "./repository.model";
import { VALUE_SERVICE } from "./valueDisplay.directive";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    viewProviders: [{ provide: VALUE_SERVICE, useValue: "Oranges" }]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model) { }

    submitForm(form: any) {
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
```

```
    }
}
```

Angular uses the provider when resolving dependencies for view children but not for content children. This means dependencies for content children are referred up the application's hierarchy as though the component had not defined a provider. In the example, this means that the view child will receive the service created by the component's provider, and the content child will receive the service created by the module's provider, as shown in Figure 18-5.

■ **Caution** Defining providers for the same service using both the providers and viewProviders properties is not supported. If you do this, the view and content children both will receive the service created by the viewProviders provider.

Figure 18-5. *Defining a provider for view children*

Controlling Dependency Resolution

Angular provides three decorators that can be used to provide instructions about how a dependency is resolved. These decorators are described in Table 18-9 and demonstrated in the following sections.

Table 18-9. *The Dependency Resolution Decorators*

Name	Description
@Host	This decorator restricts the search for a provider to the nearest component.
@Optional	This decorator stops Angular from reporting an error if the dependency cannot be resolved.
@SkipSelf	This decorator excludes the providers defined by the component/directive whose dependency is being resolved.

Restricting the Provider Search

The @Host decorator restricts the search for a suitable provider so that it stops once the closest component has been reached. The decorator is typically combined with @Optional, which prevents Angular from throwing an exception if a service dependency cannot be resolved. Listing 18-29 shows the addition of both decorators to the directive in the example.

Listing 18-29. Adding Dependency Decorators in the valueDisplay.directive.ts File in the src/app Folder

```
import { Directive, InjectionToken, Inject,
    HostBinding, Host, Optional} from "@angular/core";

export const VALUE_SERVICE = new InjectionToken("value_service");

@Directive({
    selector: "[paDisplayValue]"
})
export class PaDisplayValueDirective {

    constructor( @Inject(VALUE_SERVICE) @Host() @Optional() serviceValue: string) {
        this.elementContent = serviceValue || "No Value";
    }

    @HostBinding("textContent")
    elementContent: string;
}
```

When using the @Optional decorator, you must ensure that the class is able to function if the service cannot be resolved, in which case the constructor argument for the service is undefined. The nearest component defines a service for its view children but not content children, which means that one instance of the directive will receive a service object and the other will not, as illustrated in Figure 18-6.

Figure 18-6. *Controlling how a dependency is resolved*

Skipping Self-Defined Providers

By default, the providers defined by a component are used to resolve its dependencies. The @SkipSelf decorator can be applied to constructor arguments to tell Angular to ignore the local providers and start the search at the next level in the application hierarchy, which means that the local providers will be used only

to resolve dependencies for children. In Listing 18-30, I have added a dependency on the VALUE_SERVICE provider that is decorated with @SkipSelf.

Listing 18-30. Skipping Local Providers in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation,
    Inject, SkipSelf } from "@angular/core";
import { Product } from "./product.model";
import { Model } from "./repository.model";
import { VALUE_SERVICE } from "./valueDisplay.directive";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    viewProviders: [{ provide: VALUE_SERVICE, useValue: "Oranges" }]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model,
            @Inject(VALUE_SERVICE) @SkipSelf() private serviceValue: string) {
        console.log("Service Value: " + serviceValue);
    }

    submitForm(form: any) {
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

When you save the changes and the browser reloads the page, you will see the following message in the browser's JavaScript console, showing that the service value defined locally (Oranges) has been skipped and allowing the dependency to be resolved by the Angular module:

```
Service Value: Apples
```

Summary

In this chapter, I explained the role that providers play in dependency injection and explained how they can be used to change how services are used to resolve dependencies. I described the different types of providers that can be used to create service objects and demonstrated how directives and components can define their own providers to resolve their own dependencies and those of their children. In the next chapter, I describe modules, which are the final building block for Angular applications.

CHAPTER 19

■ ■ ■

Using and Creating Modules

In this chapter, I describe the last of the Angular building blocks: modules. In the first part of the chapter, I describe the root module, which every Angular application uses to describe the configuration of the application to Angular. In the second part of the chapter, I describe feature modules, which are used to add structure to an application so that related features can be grouped as a single unit. Table 19-1 puts modules in context.

Table 19-1. *Putting Modules in Context*

Question	Answer
What are they?	Modules provide configuration information to Angular.
Why are they useful?	The root module describes the application to Angular, setting up essential features such as components and services. Feature modules are useful for adding structure to complex projects, which makes them easier to manage and maintain.
How are they used?	Modules are classes to which the @NgModule decorator has been applied. The properties used by the decorator have different meanings for root and feature modules.
Are there any pitfalls or limitations?	There is no module-wide scope for providers, which means that the providers defined by a feature module will be available as though they had been defined by the root module.
Are there any alternatives?	Every application must have a root module, but the use of feature modules is entirely optional. However, if you don't use feature modules, then the files in an application can become difficult to manage.

Table 19-2 summarizes the chapter.

Table 19-2. *Chapter Summary*

Problem	Solution	Listing
Describing an application and the building blocks it contains	Use the root module	1–7
Grouping related features together	Create a feature module	8–28

Preparing the Example Project

As with the other chapters in this part of the book, I am going to use the example project that was created in Chapter 9 and has been expanded and extended in each chapter since.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book— from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

To prepare for this chapter, I have removed some functionality from the component templates. Listing 19-1 shows the template for the product table, in which I have commented out the elements for the discount editor and display components.

Listing 19-1. The Contents of the productTable.component.html File in the src/app Folder

```html
<table class="table table-sm table-bordered table-striped">
    <thead>
        <tr><th></th><th>Name</th><th>Category</th><th>Price</th><th></th></tr>
    </thead>
    <tbody>
        <tr *paFor="let item of getProducts(); let i = index">
            <td>{{i + 1}}</td>
            <td>{{item.name}}</td>
            <td>{{item.category}}</td>
            <td [pa-price]="item.price" #discount="discount">
                {{ discount.discountAmount | currency:"USD":"symbol"}}
            </td>
            <td class="text-center">
                <button class="btn btn-danger btn-sm"
                        (click)="deleteProduct(item.id)">
                    Delete
                </button>
            </td>
        </tr>
    </tbody>
</table>

<!-- <paDiscountEditor></paDiscountEditor> -->
<!-- <paDiscountDisplay></paDiscountDisplay> -->
```

Listing 19-2 shows the template from the product form component, in which I have commented out the elements that I used to demonstrate the difference between providers for view children and content children in Chapter 18.

Listing 19-2. The Contents of the productForm.component.html File in the src/app Folder

```html
<form #form="ngForm" (ngSubmit)="submitForm(form)">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control"
```

```
                name="name" [(ngModel)]="newProduct.name" />
        </div>
        <div class="form-group">
            <label>Category</label>
            <input class="form-control"
                name="category" [(ngModel)]="newProduct.category" />
        </div>
        <div class="form-group">
            <label>Price</label>
            <input class="form-control"
                name="name" [(ngModel)]="newProduct.price" />
        </div>
        <button class="btn btn-primary mt-2" type="submit">
                Create
        </button>
</form>

<!-- <div class="bg-info text-white m-2 p-2">
    View Child Value: <span paDisplayValue></span>
</div>
<div class="bg-info text-white m-2 p-2">
    Content Child Value: <ng-content></ng-content>
</div> -->
```

Run the following command in the example folder to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 19-1.

Figure 19-1. *Running the example application*

Understanding the Root Module

Every Angular has at least one module, known as the *root module*. The root module is conventionally defined in a file called app.module.ts in the src/app folder, and it contains a class to which the @NgModule decorator has been applied. Listing 19-3 shows the root module from the example application.

Listing 19-3. The Root Module in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService,
    LogLevel, LOG_LEVEL} from "./log.service";
import { VALUE_SERVICE, PaDisplayValueDirective} from "./valueDisplay.directive";

let logger = new LogService();
logger.minimumLevel = LogLevel.DEBUG;

registerLocaleData(localeFr);
```

```
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective, PaDisplayValueDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model, LogService,
        { provide: VALUE_SERVICE, useValue: "Apples" }],
    bootstrap: [ProductComponent]
})
export class AppModule { }
```

There can be multiple modules in a project, but the root module is the one used in the bootstrap file, which is conventionally called main.ts and is defined in the src folder. Listing 19-4 shows the main.ts file for the example project.

Listing 19-4. The Angular Bootstrap in the main.ts File in the src Folder

```
import { enableProdMode } from '@angular/core';
import { platformBrowserDynamic } from '@angular/platform-browser-dynamic';

import { AppModule } from './app/app.module';
import { environment } from './environments/environment';

if (environment.production) {
  enableProdMode();
}

platformBrowserDynamic().bootstrapModule(AppModule)
  .catch(err => console.error(err));
```

Angular applications can be run in different environments, such as web browsers and native application containers. The job of the bootstrap file is to select the platform and identify the root module. The platformBrowserDynamic method creates the browser runtime, and the bootstrapModule method is used to specify the module, which is the AppModule class from Listing 19-3.

When defining the root module, the @NgModule decorator properties described in Table 19-3 are used. (There are additional decorator properties, which are described later in the chapter.)

Table 19-3. *The @NgModule Decorator Root Module Properties*

Name	Description
imports	This property specifies the Angular modules that are required to support the directives, components, and pipes in the application.
declarations	This property is used to specify the directives, components, and pipes that are used in the application.
providers	This property defines the service providers that will be used by the module's injector. These are the providers that will be available throughout the application and used when no local provider for a service is available, as described in Chapter 18.
bootstrap	This property specifies the root components for the application.

Understanding the imports Property

The imports property is used to list the other modules that the application requires. In the example application, these are all modules provided by the Angular framework.

```
...
imports: [
    BrowserModule,
    BrowserAnimationsModule,
    FormsModule, ReactiveFormsModule
],
...
```

The BrowserModule provides the functionality required to run Angular applications in web browsers. The BrowserAnimationsModule module was added to the project by the Angular Material package and enables the animation features described in Chapter 27. The other two modules provide support for working with HTML forms. There are other Angular modules, which are introduced in later chapters.

The imports property is also used to declare dependencies on custom modules, which are used to manage complex Angular applications and to create units of reusable functionality. I explain how custom modules are defined in the "Creating Feature Modules" section.

Understanding the declarations Property

The declarations property is used to provide Angular with a list of the directives, components, and pipes that the application requires, known collectively as the *declarable classes*. The declarations property in the example project root module contains a long list of classes, each of which is available for use elsewhere in the application only because it is listed here.

```
...
declarations: [ProductComponent, PaAttrDirective, PaModel,
    PaStructureDirective, PaIteratorDirective,
    PaCellColor, PaCellColorSwitcher, ProductTableComponent,
    ProductFormComponent, PaToggleView, PaAddTaxPipe,
    PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
    PaDiscountPipe, PaDiscountAmountDirective, PaDisplayValueDirective],
```

...

Notice that the built-in declarable classes, such as the directives described in Chapter 11 and the pipes described in Chapter 16, are not included in the declarations property for the root module. This is because they are part of the BrowserModule module, and when you add a module to the imports property, its declarable classes are automatically available for use in the application.

Understanding the providers Property

The providers property is used to define the service providers that will be used to resolve dependencies when there are no suitable local providers available. The use of providers for services is described in detail in Chapters 17 and 19.

Understanding the bootstrap Property

The bootstrap property specifies the root component or components for the application. When Angular processes the main HTML document, which is conventionally called index.html, it inspects the root components and applies them using the value of the selector property in the @Component decorators.

■ **Tip** The components listed in the bootstrap property must also be included in the declarations list.

Here is the bootstrap property from the example project's root module:

```
...
bootstrap: [ProductComponent]
...
```

The ProductComponent class provides the root component, and its selector property specifies the app element, as shown in Listing 19-5.

Listing 19-5. The Root Component in the component.ts File in the src/app Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "app",
    templateUrl: "template.html"
})
export class ProductComponent {

}
```

When I started the example project in Chapter 9, the root component had a lot of functionality. But since the introduction of additional components, the role of this component has been reduced, and it is now essentially a placeholder that tells Angular to project the contents of the app/template.html file into the app element in the HTML document, which allows the components that do the real work in the application to be loaded.

There is nothing wrong with this approach, but it does mean the root component in the application doesn't have a great deal to do. If this kind of redundancy feels untidy, then you can specify multiple root components in the root module, and all of them will be used to target elements in the HTML document. To demonstrate, I have removed the existing root component from the root module's bootstrap property and replaced it with the component classes that are responsible for the product form and the product table, as shown in Listing 19-6.

Listing 19-6. Specifying Multiple Root Components in the app.module.ts File in the src/app Folder

```
...
@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective, PaDisplayValueDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model, LogService,
        { provide: VALUE_SERVICE, useValue: "Apples" }],
    bootstrap: [ProductFormComponent, ProductTableComponent]
})
export class AppModule { }
...
```

Listing 19-7 reflects the change in the root components in the main HTML document. The inconsistent element names are from an earlier chapter, where I changed the selector for the form component to demonstrate the use of the shadow DOM feature.

Listing 19-7. Changing the Root Component Elements in the index.html File in the src Folder

```
<!doctype html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Example</title>
  <base href="/">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <link rel="icon" type="image/x-icon" href="favicon.ico">
  <link rel="preconnect" href="https://fonts.gstatic.com">
  <link
  href="https://fonts.googleapis.com/css2?family=Roboto:wght@300;400;500&display=swap"
    rel="stylesheet">
  <link href="https://fonts.googleapis.com/icon?family=Material+Icons"
    rel="stylesheet">
</head>
<body class="container-fluid">
    <div class="row">
```

```
        <div class="col-8 p-2">
            <paProductTable></paProductTable>
        </div>
        <div class="col-4 p-2">
            <pa-productform></pa-productform>
        </div>
    </div>
</body>
</html>
```

I have reversed the order in which these components appear compared to previous examples, just to create a detectable change in the application's layout. When all the changes are saved and the browser has reloaded the page, you will see the new root components displayed, as illustrated by Figure 19-2.

Figure 19-2. *Using multiple root components*

The module's service providers are used to resolve dependencies for all root components. In the case of the example application, this means there is a single Model service object that is shared throughout the application and that allows products created with the HTML form to be displayed automatically in the table, even though these components have been promoted to be root components.

Creating Feature Modules

The root module has become increasingly complex as I added features in earlier chapters, with a long list of import statements to load JavaScript modules and a set of classes in the declarations property of the @NgModule decorator that spans several lines, as shown in Listing 19-8.

Listing 19-8. The Contents of the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';
```

```
import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService,
    LogLevel, LOG_LEVEL} from "./log.service";
import { VALUE_SERVICE, PaDisplayValueDirective} from "./valueDisplay.directive";

let logger = new LogService();
logger.minimumLevel = LogLevel.DEBUG;

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective, PaDisplayValueDirective],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule
    ],
    providers: [DiscountService, SimpleDataSource, Model, LogService,
        { provide: VALUE_SERVICE, useValue: "Apples" }],
```

```
    bootstrap: [ProductFormComponent, ProductTableComponent]
})
export class AppModule { }
```

Feature modules are used to group related functionality so that it can be used as a single entity, just like the Angular modules such as `BrowserModule`. When I need to use the features for working with forms, for example, I don't have to add `import` statements and `declarations` entries for each individual directive, component, or pipe. Instead, I just add `BrowserModule` to the decorator's `imports` property, and all of the functionality it contains is available throughout the application.

When you create a feature module, you can choose to focus on an application function or elect to group a set of related building blocks that provide your application's infrastructure. I'll do both in the sections that follow because they work in slightly different ways and have different considerations. Feature modules use the same `@NgModule` decorator but with an overlapping set of configuration properties, some of which are new and some of which are used in common with the root module but have a different effect. I explain how these properties are used in the following sections, but Table 19-4 provides a summary for quick reference.

***Table 19-4.** The @NgModule Decorator Properties for Feature Modules*

Name	Description
imports	This property is used to import the modules that are required by the classes in the modules.
providers	This property is used to define the module's providers. When the feature module is loaded, the set of providers is combined with those in the root module, which means that the feature module's services are available throughout the application (and not just within the module).
declarations	This property is used to specify the directives, components, and pipes in the module. This property must contain the classes that are used within the module and those that are exposed by the module to the rest of the application.
exports	This property is used to define the public exports from the module. It contains some or all of the directives, components, and pipes from the `declarations` property and some or all of the modules from the `imports` property.

Creating a Model Module

The term *model module* might be a tongue twister, but it is generally a good place to start when refactoring an application using feature modules because just about every other building block in the application depends on the model.

The first step is to create the folder that will contain the module. Module folders are defined within the `src/app` folder and are given a meaningful name. For this module, I created an `src/app/model` folder by running the following command in the `example` folder:

```
mkdir src/app/model
```

The naming conventions used for Angular files make it easy to move and delete multiple files. Run the following command in the `example` folder to move the files (they will work in Windows PowerShell, Linux, and macOS):

```
mv src/app/*.model.ts src/app/model/
```

The result is that the files listed in Table 19-5 are moved to the model folder.

Table 19-5. *The File Moves Required for the Module*

File	New Location
src/app/datasource.model.ts	src/app/model/datasource.model.ts
src/app/product.model.ts	src/app/model/product.model.ts
src/app/repository.model.ts	src/app/model/repository.model.ts

If you try to build the project once you have moved the files, the TypeScript compiler will list a series of compiler errors because some of the key declarable classes are unavailable. I'll deal with these problems shortly.

Creating the Module Definition

The next step is to define a module that brings together the functionality in the files that have been moved to the new folder. I added a file called model.module.ts in the src/app/model folder and defined the module shown in Listing 19-9.

Listing 19-9. The Contents of the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { SimpleDataSource } from "./datasource.model";
import { Model } from "./repository.model";

@NgModule({
    providers: [Model, SimpleDataSource]
})
export class ModelModule { }
```

The purpose of a feature module is to selectively expose the contents of the folder to the rest of the application. The @NgModule decorator for this module uses only the providers property to define class providers for the Model and SimpleDataSource services. When you use providers in a feature module, they are registered with the root module's injector, which means they are available throughout the application, which is exactly what is required for the data model in the example application.

■ **Tip** A common mistake is to assume that services defined in a module are accessible only to the classes within that module. There is no module scope in Angular. Providers defined by a feature module are used as though they were defined by the root module. Local providers defined by directives and components in the feature module are available to their view and content children even if they are defined in other modules.

Updating the Other Classes in the Application

Moving classes into the model folder has broken import statements in other parts of the application. The next step is to update those import statements to point to the new module. There are four affected

files: attr.directive.ts, categoryFilter.pipe.ts, productForm.component.ts, and productTable.
component.ts. Listing 19-10 shows the changes required to the attr.directive.ts file.

Listing 19-10. Updating the Import Reference in the attr.directive.ts File in the src/app Folder

```
import { Directive, ElementRef, Input, SimpleChanges, Output,
    EventEmitter, HostListener, HostBinding } from "@angular/core";
import { Product } from "./model/product.model";

@Directive({
    selector: "[pa-attr]",
})
export class PaAttrDirective {

    @Input("pa-attr")
    @HostBinding("class")
    bgClass: string | null = "";

    @Input("pa-product")
    product: Product = new Product();

    @Output("pa-category")
    click = new EventEmitter<string>();

    @HostListener("click")
    triggerCustomEvent() {
        if (this.product != null) {
            this.click.emit(this.product.category);
        }
    }
}
```

The only change that is required is to update the path used in the import statement to reflect the new
location of the code file. Listing 19-11 shows the same change applied to the categoryFilter.pipe.ts file.

Listing 19-11. Updating the Import Reference in the categoryFilter.pipe.ts File in the src/app Folder

```
import { Pipe } from "@angular/core";
import { Product } from "./model/product.model";

@Pipe({
    name: "filter",
    pure: false
})
export class PaCategoryFilterPipe {

    transform(products: Product[] | undefined, category: string | undefined): Product[] {
        if (products == undefined) {
            return [];
        }
        return category == undefined ?
            products : products.filter(p => p.category == category);
```

559

```
    }
}
```

Listing 19-12 updates the import statements in the `productForm.component.ts` file.

Listing 19-12. Updating Import Paths in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation,
    Inject, SkipSelf } from "@angular/core";
import { Product } from "./model/product.model";
import { Model } from "./model/repository.model";
import { VALUE_SERVICE } from "./valueDisplay.directive";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    viewProviders: [{ provide: VALUE_SERVICE, useValue: "Oranges" }]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model,
            @Inject(VALUE_SERVICE) @SkipSelf() private serviceValue: string) {
        console.log("Service Value: " + serviceValue);
    }

    submitForm(form: any) {
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

Listing 19-13 updates the paths in the final file, `productTable.component.ts`.

Listing 19-13. Updating Import Paths in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./model/repository.model";
import { Product } from "./model/product.model";
import { DiscountService } from "./discount.service";
import { LogService } from "./log.service";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html",
    providers:[LogService]
})
export class ProductTableComponent {

    // ...statements omitted for brevity...
}
```

560

USING A JAVASCRIPT MODULE WITH AN ANGULAR MODULE

Creating an Angular module allows related application features to be grouped together but still requires that each one is imported from its own file when it is needed elsewhere in the application, as you have seen in the listings in this section.

You can also define a JavaScript module that exports the public-facing features of the Angular module so they can be accessed with the same kind of import statement that is used for the @angular/core module, for example. To use a JavaScript module, add a file called index.ts alongside the TypeScript file that defines the Angular module, which is the src/app/model folder for the examples in this section. For each of the application features that you want to use outside of the application, add an export...from statement, like this:

```
...
export { ModelModule } from "./model.module";
export { Product } from "./product.model";
export { SimpleDataSource } from "./datasource.model";
export { Model } from "./repository.model";
...
```

These statements export the contents of the individual TypeScript files. You can then import the features you require without having to specify individual files, like this:

```
...
import { Component, Output, EventEmitter, ViewEncapsulation,
    Inject, SkipSelf } from "@angular/core";
import { Product, Model } from "./model";
import { VALUE_SERVICE } from "./valueDisplay.directive";
...
```

Using the filename index.ts means that you only have to specify the name of the folder in the import statement, producing a result that is neater and more consistent with the Angular core packages.

That said, I don't use this technique in my own projects. Using an index.ts file means you have to remember to add every feature to both the Angular and JavaScript modules, which is an extra step that I often forget to do. Instead, I use the approach shown in this chapter and import directly from the files that contain the application's features.

Updating the Root Module

The final step is to update the root module so that the services defined in the feature module are made available throughout the application. Listing 19-14 shows the required changes.

Listing 19-14. Updating the Root Module in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { PaAttrDirective } from "./attr.directive";
import { PaModel } from "./twoway.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { ProductTableComponent } from "./productTable.component";
import { ProductFormComponent } from "./productForm.component";
import { PaToggleView } from "./toggleView.component";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { DiscountService } from "./discount.service";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
// import { SimpleDataSource } from "./datasource.model";
// import { Model } from "./repository.model";
import { LogService, LOG_SERVICE, SpecialLogService,
    LogLevel, LOG_LEVEL} from "./log.service";
import { VALUE_SERVICE, PaDisplayValueDirective} from "./valueDisplay.directive";
import { ModelModule } from "./model/model.module";

let logger = new LogService();
logger.minimumLevel = LogLevel.DEBUG;

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, PaAttrDirective, PaModel,
        PaStructureDirective, PaIteratorDirective,
        PaCellColor, PaCellColorSwitcher, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaAddTaxPipe,
        PaCategoryFilterPipe, PaDiscountDisplayComponent, PaDiscountEditorComponent,
        PaDiscountPipe, PaDiscountAmountDirective, PaDisplayValueDirective],
```

```
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule, ModelModule
    ],
    providers: [DiscountService, LogService,
        { provide: VALUE_SERVICE, useValue: "Apples" }],
    bootstrap: [ProductFormComponent, ProductTableComponent]
})
export class AppModule { }
```

I imported the feature module and added it to the root module's imports list. Since the feature module defines providers for Model and SimpleDataSource, I removed the entries from the root module's providers list and removed the associated import statements.

Once you have saved the changes, you can run ng serve to start the Angular development tools. The application will compile, and the revised root module will provide access to the model service. There are no visible changes to the content displayed in the browser, and the changes are limited to the structure of the project. (You may need to restart the Angular development tools and reload the browser to see the changes.)

Creating a Utility Feature Module

A model module is a good place to start because it demonstrates the basic structure of a feature module and how it relates to the root module. The impact on the application was slight, however, and not a great deal of simplification was achieved.

The next step up in complexity is a utility feature module, which groups together all of the common functionality in the application, such as pipes and directives. In a real project, you might be more selective about how you group these types of building blocks together so that there are several modules, each containing similar functionality. For the example application, I am going to move all of the pipes, directives, and services into a single module.

Creating the Module Folder and Moving the Files

As with the previous module, the first step is to create the folder. For this module, I created a folder called src/app/common and moved code files for the pipes and directives by running the following commands in the example folder:

```
mkdir src/app/common
mv src/app/*.pipe.ts src/app/common/
mv src/app/*.directive.ts src/app/common/
```

These commands should work in Windows PowerShell, Linux, and macOS. Some of the directives and pipes in the application rely on the DiscountService and LogServices classes, which are provided to them through dependency injection. Run the following command in the example folder to move the TypeScript file for the service into the module folder:

```
mv src/app/*.service.ts src/app/common/
```

The result is that the files listed in Table 19-6 are moved to the common module folder.

Table 19-6. *The File Moves Required for the Module*

File	New Location
app/addTax.pipe.ts	app/common/addTax.pipe.ts
app/attr.directive.ts	app/common/attr.directive.ts
app/categoryFilter.pipe.ts	app/common/categoryFilter.pipe.ts
app/cellColor.directive.ts	app/common/cellColor.directive.ts
app/cellColorSwitcher.directive.ts	app/common/cellColorSwitcher.directive.ts
app/discount.pipe.ts	app/common/discount.pipe.ts
app/discountAmount.directive.ts	app/common/discountAmount.directive.ts
app/iterator.directive.ts	app/common/iterator.directive.ts
app/structure.directive.ts	app/common/structure.directive.ts
app/twoway.directive.ts	app/common/twoway.directive.ts
app/valueDisplay.directive.ts	app/common/valueDisplay.directive.ts
app/discount.service.ts	app/common/discount.service.ts
app/log.service.ts	app/common/log.service.ts

Updating the Classes in the New Module

Some of the classes that have been moved into the new folder have `import` statements that have to be updated to reflect the new path to the model module. Listing 19-15 shows the change required to the `attr. directive.ts` file.

Listing 19-15. Updating the Imports in the attr.directive.ts File in the src/app/common Folder

```
import { Directive, ElementRef, Input, SimpleChanges, Output,
    EventEmitter, HostListener, HostBinding } from "@angular/core";
import { Product } from "../model/product.model";

@Directive({
    selector: "[pa-attr]",
})
export class PaAttrDirective {

    // ...statements omitted for brevity...
}
```

Listing 19-16 shows the corresponding change to the `categoryFilter.pipe.ts` file.

Listing 19-16. Updating the Imports in the categoryFilter.pipe.ts File in the src/app/common Folder

```
import { Pipe } from "@angular/core";
import { Product } from "../model/product.model";

@Pipe({
    name: "filter",
    pure: false
})
export class PaCategoryFilterPipe {

    transform(products: Product[] | undefined, category: string | undefined):
            Product[] {
        if (products == undefined) {
            return [];
        }
        return category == undefined ?
            products : products.filter(p => p.category == category);
    }
}
```

Creating the Module Definition

The next step is to define a module that brings together the functionality in the files that have been moved to the new folder. I added a file called common.module.ts in the src/app/common folder and defined the module shown in Listing 19-17.

Listing 19-17. The Contents of the common.module.ts File in the src/app/common Folder

```
import { NgModule } from "@angular/core";
import { PaAddTaxPipe } from "./addTax.pipe";
import { PaAttrDirective } from "./attr.directive";
import { PaCategoryFilterPipe } from "./categoryFilter.pipe";
import { PaCellColor } from "./cellColor.directive";
import { PaCellColorSwitcher } from "./cellColorSwitcher.directive";
import { PaDiscountPipe } from "./discount.pipe";
import { PaDiscountAmountDirective } from "./discountAmount.directive";
import { PaIteratorDirective } from "./iterator.directive";
import { PaStructureDirective } from "./structure.directive";
import { PaModel } from "./twoway.directive";
import { VALUE_SERVICE, PaDisplayValueDirective} from "./valueDisplay.directive";
import { DiscountService } from "./discount.service";
import { LogService } from "./log.service";
import { ModelModule } from "../model/model.module";

@NgModule({
    imports: [ModelModule],
    providers: [LogService, DiscountService,
        { provide: VALUE_SERVICE, useValue: "Apples" }],
    declarations: [PaAddTaxPipe, PaAttrDirective, PaCategoryFilterPipe,
```

```
        PaCellColor, PaCellColorSwitcher, PaDiscountPipe,
        PaDiscountAmountDirective, PaIteratorDirective, PaStructureDirective,
        PaModel, PaDisplayValueDirective],
    exports: [PaAddTaxPipe, PaAttrDirective, PaCategoryFilterPipe,
        PaCellColor, PaCellColorSwitcher, PaDiscountPipe,
        PaDiscountAmountDirective, PaIteratorDirective, PaStructureDirective,
        PaModel, PaDisplayValueDirective]
})
export class CommonModule { }
```

This is a more complex module than the one required for the data model. In the sections that follow, I describe the values that are used for each of the decorator's properties.

Understanding the Imports

Some of the directives and pipes in the module depend on the services defined in the model module, created earlier in this chapter. To ensure that the features in that module are available, I have added to the common module's imports property.

Understanding the Providers

The providers property ensures that the services, directives, and pipes in the feature module have access to the services they require. This means adding class providers to create LogService and DiscountService services, which will be added to the root module's providers when the module is loaded. Not only will the services be available to the directives and pipes in the common module; they will also be available throughout the application.

Understanding the Declarations

The declarations property is used to provide Angular with a list of the directives and pipes (and components, if there are any) in the module. In a feature module, this property has two purposes: it enables the declarable classes for use in any templates contained within the module, and it allows a module to make those declarable classes available outside of the module. I create a module that contains template content later in this chapter, but for this module, the value of the declarations property is that it must be used to prepare for the exports property, described in the next section.

Understanding the Exports

For a module that contains directives and pipes intended for use elsewhere in the application, the exports property is the most important in the @NgModule decorator because it defines the set of directives, components, and pipes that the module provides for use when it is imported elsewhere in the application. The exports property can contain individual classes and module types, although both must already be listed in the declarations or imports property. When the module is imported, the types listed behave as though they had been added to the importing module's declarations property.

Updating the Other Classes in the Application

Now that the module has been defined, I can update the other files in the application that contain import statements for the types that are now part of the common module. Listing 19-18 shows the changes required to the discountDisplay.component.ts file.

Listing 19-18. Updating the Import in the discountDisplay.component.ts File in the src/app Folder

```
import { Component, Input } from "@angular/core";
import { DiscountService } from "./common/discount.service";

@Component({
    selector: "paDiscountDisplay",
    template: `<div class="bg-info text-white p-2 my-2">
                 The discount is {{discounter?.discount }}
               </div>`
})
export class PaDiscountDisplayComponent {

    constructor(public discounter: DiscountService) { }
}
```

Listing 19-19 shows the changes to the discountEditor.component.ts file.

Listing 19-19. Updating the Import Reference in the discountEditor.component.ts File in the src/app Folder

```
import { Component, Input } from "@angular/core";
import { DiscountService } from "./common/discount.service";

@Component({
    selector: "paDiscountEditor",
    template: `<div class="form-group">
                  <label>Discount</label>
                  <input [(ngModel)]="discounter.discount"
                      class="form-control" type="number" />
               </div>`
})
export class PaDiscountEditorComponent {

    constructor(public discounter: DiscountService) { }
}
```

Listing 19-20 shows the changes to the productForm.component.ts file.

Listing 19-20. Updating the Import Reference in the productForm.component.ts File in the src/app Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation,
    Inject, SkipSelf } from "@angular/core";
import { Product } from "./model/product.model";
import { Model } from "./model/repository.model";
import { VALUE_SERVICE } from "./common/valueDisplay.directive";
```

```
@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    viewProviders: [{ provide: VALUE_SERVICE, useValue: "Oranges" }]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model,
            @Inject(VALUE_SERVICE) @SkipSelf() private serviceValue: string) {
        console.log("Service Value: " + serviceValue);
    }

    submitForm(form: any) {
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

The final change is to the `productTable.component.ts` file, as shown in Listing 19-21.

Listing 19-21. Updating the Import Reference in the productTable.component.ts File in the src/app Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "./model/repository.model";
import { Product } from "./model/product.model";
import { DiscountService } from "./common/discount.service";
import { LogService } from "./common/log.service";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html",
    providers:[LogService]
})
export class ProductTableComponent {

    constructor(private dataModel: Model) { }

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }

    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }
```

```
registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent, ProductTableComponent,
        ProductFormComponent, PaToggleView, PaDiscountDisplayComponent,
        PaDiscountEditorComponent],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
        FormsModule, ReactiveFormsModule, ModelModule, CommonModule
    ],
    // providers: [DiscountService, LogService,
    //     { provide: VALUE_SERVICE, useValue: "Apples" }],
    bootstrap: [ProductFormComponent, ProductTableComponent]
})
export class AppModule { }
```

The root module has been substantially simplified with the creation of the common module, which has been added to the imports list. All of the individual classes for directives and pipes have been removed from the declarations list, and their associated import statements have been removed from the file. When the common module is imported, all of the types listed in its exports property will be added to the root module's declarations property.

Once you have saved the changes in this section, you can run the ng serve command to start the Angular development tools. Once again, there is no visible change in the content presented to the user, and the differences are all in the structure of the application.

Creating a Feature Module with Components

The final module that I am going to create will contain the application's components. The process for creating the module is the same as in the previous examples, as described in the sections that follow.

Creating the Module Folder and Moving the Files

The module will be called components, and I created the folder src/app/components to contain the files. Run the following commands in the example folder to create the folder; move the directive TypeScript, HTML, and CSS files into the new folder; and delete the corresponding JavaScript files:

```
mkdir src/app/components
mv src/app/*.component.ts src/app/components/
mv src/app/*.component.html src/app/components/
mv src/app/*.component.css src/app/components/
```

The result of these commands is that the component code files, templates, and style sheets are moved into the new folder, as listed in Table 19-7.

Table 19-7. *The File Moves Required for the Component Module*

File	New Location
src/app/app.component.ts	src/app/components/app.component.ts
src/app/app.component.html	src/app/components/app.component.html
src/app/app.component.css	src/app/components/app.component.css

src/app
   /discountDisplay.component.ts
	src/app/components
	     /discountDisplay.component.ts

src/app/discountEditor.component.ts	src/app/components/discountEditor.component.ts
src/app/productForm.component.ts	src/app/components/productForm.component.ts
src/app/productForm.component.html	src/app/components/productForm.component.html
src/app/productForm.component.css	src/app/components/productForm.component.css
src/app/productTable.component.ts	src/app/components/productTable.component.ts
src/app/productTable.component.html	src/app/components/productTable.component.html
src/app/productTable.component.css	src/app/components/productTable.component.css
src/app/toggleView.component.ts	src/app/components/toggleView.component.ts
src/app/toggleView.component.html	src/app/components/toggleView.component.ts

Creating the Module Definition

To create the module, I added a file called components.module.ts to the src/app/components folder and added the statements shown in Listing 19-23.

Listing 19-23. The Contents of the components.module.ts File in the src/app/components Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { CommonModule } from "../common/common.module";
import { FormsModule, ReactiveFormsModule } from "@angular/forms"
import { PaDiscountDisplayComponent } from "./discountDisplay.component";
import { PaDiscountEditorComponent } from "./discountEditor.component";
import { ProductFormComponent } from "./productForm.component";
import { ProductTableComponent } from "./productTable.component";

@NgModule({
    imports: [BrowserModule, FormsModule, ReactiveFormsModule, CommonModule],
    declarations: [PaDiscountDisplayComponent, PaDiscountEditorComponent,
        ProductFormComponent, ProductTableComponent],
    exports: [ProductFormComponent, ProductTableComponent]
})
export class ComponentsModule { }
```

This module imports BrowserModule and CommonModule to ensure that the directives have access to the services and the declarable classes they require. It exports the ProductFormComponent and ProductTableComponent components, which are the two components used in the root component's bootstrap property. The other components are private to the module.

Updating the Other Classes

Moving the TypeScript files into the components folder requires some changes to the paths in the import statements. Listing 19-24 shows the change required for the discountDisplay.component.ts file.

Listing 19-24. Updating a Path in the discountDisplay.component.ts File in the src/app/component Folder

```
import { Component, Input } from "@angular/core";
import { DiscountService } from "../common/discount.service";

@Component({
    selector: "paDiscountDisplay",
    template: `<div class="bg-info text-white p-2 my-2">
                The discount is {{discounter?.discount }}
               </div>`
})
export class PaDiscountDisplayComponent {

    constructor(public discounter: DiscountService) { }
}
```

Listing 19-25 shows the change required to the discountEditor.component.ts file.

Listing 19-25. Updating a Path in the discountEditor.component.ts File in the src/app/component Folder

```
import { Component, Input } from "@angular/core";
import { DiscountService } from "../common/discount.service";

@Component({
    selector: "paDiscountEditor",
    template: `<div class="form-group">
                    <label>Discount</label>
                    <input [(ngModel)]="discounter.discount"
                        class="form-control" type="number" />
               </div>`
})
export class PaDiscountEditorComponent {

    constructor(public discounter: DiscountService) { }
}
```

Listing 19-26 shows the changes required for the productForm.component.ts file.

Listing 19-26. Updating a Path in the productForm.component.ts File in the src/app/component Folder

```
import { Component, Output, EventEmitter, ViewEncapsulation,
    Inject, SkipSelf } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { VALUE_SERVICE } from "../common/valueDisplay.directive";

@Component({
    selector: "pa-productform",
    templateUrl: "productForm.component.html",
    viewProviders: [{ provide: VALUE_SERVICE, useValue: "Oranges" }]
})
export class ProductFormComponent {
    newProduct: Product = new Product();

    constructor(private model: Model,
            @Inject(VALUE_SERVICE) @SkipSelf() private serviceValue: string) {
        console.log("Service Value: " + serviceValue);
    }

    submitForm(form: any) {
        this.model.saveProduct(this.newProduct);
        this.newProduct = new Product();
        form.resetForm();
    }
}
```

Listing 19-27 shows the changes required to the productTable.component.ts file.

Listing 19-27. Updating a Path in the productTable.component.ts File in the src/app/component Folder

```
import { Component, Input, QueryList, ViewChildren } from "@angular/core";
import { Model } from "../model/repository.model";
import { Product } from "../model/product.model";
import { DiscountService } from "../common/discount.service";
import { LogService } from "../common/log.service";

@Component({
    selector: "paProductTable",
    templateUrl: "productTable.component.html",
    providers:[LogService]
})
export class ProductTableComponent {

    constructor(private dataModel: Model) { }

    getProduct(key: number): Product | undefined {
        return this.dataModel?.getProduct(key);
    }
```

```
    getProducts(): Product[] | undefined {
        return this.dataModel?.getProducts();
    }

    deleteProduct(key: number) {
        this.dataModel?.deleteProduct(key);
    }

    taxRate: number = 0;
    categoryFilter: string | undefined;
    itemCount: number = 3;
}
```

Updating the Root Module

The final step is to update the root module to remove the outdated references to the individual files and to import the new module, as shown in Listing 19-28.

Listing 19-28. Importing a Feature Module in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

//import { AppComponent } from './app.component';
import { BrowserAnimationsModule } from '@angular/platform-browser/animations';

import { ProductComponent } from './component';
import { FormsModule, ReactiveFormsModule } from "@angular/forms";

import { ProductTableComponent } from "./components/productTable.component";
import { ProductFormComponent } from "./components/productForm.component";
// import { PaToggleView } from "./toggleView.component";

import { LOCALE_ID } from "@angular/core";
import localeFr from '@angular/common/locales/fr';
import { registerLocaleData } from '@angular/common';

// import { PaDiscountDisplayComponent } from "./discountDisplay.component";
// import { PaDiscountEditorComponent } from "./discountEditor.component";

import { ModelModule } from "./model/model.module";
import { CommonModule } from "./common/common.module";
import { ComponentsModule } from "./components/components.module";

registerLocaleData(localeFr);

@NgModule({
    declarations: [ProductComponent],
    imports: [
        BrowserModule,
        BrowserAnimationsModule,
```

```
        FormsModule, ReactiveFormsModule, ModelModule, CommonModule,
        ComponentsModule
    ],
    bootstrap: [ProductFormComponent, ProductTableComponent]
})
export class AppModule { }
```

Restart the Angular development tools to build and display the application. Adding modules to the application has radically simplified the root module and allows related features to be defined in self-contained blocks, which can be extended or modified in relative isolation from the rest of the application.

Summary

In this chapter, I described the last of the Angular building blocks: modules. I explained the role of the root module and demonstrated how to create feature modules to add structure to an application. In the next part of the book, I describe the features that Angular provides to shape the building blocks into complex and responsive applications.

CHAPTER 20

■ ■ ■

Creating the Example Project

Throughout the chapters in the previous part of the book, I added classes and content to the example project to demonstrate different Angular features and then, in Chapter 19, introduced feature modules to add some structure to the project. The result is a project with a lot of redundant and unused functionality, and for this part of the book, I am going to start a new project that takes some of the core features from earlier chapters and provides a clean foundation on which to build in the chapters that follow.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book— from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Starting the Example Project

To create the project and populate it with tools and placeholder content, open a new command prompt, navigate to a convenient location, and run the command shown in Listing 20-1.

Listing 20-1.   Creating the Example Project

```
ng new exampleApp --routing false --style css --skip-git --skip-tests
```

To distinguish the project used in this part of the book from earlier examples, I created a project called `exampleApp`. The project initialization process will take a while to complete as all the required packages are downloaded.

Adding and Configuring the Bootstrap CSS Package

I continue to use the Bootstrap CSS framework to style the HTML elements in this chapter and the rest of the book. Run the command shown in Listing 20-2 in the `exampleApp` folder to add the Bootstrap package to the project.

Listing 20-2.   Adding a Package to the Project

```
npm install bootstrap@5.1.3
```

The Bootstrap package isn't specific to Angular development and doesn't use the schematics API, which means that a manual change must be made to the angular.config file to include the Bootstrap CSS stylesheet in the styles bundle. Run the command shown in Listing 20-3 in the exampleApp folder. Take care to enter the command exactly as shown and do not introduce additional spaces or quotes.

Listing 20-3. Changing the Application Configuration

```
ng config projects.exampleApp.architect.build.options.styles \
'["src/styles.css",'\
'"node_modules/bootstrap/dist/css/bootstrap.min.css"]'
```

If you are using Windows, then use a PowerShell prompt to run the command shown in Listing 20-4 in the exampleApp folder.

Listing 20-4. Changing the Application Configuration Using PowerShell

```
ng config projects.exampleApp.architect.build.options.styles `
'[""src/styles.css"", ""node_modules/bootstrap/dist/css/bootstrap.min.css""]'
```

Creating the Project Structure

Create the folders shown in Table 20-1 in preparation for the feature modules that the example project will contain.

Table 20-1. *The Folders Created for the Example Application*

Name	Description
src/app/model	This folder will contain a feature module containing the data model.
src/app/core	This folder will contain a feature module containing components that provide the core features of the application.
src/app/messages	This folder will contain a feature module that is used to display messages and errors to the user.

Creating the Model Module

The first feature module will contain the project's data model, which is similar to the one used in Part 2.

Creating the Product Data Type

To define the basic data type around which the application is based, I added a file called product.model.ts to the src/app/model folder and defined the class shown in Listing 20-5.

Listing 20-5. The Contents of the product.model.ts File in the src/app/model Folder

```
export class Product {

    constructor(public id?: number,
        public name?: string,
        public category?: string,
        public price?: number) { }
}
```

Creating the Data Source and Repository

To provide the application with some initial data, I created a file called `static.datasource.ts` in the `src/app/model` folder and defined the service shown in Listing 20-6. This class will be used as the data source until Chapter 23, where I explain how to use asynchronous HTTP requests to request data from web services.

■ **Tip**   I am more relaxed about following the name conventions for Angular files when creating files within a feature module, especially if the purpose of the module is obvious from its name.

Listing 20-6. The Contents of the static.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";

@Injectable()
export class StaticDataSource {
    private data: Product[];

    constructor() {
        this.data = new Array<Product>(
            new Product(1, "Kayak", "Watersports", 275),
            new Product(2, "Lifejacket", "Watersports", 48.95),
            new Product(3, "Soccer Ball", "Soccer", 19.50),
            new Product(4, "Corner Flags", "Soccer", 34.95),
            new Product(5, "Thinking Cap", "Chess", 16));
    }

    getData(): Product[] {
        return this.data;
    }
}
```

The next step is to define the repository, through which the rest of the application will access the model data. I created a file called `repository.model.ts` in the `src/app/model` folder and used it to define the class shown in Listing 20-7.

581

Listing 20-7. The Contents of the repository.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";

@Injectable()
export class Model {
    private products: Product[];
    private locator = (p: Product, id?: number) => p.id == id;

    constructor(private dataSource: StaticDataSource) {
        this.products = new Array<Product>();
        this.dataSource.getData().forEach(p => this.products.push(p));
    }

    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }

    saveProduct(product: Product) {
        if (product.id == 0 || product.id == null) {
            product.id = this.generateID();
            this.products.push(product);
        } else {
            let index = this.products
                .findIndex(p => this.locator(p, product.id));
            this.products.splice(index, 1, product);
        }
    }

    deleteProduct(id: number) {
        let index = this.products.findIndex(p => this.locator(p, id));
        if (index > -1) {
            this.products.splice(index, 1);
        }
    }

    private generateID(): number {
        let candidate = 100;
        while (this.getProduct(candidate) != null) {
            candidate++;
        }
        return candidate;
    }
}
```

Completing the Model Module

To complete the data model, I need to define the module. I created a file called `model.module.ts` in the `src/app/model` folder and used it to define the Angular module shown in Listing 20-8.

Listing 20-8. The Contents of the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { StaticDataSource } from "./static.datasource";
import { Model } from "./repository.model";

@NgModule({
    providers: [Model, StaticDataSource]
})
export class ModelModule { }
```

Creating the Messages Module

The messages module will contain a service that is used to report messages or errors that should be displayed to the user and a component that presents them.

Creating the Message Model and Service

To represent messages that should be displayed to the user, I added a file called `message.model.ts` to the `src/app/messages` folder and added the code shown in Listing 20-9.

Listing 20-9. The Contents of the message.model.ts File in the src/app/messages Folder

```
export class Message {

    constructor(public text: string,
        public error: boolean = false) { }
}
```

The `Message` class defines properties that present the text that will be displayed to the user and whether the message represents an error. Next, I created a file called `message.service.ts` in the `src/app/messages` folder and used it to define the service shown in Listing 20-10, which will be used to register messages that should be displayed to the user.

Listing 20-10. The Contents of the message.service.ts File in the src/app/messages Folder

```
import { Injectable } from "@angular/core";
import { Message } from "./message.model";
import { Observable, ReplaySubject, Subject } from "rxjs";

@Injectable()
export class MessageService {

    messages: Observable<Message> = new ReplaySubject<Message>(1);
```

```
    reportMessage(msg: Message) {
        (this.messages as Subject<Message>).next(msg);
    }
}
```

Angular services don't support output properties but can still use the features provided by the RxJS package to send events. This service defines a `reportMessage` method that sends a new event through a `ReplaySubject<Message>` that is presented to the rest of the application as an `Observable<Message>`. I used a `ReplaySubject` so that new subscribers will immediately receive the most recent message.

This service is essentially used to provide access to the observable/subject, and I could have made this object available directly as a service using the service provider features described in Chapter 18. However, I prefer to introduce a lightweight service as a wrapper around the observable so that I can easily alter the way that events are created by modifying the `reportMessage` method.

Creating the Component and Template

Now that I have a source of messages, I can create a component that will display them to the user. I added a file called `message.component.ts` to the `src/app/messages` folder and defined the component shown in Listing 20-11.

Listing 20-11. The Contents of the message.component.ts File in the src/app/messages Folder

```
import { Component } from "@angular/core";
import { MessageService } from "./message.service";
import { Message } from "./message.model";

@Component({
    selector: "paMessages",
    templateUrl: "message.component.html",
})
export class MessageComponent {
    lastMessage?: Message;

    constructor(messageService: MessageService) {
        messageService.messages.subscribe(msg => this.lastMessage = msg);
    }
}
```

The component receives a `MessageService` object as its constructor argument and subscribes to the events it emits in order to receive messages, the most recent of which is assigned to a property called `lastMessage`. To provide a template for the component, I created a file called `message.component.html` in the `src/app/messages` folder and added the markup shown in Listing 20-12, which displays the message to the user.

Listing 20-12. The Contents of the message.component.html File in the src/app/messages Folder

```
<div *ngIf="lastMessage"
    class="bg-primary text-white p-2 text-center"
    [class.bg-danger]="lastMessage.error">
        <h4>{{lastMessage.text}}</h4>
</div>
```

Completing the Message Module

I added a file called message.module.ts in the src/app/messages folder and defined the module shown in Listing 20-13.

Listing 20-13. The Contents of the message.module.ts File in the src/app/messages Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { MessageComponent } from "./message.component";
import { MessageService } from "./message.service";

@NgModule({
    imports: [BrowserModule],
    declarations: [MessageComponent],
    exports: [MessageComponent],
    providers: [MessageService]
})
export class MessageModule { }
```

Creating the Core Module

The core module will contain the central functionality of the application, built on features that were described in Part 2, that presents the user with a list of the products in the model and the ability to create and edit them.

Creating the Shared State Service

To help the components in this module to collaborate, I am going to add a service that records the current mode, noting whether the user is editing or creating a product. I added a file called sharedState.service.ts to the src/app/core folder and defined the enum and class shown in Listing 20-14.

Listing 20-14. The Contents of the sharedState.service.ts File in the src/app/core Folder

```
import { Injectable } from "@angular/core";
import { Observable, Subject } from "rxjs"

export enum MODES {
    CREATE, EDIT
}

export interface StateUpdate {
    mode: MODES
    id?: number
}

@Injectable()
export class SharedState {
    private modeValue: MODES = MODES.EDIT;
    private idValue?: number;
```

```
    constructor() {
        this.changes = new Subject<StateUpdate>();
    }

    get id(): number | undefined { return this.idValue };
    get mode(): MODES { return this.modeValue };

    changes: Observable<StateUpdate>

    update(mode: MODES, id?: number) {
        this.modeValue = mode;
        this.idValue = id;
        (this.changes as Subject<StateUpdate>).next({
            mode: this.modeValue, id: this.idValue
        });
    }
}
```

The SharedState class contains two get-only properties that reflect the current mode and the ID of the data model object that is being operated on. These properties return the values of private fields. The state is changed using the update method, which sends out events through an RXJS Subject, which is publicly presented as an Observable to present other components from creating their own events.

Creating the Table Component

This component will present the user with the table that lists all the products in the application and that will be the main focal point in the application, providing access to other areas of functionality through buttons that allow objects to be created, edited, or deleted. Listing 20-15 shows the contents of the table. component.ts file, which I created in the src/app/core folder.

Listing 20-15. The Contents of the table.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { MODES, SharedState } from "./sharedState.service";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html"
})
export class TableComponent {

    constructor(private model: Model, private state: SharedState) { }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }
```

```
    getProducts(): Product[] {
        return this.model.getProducts();
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    editProduct(key?: number) {
        this.state.update(MODES.EDIT, key)
    }

    createProduct() {
        this.state.update(MODES.CREATE);
    }
}
```

This component provides the same basic functionality used in Part 2, with the addition of the editProduct and createProduct methods. These methods update the shared state service when the user wants to edit or create a product.

Creating the Table Component Template

To provide the table component with a template, I added an HTML file called table.component.html to the src/app/core folder and added the markup shown in Listing 20-16.

Listing 20-16. The Contents of the table.component.html File in the src/app/core Folder

```html
<table class="table table-sm table-bordered table-striped">
  <thead>
    <tr>
        <th>ID</th><th>Name</th><th>Category</th><th>Price</th><th></th>
    </tr>
  </thead>
  <tbody>
    <tr *ngFor="let item of getProducts()">
        <td>{{item.id}}</td>
        <td>{{item.name}}</td>
        <td>{{item.category}}</td>
        <td>{{item.price | currency:"USD" }}</td>
        <td class="text-center">
            <button class="btn btn-danger btn-sm m-1"
                    (click)="deleteProduct(item.id)">
                Delete
            </button>
            <button class="btn btn-warning btn-sm" (click)="editProduct(item.id)">
                Edit
            </button>
        </td>
```

```
    </tr>
  </tbody>
</table>
<button class="btn btn-primary mt-1" (click)="createProduct()">
  Create New Product
</button>
```

This template uses the ngFor directive to create rows in a table for each product in the data model, including buttons that call the deleteProduct and editProduct methods. There is also a button element outside of the table that calls the component's createProduct method when it is clicked.

Creating the Form Component

For this project, I am going to create a form component that will manage an HTML form that will allow new products to be created and allow existing products to be modified. To define the component, I added a file called form.component.ts to the src/app/core folder and added the code shown in Listing 20-17.

Listing 20-17. The Contents of the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { NgForm } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
        } else {
```

```
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
        }
    }

    submitForm(form: NgForm) {
        if (form.valid) {
            this.model.saveProduct(this.product);
            this.product = new Product();
            form.resetForm();
        }
    }
}
}
```

A single component will present a form used to both create new products and edit existing ones. The component depends on two services. The SharedState service provides events that are used to change the details of the form shown to the user, based on whether a product is being created or edited. The MessageService service is used to send messages that indicate the create/edit mode so they can be displayed to the user.

Notice that an initial message is sent via the MessageService object using the JavaScript setTimeout method. This prevents the message from being lost.

Creating the Form Component Template

To provide the component with a template, I added an HTML file called form.component.html to the src/app/core folder and added the markup shown in Listing 20-18.

Listing 20-18. The Contents of the form.component.html File in the src/app/core Folder

```
<form #form="ngForm" (ngSubmit)="submitForm(form)" (reset)="form.resetForm()" >
  <div class="form-group">
      <label>Name</label>
      <input class="form-control" name="name"
             [(ngModel)]="product.name" required />
  </div>

  <div class="form-group">
      <label>Category</label>
      <input class="form-control" name="category"
             [(ngModel)]="product.category" required />
  </div>

  <div class="form-group">
      <label>Price</label>
      <input class="form-control" name="price"
             [(ngModel)]="product.price"
             required pattern="^[0-9\.]+$" />
  </div>
```

```
  <div class="mt-2">
    <button type="submit" class="btn btn-primary"
            [class.btn-warning]="editing" [disabled]="form.invalid">
        {{editing ? "Save" : "Create"}}
    </button>
    <button type="reset" class="btn btn-secondary m-1">Cancel</button>
  </div>
</form>
```

The most important part of this template is the form element, which contains input elements for the name, category, and price properties required to create or edit a product. The header at the top of the template and the submit button for the form change their content and appearance based on the editing mode to distinguish between different operations.

Creating the Form Component Styles

To keep the example simple, I have used the basic form validation without any error messages. Instead, I rely on CSS styles that are applied using Angular validation classes. I added a file called form.component.css to the src/app/core folder and defined the styles shown in Listing 20-19.

Listing 20-19. The Contents of the form.component.css File in the src/app/core Folder

```
input.ng-dirty.ng-invalid { border: 2px solid #ff0000 }
input.ng-dirty.ng-valid { border: 2px solid #6bc502 }
```

Completing the Core Module

To define the module that contains the components, I added a file called core.module.ts to the src/app/ core folder and created the Angular module shown in Listing 20-20.

Listing 20-20. The Contents of the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
import { SharedState } from "./sharedState.service";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule],
    declarations: [TableComponent, FormComponent],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [SharedState]
})
export class CoreModule { }
```

This module imports the core Angular functionality, the Angular form features, and the application's data model, created earlier in the chapter. It also sets up a provider for the SharedState service.

Completing the Project

To bring all the different modules together, I made the changes shown in Listing 20-21 to the root module.

Listing 20-21. Configuring the Application in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';

//import { AppComponent } from './app.component';

import { ModelModule } from "./model/model.module";
import { CoreModule } from "./core/core.module";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { MessageModule } from "./messages/message.module";
import { MessageComponent } from "./messages/message.component";

@NgModule({
  declarations: [],
  imports: [BrowserModule, ModelModule, CoreModule, MessageModule],
  providers: [],
  bootstrap: [TableComponent, FormComponent, MessageComponent]
})
export class AppModule { }
```

The module imports the feature modules created in this chapter and specifies three bootstrap components, two of which were defined in CoreModule and one from MessageModule. These will display the product table and form and any messages or errors.

The final step is to update the HTML file so that it contains elements that will be matched by the selector properties of the bootstrap components, as shown in Listing 20-22.

Listing 20-22. Adding Custom Elements in the index.html File in the src Folder

```
<!doctype html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <title>ExampleApp</title>
    <base href="/">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <link rel="icon" type="image/x-icon" href="favicon.ico">
</head>
<body>
    <paMessages></paMessages>
    <div class="row m-2">
        <div class="col-8 p-2">
            <paTable></paTable>
        </div>
        <div class="col-4 p-2">
            <paForm></paForm>
```

```
        </div>
    </div>
</body>
</html>
```

Run the following command in the exampleApp folder to start the Angular development tools and build the project:

```
ng serve
```

Once the initial build process has completed, open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 20-1.

Figure 20-1. *Running the example application*

Fill out the form and click the Create button to add a product to the repository. You can also click the Edit button to select a product for editing and click the Delete button to remove a button.

Summary

In this chapter, I created the example project that I will use in this part of the book. The basic structure is the same as the example used in earlier chapters but without the redundant code and markup that I used to demonstrate earlier features. In the next chapter, I describe the advanced features Angular provides for working with forms.

CHAPTER 21

■ ■ ■

Using the Forms API, Part 1

In this chapter, I describe the Angular forms API, which provides an alternative to the template-based approach to forms introduced in Chapter 12. The forms API is a more complicated way of creating forms, but it allows fine-grained control over how forms behave, how they respond to user interaction, and how they are validated. Table 21-1 puts the forms API in context.

Table 21-1. *Putting the Forms API in Context*

Question	Answer
What is it?	The forms API allows for the creation of reactive forms, which are managed using the code in a component class.
Why is it useful?	The forms API provides a component with more control over the elements in forms and allows their behavior to be customized.
How is it used?	`FormControl` and `FormGroup` objects are created by the component class and associated with elements in the template using directives.
Are there any pitfalls or limitations?	The forms API is complex, and additional work is required to ensure that features such as validation behave consistently.
Are there any alternatives?	The forms API is optional. Forms can be defined using the basic features described in Chapter 12.

Table 21-2 summarizes the chapter.

Table 21-2. *Chapter Summary*

Problem	Solution	Listing
Creating a reactive form	Create a `FormControl` object in the component class and associate it with a form element in the template using the `formControl` directive	1–3
Responding to element value changes	Use the observable `valueChanges` property defined by the `FormControl` class	4, 5
Managing element state	Use the properties defined by the `FormControl` class	6
Responding to element validation changes	Use the observable `statusChanges` property defined by the `FormControl` class	7–13
Defining multiple related form elements	Use a `FormGroup` object	14–18, 22–26
Displaying validation messages for controls in a group	Obtain a `FormControl` object through the enclosing `FormGroup` object	19–20, 27, 28

Preparing for This Chapter

For this chapter, I will continue using the exampleApp project that I created in Chapter 20. No changes are required for this chapter.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

To start the development server, open a command prompt, navigate to the exampleApp folder, and run the following command:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 21-1.

Figure 21-1. *Running the example application*

Understanding the Reactive Forms API

The simplest way to use HTML forms is to use Angular two-way bindings to connect input elements to component properties, which is the approach I demonstrated in Chapter 12 and which I used to create the form in the example project in Chapter 20. These are known as *template-driven forms*.

For more complex forms, Angular provides a complete API that exposes the state of HTML forms and allows their data and structure to be managed, known as *reactive forms*. You can get a glimpse of the API in the way that the form element is defined in the form.component.html file in the src/app folder:

```
...
<form #form="ngForm" (ngSubmit)="submitForm(form)" (reset)="form.resetForm()">
...
```

The template variable named form is assigned the value ngForm, which is then used in the event bindings, as a method argument in the ngSubmit event or to invoke a method in the reset event. The ngForm value and the events themselves are defined as part of the Angular form API.

One of the themes of this book has been that nothing in Angular is magic. Every feature is implanted using the capabilities of the browser or builds on other Angular features. This includes ngForm, which is a directive that acts as a wrapper around a FormGroup object, exposing its capabilities using the directive features described in Chapter 12. The FormGroup class, which is defined in the @angular/forms package, provides an API for working with a form and can be used directly in a component class, allowing forms

595

to be manipulated in code and not just through HTML elements in a template. In turn, the `FormGroup` is a container for `FormControl` objects, each of which represents an element in the form. As you will learn, the `FormGroup` and `FormControl` classes are the building blocks of the reactive forms API, and the `ngForm` directive, with which you are already familiar, simply presents this API so it can be used easily in templates.

Rebuilding the Form Using the API

The simplest way to get started is with a single form element so you can understand the basic building blocks of the API. The reactive form features require a new module, `ReactiveFormsModule`, as shown in Listing 21-1.

Listing 21-1. Importing a Module in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
import { SharedState } from "./sharedState.service";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule],
    declarations: [TableComponent, FormComponent],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [SharedState]
})
export class CoreModule { }
```

Listing 21-2 simplifies the form template so that it contains only a single `input` element, along with a `label` and a `div` element.

Listing 21-2. Simplifying the HTML Template in the form.component.html File in the src/app/core Folder

```
<div class="form-group">
    <label>Name</label>
    <input class="form-control" name="name" [formControl]="nameField" />
</div>
```

In addition to simplifying the template, Listing 21-1 makes an important change in the way that the `input` element is configured. The `ngModel` directive isn't used with the forms API, and a different directive is applied:

```
...
<input class="form-control" name="name" [formControl]="nameField" />
...
```

The `formControl` directive creates the relationship between the HTML element in the template and a `FormControl` property in the component class, through which the element will be managed. Listing 21-3 simplifies the component, adds a property for the `formControl` component to use, and takes advantage of one of the features provided by the `FormControl` class.

Listing 21-3. Using the Forms API in the form.components.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("Initial Value");

    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
            this.nameField.setValue(this.product.name);
        } else {
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
            this.nameField.setValue("");
        }
    }

    // submitForm(form: NgForm) {
    //     if (form.valid) {
    //         this.model.saveProduct(this.product);
    //         this.product = new Product();
    //         form.resetForm();
    //     }
    // }
}
```

Individual form controls are represented by FormControl properties, and Listing 21-3 defines such a property with the name specified by the formControl directive in Listing 21-2, creating the relationship between the HTML element and the component class. The constructor accepts an optional argument that sets the initial value for the element:

```
...
nameField: FormControl = new FormControl("Initial Value");
...
```

When the input element is presented to the user, it will contain the string Initial Value.

The reactive forms API provides direct access to the features that were previously managed through the ngForm and ngModel directives. In this case, I have used the setValue method to set the contents of the input element when the user clicks an Edit button:

```
...
this.nameField.setValue(this.product.name);
...
```

As its name suggests, the setValue method sets the value of the form control, which was previously done by the ngModel directive. The setValue method is one of the basic features provided by the FormControl class, the most useful of which are described in Table 21-3 and which I describe in the following sections.

■ **Note** Some of the methods described in Table 21-3 and later tables take an optional argument that manages the effect of changes. I don't describe these options because they are not typically required, but see the Angular API description for the FormControl class (https://angular.io/api/forms/FormControl) for details.

Table 21-3. *Useful Basic FormControl Members*

Name	Description
value	This property returns the current value of the form control, defined using the any type.
setValue(value)	This method sets the value of the form control.
valueChanges	This property returns an Observable<any>, through which changes can be observed.
enabled	This property returns true if the form control is enabled.
disabled	This property returns true if the form control is disabled.
enable()	This method enables the form control.
disable()	This method disables the form control.
reset(value)	This method resets the form control, with an optional value. The form control will be reset to its default state if the value argument is omitted.

The overall effect is to transfer control of the input element from the template to the component, through the FormControl property. When the form component is displayed, the input element is populated with an initial value, which is replaced when the user clicks one of the Edit buttons, as shown in Figure 21-2.

Figure 21-2. Using a FormControl

Responding to Form Control Changes

The valueChanges property returns an observable that emits new values from the form control. Components can observe these changes to respond to user interaction, as shown in Listing 21-4.

Listing 21-4. Observing Changes in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("Initial Value");
```

599

```
    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    ngOnInit() {
        this.nameField.valueChanges.subscribe(newValue => {
            this.messageService.reportMessage(new Message(newValue || "(Empty)"));
        });
    }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
            this.nameField.setValue(this.product.name);
        } else {
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
            this.nameField.setValue("");
        }
    }
}
```

In the ngOnInit method, the component subscribes to the Observable<any> returned by the valueChanges property and passes on the values it receives to the message service. As the user types into the input element, the changed value is displayed at the top of the layout, as shown in Figure 21-3.

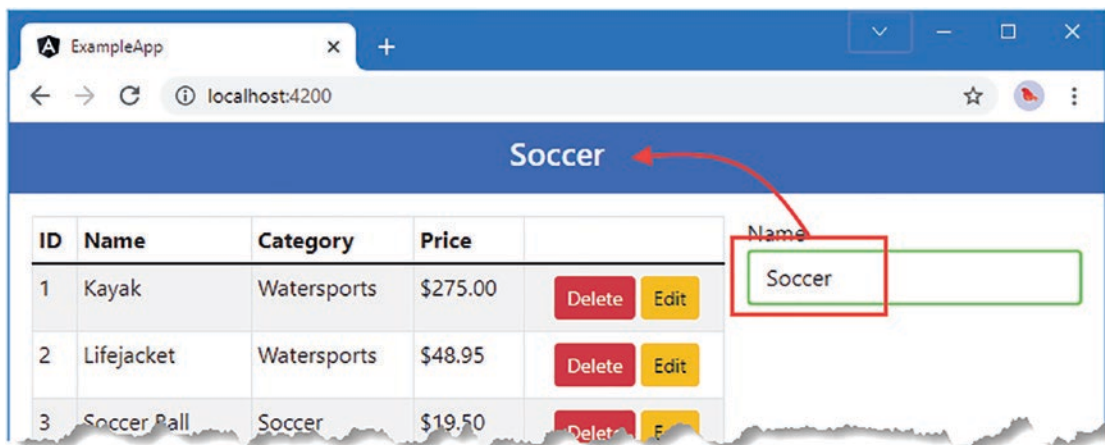

Figure 21-3. Responding to form control changes

By default, the observable will emit a new event in response to the HTML element's change event, but this can be altered by configuring the FormControl with a constructor argument, as shown in Listing 21-5.

Listing 21-5. Configuring a FormControl in the form.component.ts File in the src/app/core Folder

```
import { Component, Input } from "@angular/core";
import { NgForm, FormControl } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("Initial Value", {
        updateOn: "blur"
    });

    // ...methods omitted for brevity...
}
```

The new argument to the FormControl constructor implements the AbstractControlOptions interface, which defines the properties described in Table 21-4. Those properties are all optional, which means you can omit those you do not need to change.

Table 21-4. The Properties Defined by the AbstractControlOptions Interface

Name	Description
validators	This property is used to configure the validation for the form control, as described in the "Managing Control Validation" section.
asyncValidators	This property is used to configure the async validation for the form control, as described in Chapter 22.
updateOn	This property is used to configure when the valueChanges observable will emit a new value. It can be set to change, the default; blur; or submit. The submit value is used with form elements.

In Listing 21-5, I used the blur value for the updateOn property, which means that the observable will emit new values only when the input element loses focus, such as when the user tabs to another element, as shown in Figure 21-4.

601

Figure 21-4. *Changing the update setting*

Managing Control State

In Chapter 12, I showed you how form elements are added to classes to denote their state. The FormControl class defines properties that indicate the state of the HTML element and methods for manually changing the state, as described in Table 21-5.

Table 21-5. *The FormControl Members for Element State*

Name	Description
untouched	This property returns true if the HTML element is untouched, meaning that the element has not been selected.
touched	This property returns true if the HTML element has been touched, meaning that the element has been selected.
markAsTouched()	Calling method marks the element as touched.
markAsUntouched()	Calling this method marks the element as untouched.
pristine	This property returns true if the element contents have not been edited by the user.
dirty	This property returns true if the element contents have been edited by the user.
markAsPristine()	Calling this method marks the element as pristine.
markAsDirty()	Calling this method marks the element as dirty.

One benefit of using the reactive forms API is that you can control the way that the form features are applied, tailoring the behavior to the needs of your project. As a simple demonstration, Listing 21-6 changes the state of the element based on the number of characters in the value.

Listing 21-6. Changing Element State in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("Initial Value", {
        updateOn: "change"
    });

    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    ngOnInit() {
        this.nameField.valueChanges.subscribe(newValue => {
            this.messageService.reportMessage(new Message(newValue || "(Empty)"));
            if (typeof(newValue) == "string" && newValue.length % 2 == 0) {
                this.nameField.markAsPristine();
            }
        });
    }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
            this.nameField.setValue(this.product.name);
        } else {
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
            this.nameField.setValue("");
        }
    }
}
```

I have changed the updateOn property so that a new value is emitted via the observable after every change, and I added an if expression to the subscriber function that calls the FormControl.markAsPristine method if the length of the character is an even number. The effect is that the border of the input element toggles on and off as the user types, as shown in Figure 21-5.

Figure 21-5. *Changing element state*

The reason the border color changes is that Angular marks form elements as valid, even if no validation requirements have been applied. This means that for an odd number of characters, the input element is added to the ng-valid, ng-touched, and ng-dirty classes, like this:

```
...
<input name="name" class="form-control ng-valid ng-touched ng-dirty">
...
```

This combination is matched by the selector for one of the styles defined in the form.component.css file, which I added to the project in Chapter 20:

```
...
input.ng-dirty.ng-valid { border: 2px solid #6bc502 }
...
```

When there is an even number of characters, the call to the markAsPristine method creates a different combination of element classes:

```
...
<input name="name" class="form-control ng-valid ng-touched ng-pristine">
...
```

This doesn't match the CSS selector, and no border is displayed. This example demonstrates that you can customize the behavior of form elements by using the reactive forms API, even if this particular behavior is unlikely to be required in many projects.

Managing Control Validation

Form elements can be subject to validation, even when using the reactive forms API. Validation constraints can be added to the template, as described in Chapter 12, or applied through the FormControl constructor, using the validators and asyncValidators properties of the AbstractControlOptions interface.

Listing 21-7 uses this feature to apply validation to the example form element, using the validators property. (I explain the use of the asyncValidators property in Chapter 22.)

Listing 21-7. Applying Validation in the form.component.ts File in the src/app/core Folder

```
import { Component, Input } from "@angular/core";
import { NgForm, FormControl, Validators } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    });

    // ...constructor and methods omitted for brevity...
}
```

The built-in validators are defined as static properties of the Validators class, where each property name corresponds to the validation attributes described in Chapter 12. Validation rules are specified using the validators property of the AbstractControlOptions constructor argument, which is assigned an array of validators. In Listing 21-7, I used the required, minLength, and pattern properties to set the validation policy for the input element. I have also changed the first constructor argument so that the input element is empty when it is first presented to the user.

In addition to the constructor, the validators applied to a form control can be managed through the FormControl properties and methods described in Table 21-6. For each entry in the table, there is a corresponding member for managing asynchronous validators, which I describe in Chapter 22.

Table 21-6. *The FormControl Members for Managing Validators*

Name	Description
validator	This property returns a function that combines all of the configured validators so that the form control can be validated with a single function call.
hasValidator(v)	This function returns true if the form control has been configured with the specified validator.
setValidators(vals)	This method sets the form control validators. The argument can be a single validator or an array of validators.
addValidators(v)	This method adds one or more validators to the form control.
removeValidators(v)	This method removes one or more validators from the control.
clearValidators()	This method removes all of the validators from the form control.

The validation state of a FormControl is determined and managed through the members described in Table 21-7.

Table 21-7. *The FormControl Members for Validation State*

Name	Description
status	This property returns the validation state of the form control, expressed using a FormControlStatus value, which will be VALID, INVALID, PENDING, or DISABLED.
statusChanges	This property returns an Observable<FormControlStatus>, which will emit a FormControlStatus value when the state of the form control changes.
valid	This property returns true if the form control's value passes validation.
invalid	This property returns true if the form control's value fails validation.
pending	This property returns true if the form control's value is being validated asynchronously, as described in Chapter 22.
errors	This property returns a ValidationErrors object that contains the errors generated by the form control's validators, or null if there are no errors.
getError(v)	This method returns the error message, if there is one, for the specified validator. This method accepts an optional path for use with nested form controls, as described in the "Working with Multiple Form Controls" section.
hasError(v)	This method returns true if the specified validator has generated an error message. This method accepts an optional path for use with nested form controls, as described in the "Working with Multiple Form Controls" section.
setErrors(errs)	This method is used to add errors to the form control's validation status, which is useful when performing manual validation in the component. This method accepts an optional path for use with nested form controls, as described in the "Working with Multiple Form Controls" section.

The effect of the validators configured in Listing 21-7 can be determined through the features described in Table 21-7. Listing 21-8 uses a subscription to the statusChanges observable to generate messages summarizing the validation state of the form control.

Listing 21-8. Generating Validation Messages in the form.component.ts File in the src/app/core Folder

```
...
ngOnInit() {
    this.nameField.statusChanges.subscribe(newStatus => {
        if (newStatus == "INVALID" && this.nameField.errors != null) {
            let errs = Object.keys(this.nameField.errors).join(", ");
            this.messageService.reportMessage(new Message(`INVALID: ${errs}`))
        } else {
            this.messageService.reportMessage(new Message(newStatus));
        }
    })
    // this.nameField.valueChanges.subscribe(newValue => {
    //     this.messageService.reportMessage(new Message(newValue || "(Empty)"));
    //     if (typeof(newValue) == "string" && newValue.length % 2 == 0) {
    //         this.nameField.markAsPristine();
    //     }
    // });
}
...
```

In response to status changes, a message is sent that details the status and, if it is INVALID, includes a list of the validators that have reported an error, as shown in Figure 21-6. (See Chapter 12 for details of how to process a `ValidationErrors` object to display validation messages that are more usefully presented to the user.)

Figure 21-6. *Responding to status changes*

The message shown in Figure 21-6 isn't especially useful to the user, but the `formControl` directive uses the `exportAs` property to provide an identifier named `ngForm` for use in template variables, and this can be used to generate more helpful validation messages for a control. To prepare, add a file named `validation_helper.ts` to the `src/app/core` folder with the content shown in Listing 21-9, which creates a pipe to format validation messages.

Listing 21-9. The Contents of the validation_helper.ts File in the src/app/core Folder

```
import { Pipe } from "@angular/core";
import { FormControl, ValidationErrors } from "@angular/forms";

@Pipe({
    name: "validationFormat"
})
export class ValidationHelper {

    transform(source: any, name: any) : string[] {
        if (source instanceof FormControl) {
            return this.formatMessages((source as FormControl).errors, name)
        }
        return this.formatMessages(source as ValidationErrors, name)
    }

    formatMessages(errors: ValidationErrors | null, name: string): string[] {
        let messages: string[] = [];
        for (let errorName in errors) {
            switch (errorName) {
                case "required":
                    messages.push(`You must enter a ${name}`);
                    break;
                case "minlength":
                    messages.push(`A ${name} must be at least
                        ${errors['minlength'].requiredLength}
                        characters`);
                    break;
                case "pattern":
                    messages.push(`The ${name} contains
                            illegal characters`);
                    break;
            }
        }
        return messages;
    }
}
```

This code is based on the approach I took in Chapter 12 to generate user-friendly messages for template-driven forms. Listing 21-10 registers the pipe so that it will be available in the rest of the module.

Listing 21-10. Registering a Pipe in the core.modules.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
```

```
@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule],
    declarations: [TableComponent, FormComponent, ValidationHelper],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [SharedState]
})
export class CoreModule { }
```

Listing 21-11 uses a template variable to obtain a reference for the FormControl object, which is used to get validation messages that can be displayed to the user.

Listing 21-11. Generating Error Messages in the form.component.html File in the src/app/core Folder

```
<div class="form-group">
    <label>Name</label>
    <input class="form-control" name="name" [formControl]="nameField"
        #name="ngForm" />
    <ul class="text-danger list-unstyled mt-1" *ngIf="name.dirty && name.invalid">
        <li *ngFor="let err of name.errors | validationFormat:'name'">
            {{ err }}
        </li>
    </ul>
</div>
```

The formControl directive defines properties that correspond to those described in Table 21-5 and Table 21-7, which provides access to the validation state and errors, which are formatted using the new pipe. Validation messages are displayed to the user, as shown in Figure 21-7, achieving the same result as with the template-based form from earlier chapters.

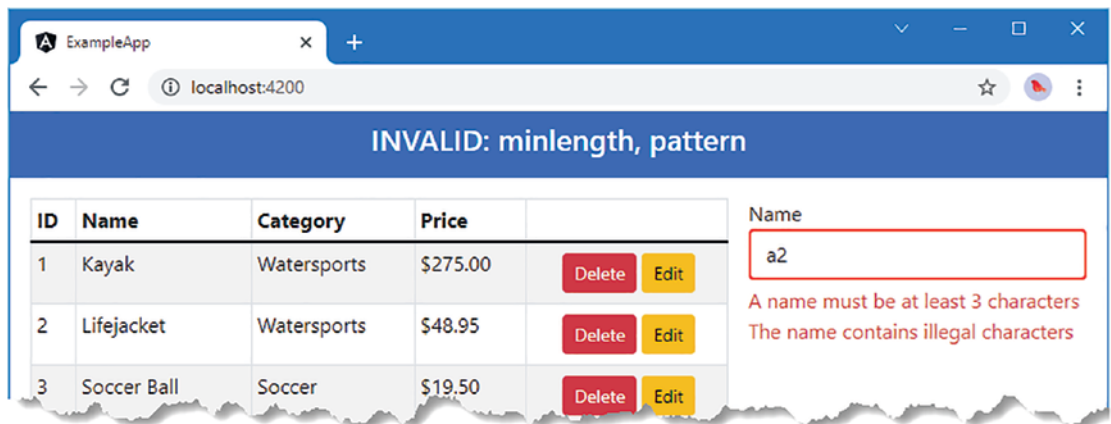

Figure 21-7. *Displaying validation messages*

609

Adding Additional Controls

The advantage of using the forms API is that you can customize the way that your forms work, and this extends to using the state of one control to determine the state of another. To prepare, Listing 21-12 introduces another input element to the template.

Listing 21-12. Adding an Element in the form.component.html File in the src/app/core Folder

```
<div class="form-group">
    <label>Name</label>
    <input class="form-control" name="name" [formControl]="nameField"
        #name="ngForm" />
    <ul class="text-danger list-unstyled mt-1" *ngIf="name.dirty && name.invalid">
        <li *ngFor="let err of name.errors | validationFormat:'name'">
            {{ err }}
        </li>
    </ul>
</div>

<div class="form-group">
    <label>Category</label>
    <input class="form-control" name="category" [formControl]="categoryField"  />
</div>
```

The new input element is configured with a formControl binding that specifies a property named categoryField. Listing 21-13 defines this property and uses the features provided by the FormControl class to change the element's state based on the name field.

Listing 21-13. Adding a FormControl in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
```

```
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    });
    categoryField: FormControl = new FormControl();

    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    ngOnInit() {
        this.nameField.statusChanges.subscribe(newStatus => {
            if (newStatus == "INVALID") {
                this.categoryField.disable();
            } else {
                this.categoryField.enable();
            }
        })
    }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
            this.nameField.setValue(this.product.name);
            this.categoryField.setValue(this.product.category);
        } else {
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
            this.nameField.setValue("");
            this.categoryField.setValue("");
        }
    }
}
```

The category input element is enabled and disabled based on the validation status of the name element. To see the effect, start typing characters into the Name field, which will be disabled by the error produced by the minlength validator. Once the minimum length is reached, the Name field will pass validation, and the Category field will be enabled, as shown in Figure 21-8.

Figure 21-8. *Working with multiple controls*

Working with Multiple Form Controls

Manipulating individual FormControl objects can be a powerful technique, but it can also be cumbersome in more complex forms, where there can be many objects to create and manage. The reactive forms API includes the FormGroup class, which represents a group of form controls, which can be manipulated individually or as a combined group. Listing 21-14 introduces a FormGroup property to the example component.

Listing 21-14. Using a FormGroup in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
```

```
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    nameField: FormControl = new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    });
    categoryField: FormControl = new FormControl();

    productForm: FormGroup = new FormGroup({
        name: this.nameField, category: this.categoryField
    });

    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    ngOnInit() {
        this.productForm.statusChanges.subscribe(newStatus => {
            if (newStatus == "INVALID") {
                let invalidControls: string[] = [];
                for (let controlName in this.productForm.controls) {
                    if (this.productForm.controls[controlName].invalid) {
                        invalidControls.push(controlName)
                    }
                }
                this.messageService.reportMessage(
                    new Message(`INVALID: ${invalidControls.join(", ")}`))
            } else {
                this.messageService.reportMessage(new Message(newStatus));
            }
        })
    }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
            // this.nameField.setValue(this.product.name);
            // this.categoryField.setValue(this.product.category);
```

613

```
        } else {
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
            // this.nameField.setValue("");
            // this.categoryField.setValue("");
        }
        this.productForm.reset(this.product);
    }
}
```

This is the simplest use of a FormGroup, where a property is used to group existing FormControl objects so they can be processed collectively. The individual FormControl objects are passed to the FormGroup constructor, in a map that assigns each a key. Controls can also be added, removed, and inspected in the FormGroup using the members defined in Table 21-8.

Table 21-8. *FormGroup Members for Adding and Removing Controls*

Name	Description
addControl(name, ctrl)	This method adds a control to the FormGroup with the specified name. No action is taken if there is already a control with this name.
setControl(name, ctrl)	This method adds a control to the FormGroup with the specified name, replacing any existing control with this name.
removeControl(name)	This method removes the control with the specified name.
controls	This property returns a map containing the controls in the group, using their names as keys.
get(name)	This property returns the control with the specified name.

In Listing 21-14, I created a FormGroup and added the existing FormControl objects with name and category keys:

```
...
productForm: FormGroup = new FormGroup({
    name: this.nameField, category: this.categoryField
});
...
```

The names used to register FormControl objects make it easy to get and set values for all the individual controls in a single step, using the property and methods described in Table 21-9.

Table 21-9. *FormGroup Methods for Managing Control Values*

Name	Description
value	This method returns an object containing the values of the form controls in the group, using the names given to each control as the names of the properties.
setValue(val)	This method sets the contents of the form controls using an object, whose property names correspond to the names given to each control. The specified value object must define properties for all the form controls in the group.
patchValue(val)	This method sets the contents of the form controls using an object, whose property names correspond to the names given to each control. Unlike the setValue method, values are not required for all form controls.
reset(val)	This method resets the form to its pristine and untouched state and uses the specified value to populate the form controls.

Being able to get and set all the form control values together makes it easier to work with complex forms. I used the reset method to populate or clear the form controls when the user clicks the Create New Product or Edit button:

```
...
this.productForm.reset(this.product);
...
```

The reset method looks for properties in the object it receives whose names correspond to those used for regular FormControl objects with the FormGroup. The value of each property is used to set the control value, as shown in Figure 21-9.

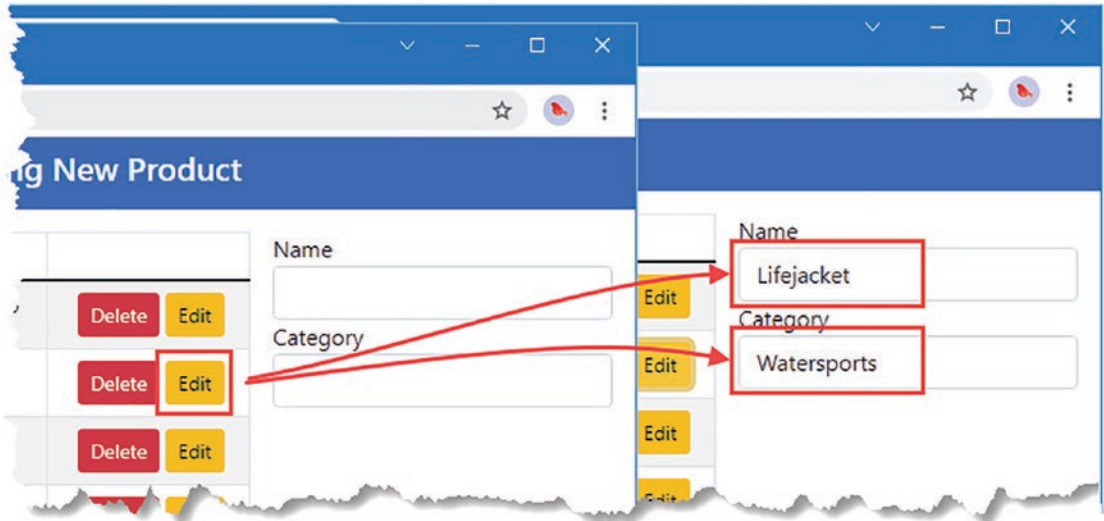

Figure 21-9. *Using a form group*

The `FormGroup` and `FormControl` classes share a common base class, which means that many of the properties and methods provided by `FormControl` are also available on a `FormGroup` object, but applied to all of the controls in the group. In Listing 21-14, I subscribed to the `FormGroup`'s `statusChanges` observable to receive events that indicate the status of the form, which Angular determines by examining all of the controls in the group:

```
...
this.productForm.statusChanges.subscribe(newStatus => {
    if (newStatus == "INVALID") {
...
```

If any of the individual controls are invalid, then the overall form status will be invalid, which allows me to assess the validation results without needing to inspect controls individually. But access to the individual controls is still available using the `controls` property, which lets me build up a list of invalid controls:

```
...
for (let controlName in this.productForm.controls) {
    if (this.productForm.controls[controlName].invalid) {
        invalidControls.push(controlName)
    }
}
...
```

The result is that a list of invalid form controls is shown to the user, as illustrated by Figure 21-10.

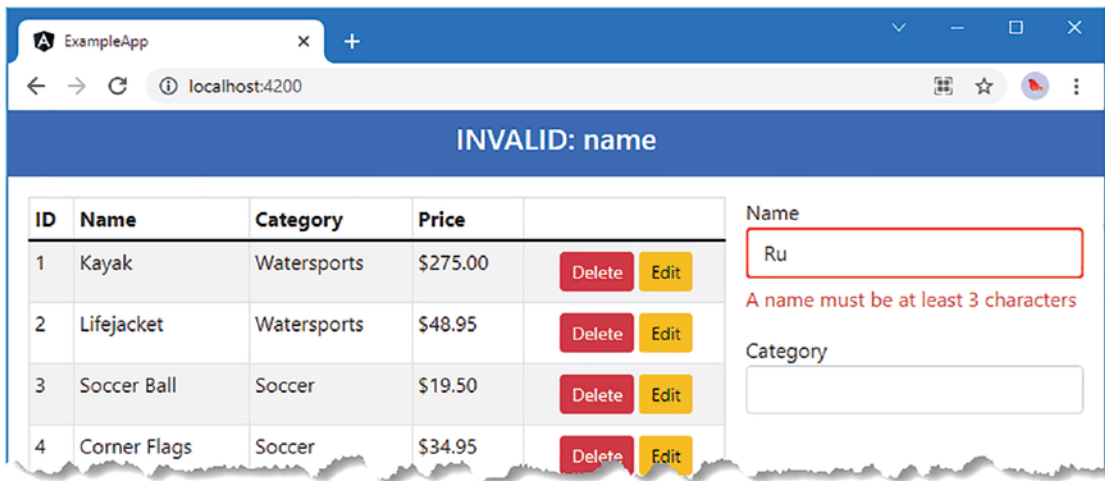

Figure 21-10. *Assessing validation status using the form group*

Using a Form Group with a Form Element

The `formGroup` directive associates a `FormGroup` object with an element in the template, in the same way the `formControl` directive is used with a `FormControl` object, as shown in Listing 21-15.

Listing 21-15. Introducing a Form Element in the form.component.html File in the src/app/core Folder

```
<form [formGroup]="productForm">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control" formControlName="name" />
        <!-- <ul class="text-danger list-unstyled mt-1" *ngIf="name.dirty -->
        <!--         && name.invalid"> -->
        <!--     <li *ngFor="let err of name.errors | validationFormat:'name'"> -->
        <!--         {{ err }} -->
        <!--     </li> -->
        <!-- </ul> -->
    </div>

    <div class="form-group">
        <label>Category</label>
        <input class="form-control" formControlName="category"  />
    </div>
</form>
```

The formGroup directive is used to specify the FormGroup object, and the individual form elements are associated with their FormControl objects using the formControlName attribute, specifying the name used when adding the FormControl to the FormGroup.

Using the formControlName attribute means that I don't have to define properties for each FormControl object in the controller class, allowing me to simplify the code, as shown in Listing 21-16.

Listing 21-16. Removing Properties in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    // nameField: FormControl = new FormControl("", {
    //     validators: [
    //         Validators.required,
    //         Validators.minLength(3),
    //         Validators.pattern("^[A-Za-z ]+$")
    //     ],
```

```
//      updateOn: "change"
// });
// categoryField: FormControl = new FormControl();

// productForm: FormGroup = new FormGroup({
//      name: this.nameField, category: this.categoryField
// });

productForm: FormGroup = new FormGroup({
    name:  new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    }),
    category: new FormControl()
});

// ...constructor and methods omitted for brevity...
}
```

There is no change in the output produced by the application, and this change just consolidates the individual form controls within the form group.

Accessing the Form Group from the Template

In addition to simplifying the application code, the formGroup directive defines some useful properties that allow me to complete the transition to the reactive forms API, restoring the features that were present when the form was managed solely through a template. Table 21-10 describes the most useful features provided by the formGroup directive.

Table 21-10. *Use Features Provided by the formGroup Directive*

Name	Description
ngSubmit	This event is triggered when the form is submitted.
submitted	This property returns true if the form has been submitted.
control	This property returns the FormControl object that has been associated with the directive.

These features ensure that the reactive forms API can still be used effectively in a template, while still providing the ability to customize the form behavior in the component class. Listing 21-17 restores the price input element that was present at the start of the chapter, along with the buttons that submit and reset the form.

Listing 21-17. Using the FormGroup Features in the form.component.html File in the src/app/core Folder

```html
<form [formGroup]="productForm" #form="ngForm"
        (ngSubmit)="submitForm()" (reset)="resetForm()">

    <div class="form-group">
        <label>Name</label>
        <input class="form-control" formControlName="name" />
    </div>

    <div class="form-group">
        <label>Category</label>
        <input class="form-control" formControlName="category"  />
    </div>

    <div class="form-group">
        <label>Price</label>
        <input class="form-control" formControlName="price" />
    </div>

    <div class="mt-2">
        <button type="submit" class="btn btn-primary"
                [class.btn-warning]="editing"
                [disabled]="form.invalid">
            {{editing ? "Save" : "Create"}}
        </button>
        <button type="reset" class="btn btn-secondary m-1">Cancel</button>
    </div>
</form>
```

I used the directive's ngForm property to create a template variable named form, through which I can check the overall validation status for the Save/Create button. The ngSubmit form is used to invoke a method named submitForm, and I used the form element's reset event to invoke a method named resetForm. Listing 21-18 shows the changes required to the component class to support the additions to the template.

Listing 21-18. Completing the Form in the form.component.ts File in the src/app/core Folder

```typescript
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;
```

619

```
productForm: FormGroup = new FormGroup({
    name:  new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    }),
    category: new FormControl("", { validators: Validators.required }),
    price: new FormControl("", {
        validators: [Validators.required, Validators.pattern("^[0-9\.]+$")]
    })
});

constructor(private model: Model, private state: SharedState,
        private messageService: MessageService) {
    this.state.changes.subscribe((upd) => this.handleStateChange(upd))
    this.messageService.reportMessage(new Message("Creating New Product"));
}

// ngOnInit() {
//     this.productForm.statusChanges.subscribe(newStatus => {
//         if (newStatus == "INVALID") {
//             let invalidControls: string[] = [];
//             for (let controlName in this.productForm.controls) {
//                 if (this.productForm.controls[controlName].invalid) {
//                     invalidControls.push(controlName)
//                 }
//             }
//             this.messageService.reportMessage(
//                 new Message(`INVALID: ${invalidControls.join(", ")}`))
//         } else {
//             this.messageService.reportMessage(new Message(newStatus));
//         }
//     })
// }

handleStateChange(newState: StateUpdate) {
    this.editing = newState.mode == MODES.EDIT;
    if (this.editing && newState.id) {
        Object.assign(this.product, this.model.getProduct(newState.id)
            ?? new Product());
        this.messageService.reportMessage(
            new Message(`Editing ${this.product.name}`));
    } else {
        this.product = new Product();
        this.messageService.reportMessage(new Message("Creating New Product"));
    }
    this.productForm.reset(this.product);
}
```

```
    submitForm() {
        if (this.productForm.valid) {
            Object.assign(this.product, this.productForm.value);
            this.model.saveProduct(this.product);
            this.product = new Product();
            this.productForm.reset();
        }
    }

    resetForm() {
        this.editing = true;
        this.product = new Product();
        this.productForm.reset();
    }
}
```

This listing adds a FormControl named price, adds validation to the category control, and defines the submitForm and resetForm method that will be invoked by the event bindings defined in Listing 21-17. The effect is to complete the form and restore the functionality that was previously defined using only the template form features, as shown in Figure 21-11.

Figure 21-11. *Using the reactive forms API*

Displaying Validation Messages with a Form Group

The `formControlName` directive doesn't export an identifier for use in a template variable, which complicates the process of displaying validation messages. Instead, errors must be obtained through the `FormGroup`, using the optional `path` argument for the error-related methods, which I have repeated in Table 21-11 for quick reference.

Table 21-11. *The FormGroup Methods for Dealing with Errors*

Name	Description
`getError(v, path)`	This method returns the error message, if there is one, for the specified validator. The optional path argument is used to identify the control.
`hasError(v, path)`	This method returns `true` if the specified validator has generated an error message. The optional path argument is used to identify the control.

These methods require the error to be specified, which means that it is possible to determine if a specific control has a specific error, like this:

```
...
form.getError("required", "category")
...
```

This expression would return details of errors reported by the `required` validator on the `category` control, which is identified by the name used to register the control in the `FormGroup`. This isn't a useful approach for the example application, where I want to display validation messages by getting all of the errors for a single `FormControl` object. For this, I can use the `get` method defined by the `FormGroup` class, although this can produce verbose and repetitive templates and so the best approach is to create a directive. Add a file named `validationErrors.directive.ts` to the `src/app/core` folder with the code shown in Listing 21-19.

Listing 21-19. The Contents of the validationErrors.directive.ts File in the src/app/core Folder

```
import { Directive, Input, TemplateRef, ViewContainerRef } from "@angular/core";
import { FormGroup } from "@angular/forms";
import { ValidationHelper } from "./validation_helper";

@Directive({
    selector:"[validationErrors]"
})
export class ValidationErrorsDirective {

    constructor(private container: ViewContainerRef,
        private template: TemplateRef<Object>) { }

    @Input("validationErrorsControl")
    name: string = ""

    @Input("validationErrorsLabel")
    label?: string;

    @Input("validationErrors")
    formGroup?: FormGroup;
```

```
    ngOnInit() {
        let formatter = new ValidationHelper();
        if (this.formGroup && this.name) {
            let control = this.formGroup?.get(this.name);
            if (control) {
                control.statusChanges.subscribe(() => {
                    if (this.container.length > 0) {
                        this.container.clear();
                    }
                    if (control && control.dirty && control.invalid
                            && control.errors) {
                        formatter.formatMessages(control.errors,
                            this.label ?? this.name).forEach(err => {
                            this.container.createEmbeddedView(this.template,
                                { $implicit: err });

                        })
                    }
                })
            }
        }
    }
}
```

The new directive obtains a FormControl object via its FormGroup and subscribes to the observable for status changes. Each time the status changes, the validation state is checked, and any error messages are formatted and used to generate template content.

This is a simple task in code, but it is more difficult to achieve in a template without creating long expressions. Listing 21-20 registers the directive so that it can be used in the module.

Listing 21-20. Registering a Directive in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [SharedState]
})
export class CoreModule { }
```

Listing 21-21 uses the new directive to display validation messages for each form element.

Listing 21-21. Displaying Validation Messages in the form.component.html File in the src/app/core Folder

```html
<form [formGroup]="productForm" #form="ngForm"
        (ngSubmit)="submitForm()" (reset)="resetForm()">
    <div class="form-group">
        <label>Name</label>
        <input class="form-control" formControlName="name" />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'name'; let err">
                {{ err }}
            </li>
        </ul>
    </div>

    <div class="form-group">
        <label>Category</label>
        <input class="form-control" formControlName="category"  />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'category'; let err">
                {{ err }}
            </li>
        </ul>
    </div>

    <div class="form-group">
        <label>Price</label>
        <input class="form-control" formControlName="price" />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'price'; let err">
                {{ err }}
            </li>
        </ul>
    </div>

    <div class="mt-2">
        <button type="submit" class="btn btn-primary"
                [class.btn-warning]="editing"
                [disabled]="form.invalid">
            {{editing ? "Save" : "Create"}}
        </button>
        <button type="reset" class="btn btn-secondary m-1">Cancel</button>
    </div>
</form>
```

The directive is configured with the FormGroup property defined by the component class and the name of the FormControl object for which errors are required. This is an indirect way of working, but it works as seamlessly as dealing with individual elements once the building blocks are in place, as shown in Figure 21-12.

Figure 21-12. *Displaying validation messages from a form group*

Nesting Form Controls

The FormGroup methods described Table 21-8 accept the AbstractControl class, which is the base class for both FormGroup and FormControl and which allows FormGroup objects to be nested, which can be a useful way to group related controls. To prepare, Listing 21-22 adds features to the Product model class.

Listing 21-22. Expanding the Model in the product.model.ts File in the src/app/model Folder

```
export class Product {

    constructor(public id?: number,
        public name?: string,
        public category?: string,
        public price?: number,
        public details?: Details) { }
}

export class Details {
    constructor(public supplier?: string,
        public keywords?: string) {}
}
```

The details property will be used to collect additional information about a product. Listing 21-23 adds values to the static data source for the new properties.

Listing 21-23. Adding Data in the static.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";

@Injectable()
export class StaticDataSource {
    private data: Product[];

    constructor() {
        this.data = new Array<Product>(
            new Product(1, "Kayak", "Watersports", 275,
                { supplier: "Acme", keywords: "boat, small"}),
            new Product(2, "Lifejacket", "Watersports", 48.95),
            new Product(3, "Soccer Ball", "Soccer", 19.50),
            new Product(4, "Corner Flags", "Soccer", 34.95),
            new Product(5, "Thinking Cap", "Chess", 16));
    }

    getData(): Product[] {
        return this.data;
    }
}
```

Listing 21-24 adds elements to the table template to display the new properties.

Listing 21-24. Displaying Details in the table.component.html File in the src/app/core Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
      <tr>
          <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
          <th>Details</th><th></th>
      </tr>
    </thead>
    <tbody>
      <tr *ngFor="let item of getProducts()">
          <td>{{item.id}}</td>
          <td>{{item.name}}</td>
          <td>{{item.category}}</td>
          <td>{{item.price | currency:"USD" }}</td>
          <td>
              <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
              </ng-container>
              <ng-template #empty>(None)</ng-template>
          </td>
          <td class="text-center">
              <button class="btn btn-danger btn-sm m-1"
                      (click)="deleteProduct(item.id)">
                  Delete
              </button>
```

```
            <button class="btn btn-warning btn-sm" (click)="editProduct(item.id)">
                Edit
            </button>
        </td>
    </tr>
    </tbody>
</table>
<button class="btn btn-primary mt-1" (click)="createProduct()">
    Create New Product
</button>
```

Listing 21-25 adds a nested FormGroup to the form component and populates it with FormControl objects that correspond to the new model properties.

Listing 21-25. Adding a Nested Form Group in the form.component.ts File in the src/app/core Folder

```
...
productForm: FormGroup = new FormGroup({
    name:  new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    }),
    category: new FormControl("", { validators: Validators.required }),
    price: new FormControl("", {
        validators: [Validators.required, Validators.pattern("^[0-9\.]+$")]
    }),
    details: new FormGroup({
        supplier: new FormControl("", { validators: Validators.required }),
        keywords: new FormControl("", { validators: Validators.required })
    })
});
...
```

To complete the process, Listing 21-26 adds new elements to the component's template.

Listing 21-26. Adding Elements in the form.component.html File in the src/app/core Folder

```
<form [formGroup]="productForm" #form="ngForm"
        (ngSubmit)="submitForm()" (reset)="resetForm()">

    <!-- existing input elements omitted for brevity... -->

    <ng-container formGroupName="details">
        <div class="form-group">
            <label>Supplier</label>
            <input class="form-control" formControlName="supplier" />
        </div>
        <div class="form-group">
```

```
            <label>Keywords</label>
            <input class="form-control" formControlName="keywords" />
        </div>
    </ng-container>

    <div class="mt-2">
        <button type="submit" class="btn btn-primary"
                [class.btn-warning]="editing"
                [disabled]="form.invalid">
            {{editing ? "Save" : "Create"}}
        </button>
        <button type="reset" class="btn btn-secondary m-1">Cancel</button>
    </div>
</form>
```

The nested FormGroup is associated with an element using the formGroupName directive, which I have applied to an ng-container element so that I don't introduce any elements into the form. Within the ng-container element, input elements are associated with FormControl objects using the formControlName directive. Angular takes care of dealing with the nested names, and the supplier input element within the details ng-container element is mapped to the supplier FormControl within the details FormGroup object.

When the value of the top-level FormGroup object is read or set, Angular also maps the nested FormGroup/FormControl objects to nested properties on the data object. Click the Edit button for the Kayak product, and you will see that the Supplier and Keywords fields are populated using the nested model properties defined, as shown in Figure 21-13. Change the values and click Save, and you will see that the mapping works in both directions.

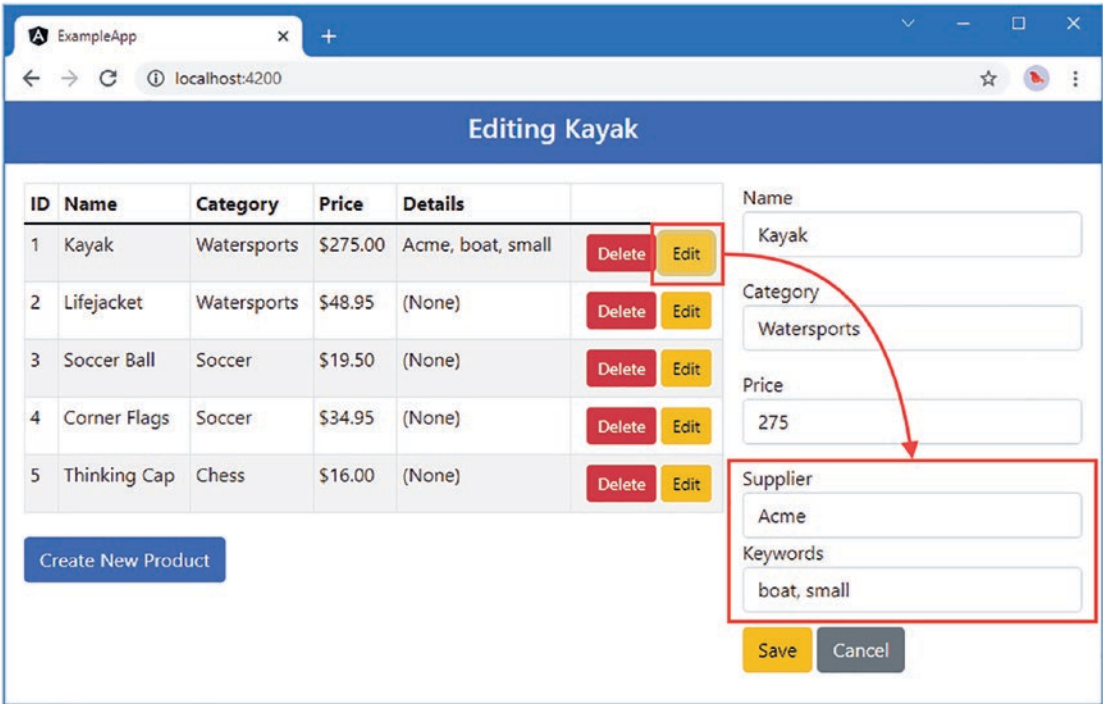

Figure 21-13. *Using a nested form group*

Validating Nested Form Controls

Nested form groups can be used to assess the status of the elements they contain, which means that the top-level FormGroup will report on all of the FormControl objects, including the nested ones, and the nested FormGroup will report on just its controls. Listing 21-27 generates messages to denote the validation status of the nested controls.

Listing 21-27. Monitoring a Nested FormGroup in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup } from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    // ...form groups and controls omitted for brevity...

    ngOnInit() {
        this.productForm.get("details")?.statusChanges.subscribe(newStatus => {
            this.messageService.reportMessage(new Message(`Details ${newStatus}`));
        })
    }

    // ...constructor and methods omitted for brevity...
}
```

Click the Edit button for the Kayak product and clear the Name field. The form is invalid, but no message is generated because the controls managed by the nested FormGroup have values. Clear the Supplier field to change the status of the nested group and produce a message, as shown in Figure 21-14.

Figure 21-14. *Monitoring a nested form group*

Validation messages can be displayed in the template by specifying the path to the nested controls, which is done by combining the name of the nested group with the control, as shown in Listing 21-28.

Listing 21-28. Nested Validation Messages in the form.component.html File in the src/app/core Folder

```
...
<ng-container formGroupName="details">
    <div class="form-group">
        <label>Supplier</label>
        <input class="form-control" formControlName="supplier" />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'details.supplier';
                label: 'supplier'; let err">
                    {{ err }}
            </li>
        </ul>
    </div>
    <div class="form-group">
        <label>Keywords</label>
        <input class="form-control" formControlName="keywords" />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'details.keywords';
            label: 'keyword'; let err">
                    {{ err }}
            </li>
```

```
        </ul>
    </div>
</ng-container>
...
```

The path for the nested control combines the name of the form group, followed by the name of the control, separated by a period:

```
...
<li *validationErrors="productForm; control:'details.keywords';
    label: 'keyword'; let err">
...
```

One issue with nested controls is that the control path can't be used in error messages, which is why I added an optional label property in the directive in Listing 21-19. Click the Edit button for the Kayak product and clear the Supplier and Keywords fields to see the error messages, as shown in Figure 21-15.

Figure 21-15. *Displaying validation messages for nested controls*

Summary

In this chapter, I introduced the Angular reactive forms API and showed you how it can be used to create and manage forms, providing a more code-centered approach than the standard template-driven forms described in Chapter 12. I explained the use of the FormControl and FormGroup classes and demonstrated their use in managing form elements. In the next chapter, I continue to describe the forms API, explaining how to create controls dynamically and how to create custom validators.

CHAPTER 22

■ ■ ■

Using the Forms API, Part 2

In this chapter, I continue to describe the Angular forms API, explaining how to create form controls dynamically and how to create custom validation. Table 22-1 summarizes the chapter.

Table 22-1. *Chapter Summary*

Problem	Solution	Listing
Creating and managing form controls dynamically	Use a `FormArray` object	1–6
Validating dynamically created form controls	Use a control's position in its enclosing `FormArray` as identification during the validation process	7, 8
Altering the values produced by dynamically created controls	Override the methods defined by the `FormArray` class	9, 10
Creating custom form validation	Create a function that returns an implementation of the `ValidatorFn` interface, which performs validation on a control's value	11–13
Applying a custom validator in a template-driven form	Create a directive that calls the validator function	14–17
Validating multiple related fields	Perform validation on a `FormGroup` or `FormArray`	18–23
Performing complex or remote validation	Create an asynchronous validator	24–27

Preparing for This Chapter

For this chapter, I will continue using the exampleApp project from Chapter 21. No changes are required for this chapter.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

To start the development server, open a command prompt, navigate to the exampleApp folder, and run the following command:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 22-1.

Figure 22-1. *Running the example application*

Creating Form Components Dynamically

The FormGroup class is useful when the structure and number of elements in the form are known in advance. For applications that need to dynamically add and remove elements, Angular provides the FormArray class. Both FormArray and FormControl are derived from the AbstractControl class and provide the same features for managing FormGroup objects; the difference is that the FormArray class allows FormControl objects to be created without specifying names and stores its controls as an array, making it easier to add and remove controls. To prepare, Listing 22-1 changes a model property to an array so that it can be used to store multiple values.

Listing 22-1. Changing a Property Type in the product.model.ts File in the src/app/model Folder

```
export class Product {

    constructor(public id?: number,
        public name?: string,
        public category?: string,
        public price?: number,
        public details?: Details) { }
}

export class Details {
    constructor(public supplier?: string,
        public keywords?: string[] ) {}
}
```

Listing 22-2 updates the static example data to reflect the change to the keywords property.

Listing 22-2. Updating the Example Data in the static.datasource.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";

@Injectable()
export class StaticDataSource {
    private data: Product[];

    constructor() {
        this.data = new Array<Product>(
            new Product(1, "Kayak", "Watersports", 275,
                { supplier: "Acme", keywords: ["boat", "small"]}),
            new Product(2, "Lifejacket", "Watersports", 48.95,
                { supplier: "Smoot Co", keywords: ["safety"]}),
            new Product(3, "Soccer Ball", "Soccer", 19.50),
            new Product(4, "Corner Flags", "Soccer", 34.95),
            new Product(5, "Thinking Cap", "Chess", 16));
    }

    getData(): Product[] {
        return this.data;
    }
}
```

Using a Form Array

The FormArray class stores its child controls in an array and provides the properties and methods described in Table 22-2 for managing the array, in addition to those it inherits from the AbstractControl class and that are shared with the FormGroup and FormControl classes.

Table 22-2. *Useful FormArray Members for Managing Controls*

Name	Description
controls	This property returns an array containing the child controls.
length	This property returns the number of controls that are in the FormArray.
at(index)	This property returns the control at the specified index in the FormArray.
push(control)	This method adds a control to the end of the array.
insert(index, control)	This method inserts a control at the specified index.
setControl(index, control)	This method replaces the control at the specified index.
removeAt(index)	This method removes the control at the specified index.
clear()	This method removes all of the controls from the FormArray.

The FormArray class also provides methods for setting the values of the controls it manages using arrays, rather than name-value maps, as described in Table 22-3.

Table 22-3. *The FormArray Methods for Setting Values*

Name	Description
setValue(values)	This method accepts an array of values and uses them to set the values of the child controls based on the order in which they are defined. The number of elements in the values array must match the number of controls in the FormArray.
patchValue(values)	This method accepts an array of values and uses them to set the values of the child controls based on the order in which they are defined. Unlike the setValue method, the number of elements in the values array does not have to match the number of controls in the FormArray, and this method will ignore values for which there are no controls and will ignore controls for which there are no values.
reset(values)	This method resets the controls in the FormArray and sets their values using the optional array argument. The number of elements in the values array does not have to match the number of controls in the FormArray. Values for which there are no controls are ignored, and controls for which there are no values are reset to their default state.

Listing 22-3 uses the features described in these tables to vary the number of controls displayed for the keywords model property.

Listing 22-3. Using a FormArray in the form.components.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
```

```
@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FormArray([
        this.createKeywordFormControl()
    ])

    productForm: FormGroup = new FormGroup({
        name:  new FormControl("", {
            validators: [
                Validators.required,
                Validators.minLength(3),
                Validators.pattern("^[A-Za-z ]+$")
            ],
            updateOn: "change"
        }),
        category: new FormControl("", { validators: Validators.required }),
        price: new FormControl("", {
            validators: [Validators.required, Validators.pattern("^[0-9\.]+$")]
        }),
        details: new FormGroup({
            supplier: new FormControl("", { validators: Validators.required }),
            keywords: this.keywordGroup
        })
    });

    constructor(private model: Model, private state: SharedState,
            private messageService: MessageService) {
        this.state.changes.subscribe((upd) => this.handleStateChange(upd))
        this.messageService.reportMessage(new Message("Creating New Product"));
    }

    // ngOnInit() {
    //     this.productForm.get("details")?.statusChanges.subscribe(newStatus => {
    //         this.messageService.reportMessage(new Message(`Details ${newStatus}`));
    //     })
    // }

    handleStateChange(newState: StateUpdate) {
        this.editing = newState.mode == MODES.EDIT;
        this.keywordGroup.clear();
        if (this.editing && newState.id) {
            Object.assign(this.product, this.model.getProduct(newState.id)
                ?? new Product());
            this.messageService.reportMessage(
                new Message(`Editing ${this.product.name}`));
```

```
            this.product.details?.keywords?.forEach(val => {
                this.keywordGroup.push(this.createKeywordFormControl());
            })
        } else {
            this.product = new Product();
            this.messageService.reportMessage(new Message("Creating New Product"));
        }
        if (this.keywordGroup.length == 0) {
            this.keywordGroup.push(this.createKeywordFormControl());
        }
        this.productForm.reset(this.product);
    }

    submitForm() {
        if (this.productForm.valid) {
            Object.assign(this.product, this.productForm.value);
            this.model.saveProduct(this.product);
            this.product = new Product();
            this.keywordGroup.clear();
            this.keywordGroup.push(this.createKeywordFormControl());
            this.productForm.reset();
        }
    }

    resetForm() {
        this.keywordGroup.clear();
        this.keywordGroup.push(this.createKeywordFormControl());
        this.editing = true;
        this.product = new Product();
        this.productForm.reset();
    }

    createKeywordFormControl(): FormControl {
        return new FormControl();
    }
}
```

I have defined a FormArray property so that I can access it in the template, which is important because there are no built-in directives that export the FormArray for use as a template variable:

```
...
keywordGroup = new FormArray([
    this.createKeywordFormControl()
])
...
```

The FormArray is initialized with the initial set of controls it will manage, expressed as an array. Notice that controls are not given names, and the features described in Table 22-2 and Table 22-3 all work on arrays. Consistency is important when creating controls, so I define the createKeywordFormControl method, which creates the FormControl objects:

```
...
createKeywordFormControl(): FormControl {
    return new FormControl();
}
...
```

Using a method to create the FormControl objects ensures that I can easily alter the control configuration without having to figure out all of the places where controls are created.

■ **Note**   Angular includes the FormBuilder class, which can be used to simplify creating and configuring FormArray objects and the controls it contains. I don't find this class useful, which is why I don't describe it in this chapter, but you may feel differently. See `https://angular.io/api/forms/FormBuilder` for details.

The FormArray is added to the overall structure of controls in the same way as a nested FormGroup:

```
...
details: new FormGroup({
    supplier: new FormControl("", { validators: Validators.required }),
    keywords: this.keywordGroup
})
...
```

Within the component, I can manage the array of controls in the FormArray to match the selected Product object, ensuring that there is at least one control in the array so the user can add values to Product objects that don't currently have any keyword values.

Listing 22-4 uses the FormArray property to create the HTML elements to match the number of FormControl objects.

Listing 22-4. Creating Elements in the form.component.html File in the src/app/core Folder

```html
<form [formGroup]="productForm" #form="ngForm"
      (ngSubmit)="submitForm()" (reset)="resetForm()">

    <div class="form-group">
        <label>Name</label>
        <input class="form-control" formControlName="name" />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'name'; let err">
                {{ err }}
            </li>
        </ul>
    </div>

    <div class="form-group">
        <label>Category</label>
        <input class="form-control" formControlName="category"  />
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'category'; let err">
```

```
                    {{ err }}
                </li>
            </ul>
        </div>

        <div class="form-group">
            <label>Price</label>
            <input class="form-control" formControlName="price" />
            <ul class="text-danger list-unstyled mt-1">
                <li *validationErrors="productForm; control:'price'; let err">
                    {{ err }}
                </li>
            </ul>
        </div>

        <ng-container formGroupName="details">
            <div class="form-group">
                <label>Supplier</label>
                <input class="form-control" formControlName="supplier" />
                <ul class="text-danger list-unstyled mt-1">
                    <li *validationErrors="productForm; control:'details.supplier';
                        label: 'supplier'; let err">
                            {{ err }}
                    </li>
                </ul>
            </div>

            <ng-container formGroupName="keywords">
                <div class="form-group" *ngFor="let c of keywordGroup.controls;
                        let i = index">
                    <label>Keyword {{ i + 1 }}</label>
                    <input class="form-control" [formControlName]="i" [value]="c.value" />
                </div>
            </ng-container>

        </ng-container>

        <div class="mt-2">
            <button type="submit" class="btn btn-primary"
                    [class.btn-warning]="editing"
                    [disabled]="form.invalid">
                {{editing ? "Save" : "Create"}}
            </button>
            <button type="reset" class="btn btn-secondary m-1">Cancel</button>
        </div>
</form>
```

It is important to reflect the structure of the FormGroup and FormArray objects when creating HTML elements, ensuring that each is correctly configured with the formGroupName directive. I used the ng-container element to avoid introducing an HTML element for the FormArray object and used the ngFor directive to create elements for each FormControl in the FormArray:

640

```
...
<div class="form-group" *ngFor="let c of keywordGroup.controls; let i = index">
...
```

Each input element must be configured with the formControlName directive, using an array position as its value, instead of a name:

```
...
<input class="form-control" [formControlName]="i" [value]="c.value" />
...
```

The result is that the number of form controls displayed to the user varies based on the Product value that is selected, as shown in Figure 22-2. Notice that Angular correctly populates the input elements through the FormArray, mapping the values in the keywords model array to the elements in the form.

Figure 22-2. *Using a form array*

Adding and Removing Form Controls

To complete the support for multiple keywords, I am going to allow the user to add and remove controls. Listing 22-5 adds methods to the control class.

Listing 22-5. Adding Methods in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
```

```
@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    // ...formgroup, constructor, and methods omitted for brevity...

    createKeywordFormControl(): FormControl {
        return new FormControl();
    }

    addKeywordControl() {
        this.keywordGroup.push(this.createKeywordFormControl());
    }

    removeKeywordControl(index: number) {
        this.keywordGroup.removeAt(index);
    }
}
```

The new methods use the FormArray features described in Table 22-2 to add and remove FormGroup objects. Listing 22-6 adds elements to the template that will invoke the new component methods and allow the user to manage the number of keywords fields.

Listing 22-6. Adding Elements in the form.component.html File in the src/app/core Folder

```
...
<ng-container formGroupName="keywords">
    <button class="btn btn-sm btn-primary my-2"
            (click)="addKeywordControl()" type="button">
        Add Keyword
    </button>
    <div class="form-group" *ngFor="let c of keywordGroup.controls;
            let i = index; let count = count">
        <label>Keyword {{ i + 1 }}</label>
        <div class="input-group">
            <input class="form-control" [formControlName]="i" [value]="c.value" />
            <button class="btn btn-danger" type="button" *ngIf="count > 1"
                    (click)="removeKeywordControl(i)">
                Delete
            </button>
        </div>
    </div>
</ng-container>
...
```

I use the count variable exported by the ngForm directive to display a Delete button only when there are multiple controls in the form array. The number of keyword fields will be initially determined by the selected Product object, after which the user can add and remove fields, as shown in Figure 22-3.

Figure 22-3. *Adding and removing form controls in a form array*

Validating Dynamically Created Form Controls

Validation for the controls in a FormArray is similar to validating the controls in a FormGroup, as shown in Listing 22-7.

Listing 22-7. Adding Validation in the form.component.ts File in the src/app/core Folder

```
...
createKeywordFormControl(): FormControl {
    return new FormControl("", { validators: Validators.pattern("^[A-Za-z ]+$") });
}
...
```

The advantage of using a method to create FormControl objects for the FormArray is that I can define the validation policy in a single place. Listing 22-8 displays validation messages to the user.

Listing 22-8. Displaying Validation Messages in the form.component.html File in the src/app/core Folder

```
...
<ng-container formGroupName="keywords">
    <button class="btn btn-sm btn-primary my-2" (click)="addKeywordControl()"
            type="button">
        Add Keyword
    </button>
```

```
    <div class="form-group" *ngFor="let c of keywordGroup.controls;
            let i = index; let count = count">
        <label>Keyword {{ i + 1 }}</label>
        <div class="input-group">
            <input class="form-control" [formControlName]="i" [value]="c.value" />
            <button class="btn btn-danger" type="button" *ngIf="count > 1"
                    (click)="removeKeywordControl(i)">
                Delete
            </button>
        </div>
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'details.keywords.' + i;
                label: 'keyword'; let err">
                    {{ err }}
            </li>
        </ul>
    </div>
</ng-container>
...
```

The path to the control uses the position in the array, rather than a name, like this:

```
...
<li *validationErrors="productForm; control:'details.keywords.' + i;
    label: 'keyword'; let err">
...
```

It is important to ensure you specify the correct position; otherwise, you will display validation messages for a different control. The user is presented with a validation error if a disallowed character is entered into a keyword field, as shown in Figure 22-4.

Figure 22-4. *Validation for a form array control*

Filtering the FormArray Values

When dealing with variable numbers of controls in a FormArray, the user may create controls and then not use them, which can cause a problem when processing the contents of the form. Figure 22-5 illustrates the problem.
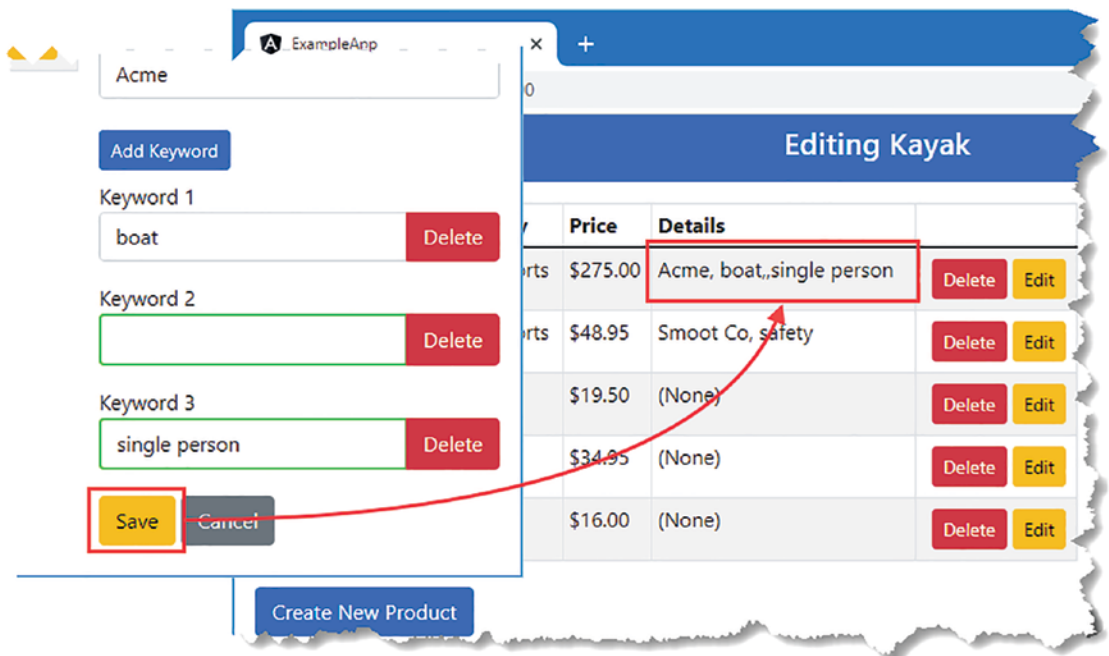

Figure 22-5. *The effect of empty fields in form array controls*

I left one of the keyword fields empty when I submitted the form, which means that an empty string has been included in the array of values assigned to the Product model object's keywords field.

I could prevent this problem using the required validator, but this requires the user to remove any empty controls before submitting the form, which would be an awkward interruption to their workflow.

My preference is to give the user some flexibility and create a custom class that will filter out unwanted values. Add a file named filteredFormArray.ts to the src/app/core folder with the contents shown in Listing 22-9.

Listing 22-9. The Contents of the filteredFormArray.ts File in the src/app/core Folder

```
import { FormArray } from "@angular/forms";

export type ValueFilter = (value: any) => boolean;

export class FilteredFormArray extends FormArray {

    filter: ValueFilter | undefined = (val) => val == "" || val == null;

    _updateValue() {
        (this as {value: any}).value =
        this.controls.filter((control) =>
          (control.enabled || this.disabled) && !this.filter?.(control.value)
        ).map((control) => control.value);
    }
}
```

645

The FilteredFormArray class defines an _updateValue method, which applies a filter function that, by default, excludes empty string and null values.

The code in Listing 22-9 is on the edge of what I would consider acceptable meddling with the Angular API. You won't see the _updateValue method in the API documentation for the FormArray class because it is part of the internal API defined, which was originally defined as an abstract method in the AbstractControl class and then overridden in the FormArray class. These methods are marked as internal, and I located them by looking at the Angular source code to figure out how these classes set the value property.

There are two issues with using methods like this. The first is that internal methods are subject to change or removal without notice, which means that figure releases of Angular may remove the _updateValue method and break the code in Listing 22-9.

The second issue is that the Angular packages are compiled using a TypeScript setting that excludes internal methods from the type declaration files that are used during project development. This means that the TypeScript compiler doesn't know that the FormArray class defines an _updateValue method and won't allow the use of the override or the super keywords. For this reason, I have had to copy the original code from the FormArray class and integrate support for filtering, rather than just calling the FormArray implementation of the method and filtering the result.

I am comfortable with these issues when it comes to small changes in functionality. You must make your own assessment of the issues and decide whether relying on internal features is reasonable for your projects.

But, even if you are not comfortable using this approach in your projects, this example does let me illustrate that, once again, there is nothing magical about the way that Angular works. In this case, I relied on the fact that Angular applications are compiled into pure JavaScript and that the JavaScript rules for locating a method apply, even if TypeScript has been configured to exclude the method from the type declaration files.

Listing 22-10 replaces the standard FormArray object with one that filters values.

Listing 22-10. Using a Customized Form Array in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FilteredFormArray([
        this.createKeywordFormControl()
    ])
```

```
productForm: FormGroup = new FormGroup({
    name:  new FormControl("", {
        validators: [
            Validators.required,
            Validators.minLength(3),
            Validators.pattern("^[A-Za-z ]+$")
        ],
        updateOn: "change"
    }),
    category: new FormControl("", { validators: Validators.required }),
    price: new FormControl("", {
        validators: [Validators.required, Validators.pattern("^[0-9\.]+$")]
    }),
    details: new FormGroup({
        supplier: new FormControl("", { validators: Validators.required }),
        keywords: this.keywordGroup
    })
});

// ...constructor and methods omitted for brevity...
}
```

The use of the filter prevents empty values from being included in the keywords array, as shown in Figure 22-6.

Figure 22-6. *Filtering values*

Creating Custom Form Validation

Angular supports custom form validators, which can be used to enforce a validation policy that is specific to the application, rather than the general-purpose validation that the built-in validators provide. A good way to understand how custom validation works is to re-create the functionality provided by one of the built-in validators.

Create the src/app/validation folder and add to it a file named limit.ts with the contents shown in Listing 22-11.

Listing 22-11. The Contents of the limit.ts File in the src/app/validation Folder

```
import { AbstractControl, ValidationErrors, ValidatorFn } from "@angular/forms";

export class LimitValidator {

    static Limit(limit:number) : ValidatorFn {
        return (control: AbstractControl) : ValidationErrors | null => {
            let val = parseFloat(control.value);
            if (isNaN(val) || val > limit) {
                return {"limit": {"limit": limit, "actualValue": val}};
            }
            return null;
        }
    }
}
```

Custom validators are functions that implement the ValidatorFn interface, which describes a factory function that creates functions that perform validation. The factory function accepts parameters that allow validation to be configured and returns functions that accept an AbstractControl parameter and return a ValidationErrors | null result:

```
...
static Limit(limit:number) : ValidatorFn {
    return (control: AbstractControl) : ValidationErrors | null => {
...
```

The factory function in this example is named Limit, and it defines a parameter named limit that specifies a maximum acceptable value, similar to the way that the built-in min validator works.

Listing 22-12 adds support for translating the validation results produced by the custom validator into messages that can be displayed to the user.

Listing 22-12. Adding Support for a New Validator in the validation_helper.ts File in the src/app/core Folder

```
import { Pipe } from "@angular/core";
import { FormControl, ValidationErrors } from "@angular/forms";

@Pipe({
    name: "validationFormat"
})
export class ValidationHelper {
```

```
    transform(source: any, name: any) : string[] {
        if (source instanceof FormControl) {
            return this.formatMessages((source as FormControl).errors, name)
        }
        return this.formatMessages(source as ValidationErrors, name)
    }

    formatMessages(errors: ValidationErrors | null, name: string): string[] {
        let messages: string[] = [];
        for (let errorName in errors) {
            switch (errorName) {
                case "required":
                    messages.push(`You must enter a ${name}`);
                    break;
                case "minlength":
                    messages.push(`A ${name} must be at least
                        ${errors['minlength'].requiredLength}
                        characters`);
                    break;
                case "pattern":
                    messages.push(`The ${name} contains
                            illegal characters`);
                    break;
                case "limit":
                    messages.push(`The ${name} must be less than
                        ${errors['limit'].limit}`);
                    break;

            }
        }
        return messages;
    }
}
```

Custom validators are applied in the same way as those built into Angular, as shown in Listing 22-13.

Listing 22-13. Using a Custom Validator in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
```

```
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FilteredFormArray([
        this.createKeywordFormControl()
    ])

    productForm: FormGroup = new FormGroup({
        name:  new FormControl("", {
            validators: [
                Validators.required,
                Validators.minLength(3),
                Validators.pattern("^[A-Za-z ]+$")
            ],
            updateOn: "change"
        }),
        category: new FormControl("", { validators: Validators.required }),
        price: new FormControl("", {
            validators: [
                Validators.required, Validators.pattern("^[0-9\.]+$"),
                LimitValidator.Limit(300)
            ]
        }),
        details: new FormGroup({
            supplier: new FormControl("", { validators: Validators.required }),
            keywords: this.keywordGroup
        })
    });

    // ...constructor and methods omitted for brevity...
}
```

To see the effect of the custom validator, enter a value in the Price field that exceeds the limit set in Listing 22-13, as shown in Figure 22-7.

Price

500

The price must be less than 300

Figure 22-7. *Using a custom validator*

Creating a Directive for a Custom Validator

A directive is required to apply a custom validator to a template element when the reactive forms API isn't used. Add a file named hilow.ts to the src/app/validation folder with the content shown in Listing 22-14.

Listing 22-14. The Contents of the hilow.ts File in the src/app/validation Folder

```
import { Directive, Input, SimpleChanges } from "@angular/core";
import { AbstractControl, NG_VALIDATORS, ValidationErrors,
    Validator, ValidatorFn } from "@angular/forms";

export class HiLowValidator {

    static HiLow(high:number, low: number) : ValidatorFn {
        return (control: AbstractControl) : ValidationErrors | null => {
            let val = parseFloat(control.value);
            if (isNaN(val) || val > high || val < low) {
                return {"hilow": {"high": high, "low": low, "actualValue": val}};
            }
            return null;
        }
    }
}

@Directive({
    selector: 'input[high][low]',
    providers: [{provide: NG_VALIDATORS, useExisting: HiLowValidatorDirective,
        multi: true}]
})
export class HiLowValidatorDirective implements Validator {

    @Input()
    high: number | string | undefined

    @Input()
    low: number | string | undefined

    validator?: (control: AbstractControl) => ValidationErrors | null;

    ngOnChanges(changes: SimpleChanges): void {
        if ("high" in changes || "low" in changes) {
            let hival = typeof(this.high) == "string"
                ? parseInt(this.high) : this.high;
            let loval = typeof(this.low) == "string"
                ? parseInt(this.low) : this.low;
            this.validator = HiLowValidator.HiLow(hival ?? Number.MAX_VALUE,
                loval ?? 0);
        }
    }

    validate(control: AbstractControl): ValidationErrors | null {
        return this.validator?.(control) ?? null;
    }
}
```

651

The `HiLowValidator` class defines a `HiLow` factory function that can be used with reactive forms. This listing also defines the `HiLowValidatorDirective` class, which implements the `Validator` interface and the `validate` method it defines. The `ngOnChanges` method is used to create a new validator when the input value changes, which is used in the `validate` method to assess the contents of a control.

Validation directives must use the `providers` property to register the `NG_VALIDATORS` service, like this:

```
...
providers: [{provide: NG_VALIDATORS,
        useExisting: HiLowValidatorDirective, multi: true}]
...
```

Without this property, Angular will not use the directive for validation. Listing 22-15 registers the validation directive so that it can be used in templates.

Listing 22-15. Registering a Directive in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [SharedState]
})
export class CoreModule { }
```

Listing 22-16 adds support for producing a validation message that can be displayed to the user.

Listing 22-16. Adding a Validation Message in the validation_helper.ts File in the src/app/core Folder

```
import { Pipe } from "@angular/core";
import { FormControl, ValidationErrors } from "@angular/forms";

@Pipe({
    name: "validationFormat"
})
export class ValidationHelper {

    transform(source: any, name: any) : string[] {
        if (source instanceof FormControl) {
            return this.formatMessages((source as FormControl).errors, name)
```

```
        }
        return this.formatMessages(source as ValidationErrors, name)
    }

    formatMessages(errors: ValidationErrors | null, name: string): string[] {
        let messages: string[] = [];
        for (let errorName in errors) {
            switch (errorName) {
                case "required":
                    messages.push(`You must enter a ${name}`);
                    break;
                case "minlength":
                    messages.push(`A ${name} must be at least
                        ${errors['minlength'].requiredLength}
                        characters`);
                    break;
                case "pattern":
                    messages.push(`The ${name} contains
                            illegal characters`);
                    break;
                case "limit":
                    messages.push(`The ${name} must be less than
                        ${errors['limit'].limit}`);
                    break;
                case "hilow":
                    messages.push(`The ${name} must be between
                        ${errors['hilow'].low} and ${errors['hilow'].high}`);
                    break;

            }
        }
        return messages;
    }
}
```

Finally, Listing 22-17 applies the validation directive in a template.

Listing 22-17. Applying a Directive in the form.component.html File in the src/app/core Folder

```html
...
<div class="form-group">
    <label>Price</label>
    <input class="form-control" formControlName="price" [high]=300 [low]=10 />
    <ul class="text-danger list-unstyled mt-1">
        <li *validationErrors="productForm; control:'price'; let err">
            {{ err }}
        </li>
    </ul>
</div>
...
```

As you enter values into the Price field, the `HiLowValidatorDirective` uses the `HiLow` factory function for validation, as shown in Figure 22-8.

Figure 22-8. *Applying a custom validator with a directive*

Validating Across Multiple Fields

Custom validators can be used to enforce policies that apply to multiple fields. This type of validator is applied to the `FormGroup` or `FormArray` that is the parent to the controls that are validated. Add a file named `unique.ts` to the `src/app/validation` folder with the contents shown in Listing 22-18.

Listing 22-18. The Contents of the unique.ts File in the src/app/validation Folder

```
import { AbstractControl, FormArray, ValidationErrors, ValidatorFn }
    from "@angular/forms";

export class UniqueValidator {

    static unique() : ValidatorFn {
        return (control: AbstractControl) : ValidationErrors | null => {
            if (control instanceof FormArray) {
                let badElems = control.controls.filter((child, index) => {
                    return control.controls.filter((c, i2) => i2 != index)
                        .some(target => target.value != ""
                            && target.value == child.value);
                });
                if (badElems.length > 0) {
                    return {"unique": {}};
                }
            }
            return null;
        }
    }
}
```

The validator function looks for duplicate values in the array of controls managed by the `FormArray` and produces an error if there are duplicates. Listing 22-19 applies the validator to the `FormArray` in the component class.

Listing 22-19. Applying a Validator in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
```

```
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";
import { UniqueValidator } from "../validation/unique";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FilteredFormArray([
        this.createKeywordFormControl(),
    ], {
        validators: UniqueValidator.unique()
    })

    // ...form structure, constructor and methods omitted for brevity...
}
```

Listing 22-20 adds a validation message that can be presented to the user.

Listing 22-20. Adding a Validation Message in the validation_helper.ts File in the src/app/core Folder

```
import { Pipe } from "@angular/core";
import { FormControl, ValidationErrors } from "@angular/forms";

@Pipe({
    name: "validationFormat"
})
export class ValidationHelper {

    transform(source: any, name: any) : string[] {
        if (source instanceof FormControl) {
            return this.formatMessages((source as FormControl).errors, name)
        }
        return this.formatMessages(source as ValidationErrors, name)
    }

    formatMessages(errors: ValidationErrors | null, name: string): string[] {
        let messages: string[] = [];
        for (let errorName in errors) {
            switch (errorName) {
                case "required":
                    messages.push(`You must enter a ${name}`);
                    break;
```

```
                    case "minlength":
                        messages.push(`A ${name} must be at least
                            ${errors['minlength'].requiredLength}
                            characters`);
                        break;
                    case "pattern":
                        messages.push(`The ${name} contains
                                illegal characters`);
                        break;
                    case "limit":
                        messages.push(`The ${name} must be less than
                            ${errors['limit'].limit}`);
                        break;
                    case "hilow":
                        messages.push(`The ${name} must be between
                            ${errors['hilow'].low} and ${errors['hilow'].high}`);
                        break;
                    case "unique":
                        messages.push(`The ${name} must be unique`);
                        break;
                }
            }
        }
        return messages;
    }
}
```

The final step is to display validation messages for the form array in the template, as shown in Listing 22-21.

Listing 22-21. Displaying Validation Messages in the form.component.html File in the src/app/core Folder

```
...
<ng-container formGroupName="keywords">
    <button class="btn btn-sm btn-primary my-2" (click)="addKeywordControl()"
            type="button">
        Add Keyword
    </button>
    <ul class="text-danger list-unstyled mt-1">
        <li *validationErrors="productForm; control:'details.keywords';
                label: 'keywords' let err">
            {{ err }}
        </li>
    </ul>
    <div class="form-group" *ngFor="let c of keywordGroup.controls;
            let i = index; let count = count">
        <label>Keyword {{ i + 1 }}</label>
        <div class="input-group">
            <input class="form-control" [formControlName]="i" [value]="c.value" />
            <button class="btn btn-danger" type="button" *ngIf="count > 1"
                    (click)="removeKeywordControl(i)">
                Delete
            </button>
```

```
        </div>
        <ul class="text-danger list-unstyled mt-1">
            <li *validationErrors="productForm; control:'details.keywords.' + i;
                label: 'keyword'; let err">
                    {{ err }}
            </li>
        </ul>
    </div>
</ng-container>
...
```

To see the effect, click the Edit button for the Kayak product and change the value of the second keyword field to boat. The validator will detect the duplicate value and display a validation message, as shown in Figure 22-9.

Figure 22-9. *Validating across fields*

The validator works as expected, but there is an important mismatch between the validation message and the color coding applied to the individual elements, which I will improve upon in the next section.

Improving Cross-Field Validation

Improving the cross-field validation experience can be done, but it requires careful navigation around the way that Angular expects groups of form controls to behave. Unlike an earlier example in this chapter, no internal methods are used, but the code relies on the SetTimeout method to trigger changes after the current update cycle to perform updates without creating an infinite update loop.

The problem is that Angular expects changes to propagate up through the structure of form controls so that the user edits a field, which triggers validation in the FormControl, and then in its enclosing FormGroup or FormArray, working its way to the top-level FormGroup. To achieve the effect I want, I have to push updates in the opposite direction so that a change in validation status in the FormArray triggers validation updates in the enclosed FormControl objects. Listing 22-22 updates the unique custom validator so that it alters the validation status of contained FormControl elements that contain the same value.

Listing 22-22. Improving Validation in the unique.ts File in the src/app/validation Folder

```
import { AbstractControl, FormArray, ValidationErrors, ValidatorFn }
    from "@angular/forms";

export class UniqueValidator {

    static uniquechild(control: AbstractControl) : ValidationErrors | null {
        return control.parent?.hasError("unique") ? {"unique-child": {}} : null;
    }

    static unique() : ValidatorFn {
        return (control: AbstractControl) : ValidationErrors | null => {
            let badElems: AbstractControl[] = [];
            let goodElems: AbstractControl[] = [];
            if (control instanceof FormArray) {
                control.controls.forEach((child, index) => {
                    if (control.controls.filter((c, i2) => i2 != index)
                        .some(target => target.value != ""
                            && target.value == child.value)) {
                        badElems.push(child);
                    } else {
                        goodElems.push(child);
                    }
                })
                setTimeout(() => {
                    badElems.forEach(c => {
                        if (!c.hasValidator(this.uniquechild)) {
                            c.markAsDirty();
                            c.addValidators(this.uniquechild)
                            c.updateValueAndValidity({onlySelf: true,
                                emitEvent: false});
                        }
                    })
                    goodElems.forEach(c => {
                        if (c.hasValidator(this.uniquechild)) {
                            c.removeValidators(this.uniquechild);
                        }
                        c.updateValueAndValidity({ onlySelf: true,
                            emitEvent: false})
                    })

                }, 0);
            }
            return badElems.length > 0 ? {"unique": {}} : null;
        }
    }
}
```

The approach I have chosen is to add a validator to child controls that have duplicate values, which will ensure they are marked in red. The additional code in Listing 22-22 takes care of adding and removing the validator and triggering validation updates when there are changes, which I do through the updateValueAndValidity method. This method, which I have described in Table 22-4 for quick reference, updates a control's value property and performs validation. This method is defined by the AbstractControl class, which means that it can be used on FormControl, FormGroup, and FormArray objects.

Table 22-4. *The AbstractControl Method for Manual Updates*

Name	Description
updateValueAndValidity(opts)	This method causes a control to update its value and perform validation. The optional argument can be used to restrict propagating the change up the form hierarchy by setting the onlySelf property to true and preventing events by setting the emitEvent property to false.

To ensure that the validation status is maintained correctly when the user adds and removes keyword fields, Listing 22-23 overrides the push and removeAt methods defined by the FormArray class.

Listing 22-23. Refreshing Controls in the filteredFormArray.ts File in the src/app/core Folder

```
import { AbstractControl, FormArray } from "@angular/forms";

export type ValueFilter = (value: any) => boolean;

export class FilteredFormArray extends FormArray {

    filter: ValueFilter | undefined = (val) => val == "" || val == null;

    _updateValue() {
        (this as {value: any}).value =
        this.controls.filter((control) =>
          (control.enabled || this.disabled) && !this.filter?.(control.value)
        ).map((control) => control.value);
    }

    override push(control: AbstractControl,
            options?: { emitEvent?: boolean | undefined; }): void {
        super.push(control, options);
        this.controls.forEach(c => c.updateValueAndValidity());
    }

    override removeAt(index: number,
            options?: { emitEvent?: boolean | undefined; }): void {
        super.removeAt(index, options);
        this.controls.forEach(c => c.updateValueAndValidity());
    }
}
```

The changes in Listing 22-22 and Listing 22-23 ensure that individual controls with the form array are marked as invalid when they contain duplicate values, as shown in Figure 22-10.

Figure 22-10. *Improving the cross-field validation experience*

Performing Validation Asynchronously

Asynchronous validation is useful for complex validation tasks or where the amount of time taken to perform validation is subject to delay, such as when a call to a remote HTTP service is required.

Add a file named prohibited.ts to the src/app/validation folder with the contents shown in Listing 22-24.

Listing 22-24. The Contents of the prohibited.ts File in the src/app/validation Folder

```
import { AbstractControl, AsyncValidatorFn, ValidationErrors } from "@angular/forms";
import { Observable, Subject } from "rxjs";

export class ProhibitedValidator {

    static prohibitedTerms: string[] = ["ski", "swim"]

    static prohibited(): AsyncValidatorFn {
        return (control: AbstractControl): Promise<ValidationErrors | null>
                | Observable<ValidationErrors | null> => {
            let subject = new Subject<ValidationErrors | null>();
            setTimeout(() => {
                let match = false;
                this.prohibitedTerms.forEach(word => {
                    if ((control.value as string).toLowerCase().indexOf(word) > -1) {
                        subject.next({"prohibited": { prohibited: word}})
                        match = true;
                    }
                });
```

```
            if (!match) {
                subject.next(null);
            }
            subject.complete();
        }, 1000);
        return subject;
    }
}
}
```

Asynchronous validators produce their results through a Promise, which is useful when using non-Angular packages, or an Observable, which is useful when using the Angular features provided for making HTTP requests. For simplicity, the validator in Listing 22-24 simulates an asynchronous operation using the setTimeout function and compares the value it receives with a list of prohibited terms.

When performing asynchronous validation, it is important to produce a ValidationErrors object or, if there are no errors, null, so that Angular knows that the validation process is complete. Listing 22-25 introduces a new validation message that can be displayed to the user.

Listing 22-25. Adding a Message in the validaton_helper.ts File in the src/app/core Folder

```
...
switch (errorName) {
    case "required":
        messages.push(`You must enter a ${name}`);
        break;
    case "minlength":
        messages.push(`A ${name} must be at least
            ${errors['minlength'].requiredLength}
            characters`);
        break;
    case "pattern":
        messages.push(`The ${name} contains
                illegal characters`);
        break;
    case "limit":
        messages.push(`The ${name} must be less than
            ${errors['limit'].limit}`);
        break;
    case "hilow":
        messages.push(`The ${name} must be between
            ${errors['hilow'].low} and ${errors['hilow'].high}`);
        break;
    case "unique":
        messages.push(`The ${name} must be unique`);
        break;
    case "prohibited":
      messages.push(`The ${name} may not contain
          "${errors["prohibited"].prohibited}"`);
      break;
}
...
```

CHAPTER 22 ■ USING THE FORMS API, PART 2

Listing 22-26 applies the asynchronous validator to a FormControl, which is done using the asyncValidators property.

Listing 22-26. Applying a Validator in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";
import { UniqueValidator } from "../validation/unique";
import { ProhibitedValidator } from "../validation/prohibited";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FilteredFormArray([
        this.createKeywordFormControl(),
    ], {
        validators: UniqueValidator.unique()
    })

    productForm: FormGroup = new FormGroup({
        name:  new FormControl("", {
            validators: [
                Validators.required,
                Validators.minLength(3),
                Validators.pattern("^[A-Za-z ]+$")
            ],
            updateOn: "change"
        }),
        category: new FormControl("", {
            validators: Validators.required,
            asyncValidators: ProhibitedValidator.prohibited()
        }),
        price: new FormControl("", {
            validators: [
                Validators.required, Validators.pattern("^[0-9\.]+$"),
                LimitValidator.Limit(300)
            ]
        }),
```

```
    details: new FormGroup({
        supplier: new FormControl("", { validators: Validators.required }),
        keywords: this.keywordGroup
    })
});

// ...constructor and methods omitted for brevity...
}
```

While waiting for an asynchronous validation result, Angular puts the FormControl object into the pending state, which adds the HTML element to the ng-pending class. Listing 22-27 defines a new CSS style that will be applied to pending elements.

Listing 22-27. Adding a Style in the form.component.css File in the src/app/core Folder

```
input.ng-dirty.ng-invalid { border: 2px solid #ff0000 }
input.ng-dirty.ng-valid { border: 2px solid #6bc502 }
input.ng-pending { border: 2px solid #ffc107 }
```

To see the asynchronous validator working, start typing into the Category field. The HTML element will be displayed with an amber border during validation, and an error will be displayed if the text you enter contains the terms *ski* or *swim*, as shown in Figure 22-11.

Figure 22-11. *Using an asynchronous validator*

There are two points of note when using an asynchronous validator. The first point is that asynchronous validation is performed only when no synchronous validator has returned an error, which can create a confusing sequence of validation messages unless the interaction between validators has been thought through.

The second point is that asynchronous validation is performed after every change to the form control (as long as there are no synchronous validation errors). This can result in a large number of validation operations, which may be slow or expensive to perform. If this is a concern, then you can change the update frequency using the updateOn option described in Chapter 21.

Summary

In this chapter, I described the Angular forms API features for creating controls dynamically using a `FormArray` and explained the different ways in which custom validation can be performed, including the use of asynchronous validators. In the next chapter, I describe the features that Angular provides for making HTTP requests.

CHAPTER 23

■ ■ ■

Making HTTP Requests

All the examples since Chapter 9 have relied on static data that has been hardwired into the application. In this chapter, I demonstrate how to use asynchronous HTTP requests, often called Ajax requests, to interact with a web service to get real data into an application. Table 23-1 puts HTTP requests in context.

Table 23-1. *Putting Asynchronous HTTP Requests in Context*

Question	Answer
What are they?	Asynchronous HTTP requests are HTTP requests sent by the browser on behalf of the application. The term *asynchronous* refers to the fact that the application continues to operate while the browser is waiting for the server to respond.
Why are they useful?	Asynchronous HTTP requests allow Angular applications to interact with web services so that persistent data can be loaded into the application and changes can be sent to the server and saved.
How are they used?	Requests are made using the `HttpClient` class, which is delivered as a service through dependency injection. This class provides an Angular-friendly wrapper around the browser's `XMLHttpRequest` feature.
Are there any pitfalls or limitations?	Using the Angular HTTP feature requires the use of Reactive Extensions `Observable` objects.
Are there any alternatives?	You can work directly with the browser's `XMLHttpRequest` object if you prefer, and some applications—those that don't need to deal with persistent data—can be written without making HTTP requests at all.

Table 23-2 summarizes the chapter.

Table 23-2. *Chapter Summary*

Problem	Solution	Listing
Sending HTTP requests in an Angular application	Use the Http service	1–8
Performing REST operations	Use the HTTP method and URL to specify an operation and a target for that operation	9–11
Making cross-origin requests	Use the HttpClient service to support CORS automatically (JSONP requests are also supported)	12–13
Including headers in a request	Set the headers property in the Request object	14–15
Responding to an HTTP error	Create an error handler class	16–19

Preparing the Example Project

This chapter uses the exampleApp project created in Chapter 22. For this chapter, I rely on a server that responds to HTTP requests with JSON data. Run the command shown in Listing 23-1 in the exampleApp folder to add the json-server package to the project.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 23-1. Adding a Package to the Project

```
npm install json-server@0.17.0
```

I added an entry in the scripts section of the package.json file to run the json-server package, as shown in Listing 23-2.

Listing 23-2. Adding a Script Entry in the package.json File in the exampleApp Folder

```
...
"scripts": {
"ng": "ng",
"start": "ng serve",
"build": "ng build",
"watch": "ng build --watch --configuration development",
"test": "ng test",
"json": "json-server --p 3500 restData.js"
},
...
```

Configuring the Model Feature Module

The @angular/common/http JavaScript module contains an Angular module called HttpClientModule, which must be imported into the application in either the root module or one of the feature modules before HTTP requests can be created. In Listing 23-3, I imported the module to the model module, which is the natural place in the example application because I will be using HTTP requests to populate the model with data.

Listing 23-3. Importing a Module in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { StaticDataSource } from "./static.datasource";
import { Model } from "./repository.model";
import { HttpClientModule } from "@angular/common/http";

@NgModule({
    imports: [HttpClientModule],
    providers: [Model, StaticDataSource]
})
export class ModelModule { }
```

Creating the Data File

To provide the json-server package with some data, I added a file called restData.js to the exampleApp folder and added the code shown in Listing 23-4.

Listing 23-4. The Contents of the restData.js File in the exampleApp Folder

```
module.exports = function () {
    var data = {
        products: [
            { id: 1, name: "Kayak", category: "Watersports", price: 275,
                details: { supplier: "Acme", keywords: ["boat", "small"]} },
            { id: 2, name: "Lifejacket", category: "Watersports", price: 48.95,
                details: { supplier: "Smoot Co", keywords: ["safety"]} },
            { id: 3, name: "Soccer Ball", category: "Soccer", price: 19.50 },
            { id: 4, name: "Corner Flags", category: "Soccer", price: 34.95 },
            { id: 5, name: "Stadium", category: "Soccer", price: 79500 },
            { id: 6, name: "Thinking Cap", category: "Chess", price: 16 },
            { id: 7, name: "Unsteady Chair", category: "Chess", price: 29.95 },
            { id: 8, name: "Human Chess Board", category: "Chess", price: 75 },
            { id: 9, name: "Bling Bling King", category: "Chess", price: 1200 }
        ]
    }
    return data
}
```

The json-server package can work with JSON or JavaScript files. If you use a JSON file, then its contents will be modified to reflect change requests made by clients. I have chosen the JavaScript option, which allows data to be generated programmatically and means that restarting the process will return to the original data.

Running the Example Project

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the data server:

```
npm run json
```

This command will start the json-server, which will listen for HTTP requests on port 3500. Open a new browser window and navigate to http://localhost:3500/products/2. The server will respond with the following data:

```
{
  "id": 2,
  "name": "Lifejacket",
  "category": "Watersports",
  "price": 48.95,
  "details": {
    "supplier": "Smoot Co",
    "keywords": [
      "safety"
    ]
  }
}
```

Leave the json-server running and use a separate command prompt to start the Angular development tools by running the following command in the exampleApp folder:

```
ng serve
```

Use the browser to navigate to http://localhost:4200 to see the content illustrated in Figure 23-1.

Figure 23-1. *Running the example application*

Understanding RESTful Web Services

The most common approach for delivering data to an application is to use the Representational State Transfer pattern, known as REST, to create a data web service. There is no detailed specification for REST, which leads to a lot of different approaches that fall under the RESTful banner. There are, however, some unifying ideas that are useful in web application development.

The core premise of a RESTful web service is to embrace the characteristics of HTTP so that request methods—also known as *verbs*—specify an operation for the server to perform, and the request URL specifies one or more data objects to which the operation will be applied.

As an example, here is a URL that might refer to a specific product in the example application:

```
http://localhost:3500/products/2
```

The first segment of the URL—products—is used to indicate the collection of objects that will be operated on and allows a single server to provide multiple services, each with separate data. The second segment—2—selects an individual object within the products collection. In the example, it is the value of the id property that uniquely identifies an object and that will be used in the URL, in this case, specifying the Lifejacket object.

669

The HTTP verb or method used to make the request tells the RESTful server what operation should be performed on the specified object. When you tested the RESTful server in the previous section, the browser sent an HTTP GET request, which the server interprets as an instruction to retrieve the specified object and send it to the client. It is for this reason that the browser displayed a JSON representation of the Lifejacket object.

Table 23-3 shows the most common combination of HTTP methods and URLs and explains what each of them does when they are sent to a RESTful server.

Table 23-3. *Common HTTP Verbs and Their Effect in a RESTful Web Service*

Verb	URL	Description
GET	/products	This combination retrieves all the objects in the products collection.
GET	/products/2	This combination retrieves the object whose id is 2 from the products collection.
POST	/products	This combination is used to add a new object to the products collection. The request body contains a JSON representation of the new object.
PUT	/products/2	This combination is used to replace the object in the products collection whose id is 2. The request body contains a JSON representation of the replacement object.
PATCH	/products/2	This combination is used to update a subset of the properties of the object in the products collection whose id is 2. The request body contains a JSON representation of the properties to update and the new values.
DELETE	/products/2	This combination is used to delete the product whose id is 2 from the products collection.

Caution is required because there can be considerable differences in the way that some RESTful web services work, caused by differences in the frameworks used to create them and the preferences of the development team. It is important to confirm how a web service uses verbs and what is required in the URL and request body to perform operations.

Some common variations include web services that won't accept any request bodies that contain id values (to ensure they are generated uniquely by the server's data store) or any web services that don't support all of the verbs (it is common to ignore PATCH requests and only accept updates using the PUT verb).

Replacing the Static Data Source

The best place to start with HTTP requests is to replace the static data source in the example application with one that retrieves data from the RESTful web service. This will provide a foundation for describing how Angular supports HTTP requests and how they can be integrated into an application.

Creating the New Data Source Service

To create a new data source, I added a file called rest.datasource.ts in the src/app/model folder and added the statements shown in Listing 23-6.

Listing 23-6. The Contents of the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {

    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.http.get<Product[]>(this.url);
    }
}
```

This is a simple-looking class, but there are some important features at work, which I described in the sections that follow.

Setting Up the HTTP Request

Angular provides the ability to make asynchronous HTTP requests through the HttpClient class, which is defined in the @angular/common/http JavaScript module and is provided as a service in the HttpClientModule feature module. The data source declared a dependency on the HttpClient class using its constructor, like this:

```
...
constructor(private http: HttpClient, @Inject(REST_URL) private url: string) { }
...
```

The other constructor argument is used so that the URL that requests are sent to doesn't have to be hardwired into the data source. I'll create a provider using the REST_URL opaque token when I configure the feature module. The HttpClient object received through the constructor is used to make an HTTP GET request in the data source's getData method, like this:

```
...
getData(): Observable<Product[]> {
    return this.http.get<Product[]>(this.url);
}
...
```

The HttpClient class defines a set of methods for making HTTP requests, each of which uses a different HTTP verb, as described in Table 23-4.

■ **Tip** The methods in Table 23-4 accept an optional configuration object, as demonstrated in the "Configuring Request Headers" section.

Table 23-4. *The HttpClient Methods*

Name	Description
get(url)	This method sends a GET request to the specified URL.
post(url, body)	This method sends a POST request using the specified object as the body.
put(url, body)	This method sends a PUT request using the specified object as the body.
patch(url, body)	This method sends a PATCH request using the specified object as the body.
delete(url)	This method sends a DELETE request to the specified URL.
head(url)	This method sends a HEAD request, which has the same effect as a GET request except that the server will return only the headers and not the request body.
options(url)	This method sends an OPTIONS request to the specified URL.
request(method, url, options)	This method can be used to send a request with any verb, as described in the "Consolidating HTTP Requests" section.

Processing the Response

The methods described in Table 23-4 accept a type parameter, which the HttpClient class uses to parse the response received from the server. The RESTful web server returns JSON data, which has become the de facto standard used by web services, and the HttpClient object will automatically convert the response into an Observable that yields an instance of the type parameter when it completes. This means that if you call the get method, for example, with a Product[] type parameter, then the response from the get method will be an Observable<Product[]> that represents the eventual response from the HTTP request.

```
...
getData(): Observable<Product[]> {
  return this.http.get<Product[]>(this.url);
}
...
```

■ **Caution** The methods in Table 23-4 prepare an HTTP request, but it isn't sent to the server until the Observer object's subscribe method is invoked. Be careful, though, because the request will be sent once per call to the subscribe method, which makes it easy to inadvertently send the same request multiple times.

Configuring the Data Source

The next step is to configure a provider for the new data source and to create a value-based provider to configure it with a URL to which requests will be sent. Listing 23-7 shows the changes to the model.module. ts file.

Listing 23-7. Configuring the Data Source in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { StaticDataSource } from "./static.datasource";
import { Model } from "./repository.model";
import { HttpClientModule } from "@angular/common/http";
import { RestDataSource, REST_URL } from "./rest.datasource";

@NgModule({
    imports: [HttpClientModule],
    providers: [Model, RestDataSource,
        { provide: REST_URL, useValue: `http://${location.hostname}:3500/products` }]
})
export class ModelModule { }
```

The two new providers enable the RestDataSource class as a service and use the REST_URL opaque token to configure the URL for the web service. I removed the provider for the StaticDataSource class, which is no longer required.

Using the REST Data Source

The final step is to update the repository class so that it declares a dependency on the new data source and uses it to get the application data, as shown in Listing 23-8.

Listing 23-8. Using the New Data Source in the repository.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";
import { Observable } from "rxjs";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class Model {
    private products: Product[];
    private locator = (p: Product, id?: number) => p.id == id;

    constructor(private dataSource: RestDataSource) {
        this.products = new Array<Product>();
        // this.dataSource.getData().forEach(p => this.products.push(p));
        this.dataSource.getData().subscribe(data => this.products = data);
    }
```

```
    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }

    saveProduct(product: Product) {
        if (product.id == 0 || product.id == null) {
            product.id = this.generateID();
            this.products.push(product);
        } else {
            let index = this.products
                .findIndex(p => this.locator(p, product.id));
            this.products.splice(index, 1, product);
        }
    }

    deleteProduct(id: number) {
        let index = this.products.findIndex(p => this.locator(p, id));
        if (index > -1) {
            this.products.splice(index, 1);
        }
    }

    private generateID(): number {
        let candidate = 100;
        while (this.getProduct(candidate) != null) {
            candidate++;
        }
        return candidate;
    }
}
```

The constructor dependency has changed so that the repository will receive a RestDataSource object when it is created. Within the constructor, the data source's getData method is called, and the subscribe method is used to receive the data objects that are returned from the server and process them.

When you save the changes, the browser will reload the application, and the new data source will be used. An asynchronous HTTP request will be sent to the RESTful web service, which will return the larger set of data objects shown in Figure 23-2.
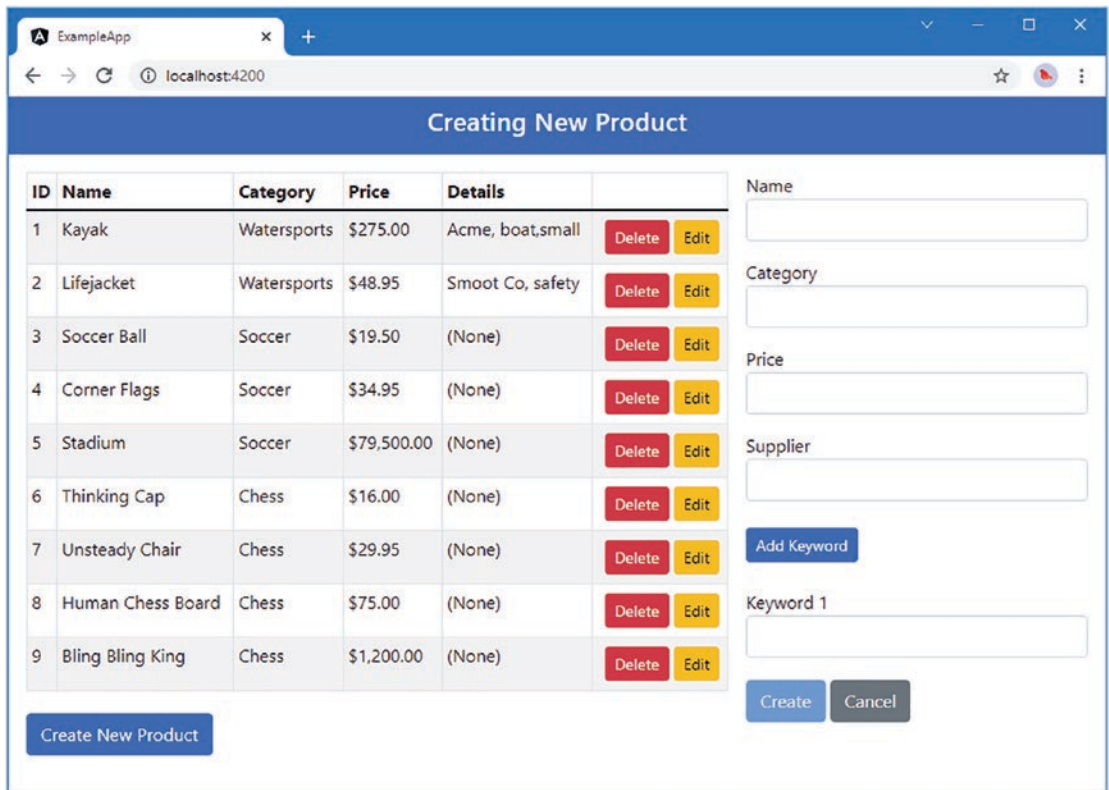

Figure 23-2. *Getting the application data*

Saving and Deleting Data

The data source can get data from the server, but it also needs to send data the other way, persisting changes that the user makes to objects in the model and storing new objects that are created. Listing 23-9 adds methods to the data source class to send HTTP requests to save or update objects using the Angular HttpClient class.

Listing 23-9. Sending Data in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {

    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }
```

675

```
    getData(): Observable<Product[]> {
        return this.http.get<Product[]>(this.url);
    }

    saveProduct(product: Product): Observable<Product> {
        return this.http.post<Product>(this.url, product);
    }

    updateProduct(product: Product): Observable<Product> {
        return this.http.put<Product>(`${this.url}/${product.id}`, product);
    }

    deleteProduct(id: number): Observable<Product> {
        return this.http.delete<Product>(`${this.url}/${id}`);
    }
}
```

The saveProduct, updateProduct, and deleteProduct methods follow the same pattern: they call one of the HttpClient class methods and return an Observable<Product> as the result.

When saving a new object, the ID of the object is generated by the server so that it is unique and clients don't inadvertently use the same ID for different objects. In this situation, the POST method is used, and the request is sent to the /products URL. When updating or deleting an existing object, the ID is already known, and a PUT request is sent to a URL that includes the ID. So, a request to update the object whose ID is 2, for example, is sent to the /products/2 URL. Similarly, to remove that object, a DELETE request would be sent to the same URL.

What these methods have in common is that the server is the authoritative data store, and the response from the server contains the official version of the object that has been saved by the server. It is this object that is returned as the result of these methods, provided through the Observable<Product>.

Listing 23-10 shows the corresponding changes in the repository class that take advantage of the new data source features.

Listing 23-10. Using the Data Source Features in the repository.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";
import { Observable } from "rxjs";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class Model {
    private products: Product[];
    private locator = (p: Product, id?: number) => p.id == id;

    constructor(private dataSource: RestDataSource) {
        this.products = new Array<Product>();
        // this.dataSource.getData().forEach(p => this.products.push(p));
        this.dataSource.getData().subscribe(data => this.products = data);
    }
```

```
    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }

    saveProduct(product: Product) {
        if (product.id == 0 || product.id == null) {
            this.dataSource.saveProduct(product)
                .subscribe(p => this.products.push(p));
        } else {
            this.dataSource.updateProduct(product).subscribe(p => {
                let index = this.products
                    .findIndex(item => this.locator(item, p.id));
                this.products.splice(index, 1, p);
            });
        }
    }

    deleteProduct(id: number) {
        this.dataSource.deleteProduct(id).subscribe(() => {
            let index = this.products.findIndex(p => this.locator(p, id));
            if (index > -1) {
                this.products.splice(index, 1);
            }
        });
    }

    // private generateID(): number {
    //     let candidate = 100;
    //     while (this.getProduct(candidate) != null) {
    //         candidate++;
    //     }
    //     return candidate;
    // }
}
```

The changes use the data source to send updates to the server and use the results to update the locally stored data so that it is displayed by the rest of the application. To test the changes, click the Edit button for the Kayak product and change its name to Green Kayak. Click the Save button, and the browser will send an HTTP PUT request to the server, which will return a modified object that is added to the repository's products array and is displayed in the table, as shown in Figure 23-3.
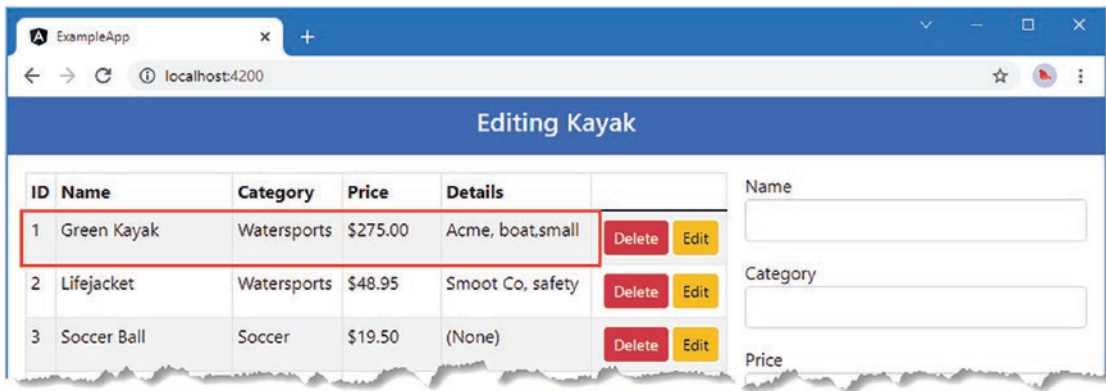

Figure 23-3. *Sending a PUT request to the server*

You can check that the server has stored the changes by using the browser to request `http://localhost:3500/products/1`, which will produce the following representation of the object:

```
{
  "id": 1,
  "name": "Green Kayak",
  "category": "Watersports",
  "price": 275,
  "details": {
    "supplier": "Acme",
    "keywords": [
      "boat",
      "small"
    ]
  }
}
```

Consolidating HTTP Requests

Each of the methods in the data source class duplicates the same basic pattern of sending an HTTP request using a verb-specific `HttpClient` method. This means that any change to the way that HTTP requests are made has to be repeated in four different places, ensuring that the requests that use the GET, POST, PUT, and DELETE verbs are all correctly updated and performed consistently.

The `HttpClient` class also defines the `request` method, which allows the HTTP verb to be specified as an argument. Listing 23-11 uses the `request` method to consolidate the HTTP requests in the data source class.

Listing 23-11. Consolidating HTTP Requests in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";
```

```
export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {
    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.sendRequest<Product[]>("GET", this.url);
    }

    saveProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("POST", this.url, product);
    }

    updateProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("PUT",
            `${this.url}/${product.id}`, product);
    }

    deleteProduct(id: number): Observable<Product> {
        return this.sendRequest<Product>("DELETE", `${this.url}/${id}`);
    }

    private sendRequest<T>(verb: string, url: string, body?: Product)
            : Observable<T> {
        return this.http.request<T>(verb, url, {
            body: body
        });
    }
}
```

The request method accepts the HTTP verb, the URL for the request, and an optional object that is used to configure the request. The configuration object is used to set the request body using the body property, and the HttpClient will automatically take care of encoding the body object and including a serialized representation of it in the request.

Table 23-5 describes the most useful properties that can be specified to configure an HTTP request made using the request method.

Table 23-5. *Useful Request Method Configuration Object Properties*

Name	Description
headers	This property returns an `HttpHeaders` object that allows the request headers to be specified, as described in the "Configuring Request Headers" section.
body	This property is used to set the request body. The object assigned to this property will be serialized as JSON when the request is sent.
withCredentials	When `true`, this property is used to include authentication cookies when making cross-site requests. This setting must be used only with servers that include the `Access-Control-Allow-Credentials` header in responses, as part of the Cross-Origin Resource Sharing (CORS) specification. See the "Making Cross-Origin Requests" section for details.
responseType	This property is used to specify the type of response expected from the server. The default value is `json`, indicating the JSON data format.

Making Cross-Origin Requests

By default, browsers enforce a security policy that allows JavaScript code to make asynchronous HTTP requests only within the same *origin* as the document that contains them. This policy is intended to reduce the risk of cross-site scripting (CSS) attacks, where the browser is tricked into executing malicious code. The details of this attack are beyond the scope of this book, but the article available at http://en.wikipedia. org/wiki/Cross-site_scripting provides a good introduction to the topic.

For Angular developers, the same-origin policy can be a problem when using web services because they are typically outside of the origin that contains the application's JavaScript code. Two URLs are considered to be in the same origin if they have the same protocol, host, and port and have different origins if this is not the case. The URL for the HTML file that contains the example application's JavaScript code is http:// localhost:3000/index.html. Table 23-6 summarizes how similar URLs have the same or different origins, compared with the application's URL.

Table 23-6. *URLs and Their Origins*

URL	Origin Comparison
http://localhost:3000/otherfile.html	Same origin
http://localhost:3000/app/main.js	Same origin
https://localhost:3000/index.html	Different origin; protocol differs
http://localhost:3500/products	Different origin; port differs
http://angular.io/index.html	Different origin; host differs

As the table shows, the URL for the RESTful web service, http://localhost:3500/products, has a different origin because it uses a different port from the main application.

HTTP requests made using the Angular `HttpClient` class will automatically use Cross-Origin Resource Sharing to send requests to different origins. With CORS, the browser includes headers in the asynchronous

HTTP request that provide the server with the origin of the JavaScript code. The response from the server includes headers that tell the browser whether it is willing to accept the request. The details of CORS are outside the scope of this book, but there is a good introduction to the topic at https://en.wikipedia.org/wiki/Cross-origin_resource_sharing.

For the Angular developer, CORS is something that is taken care of automatically, just as long as the server that receives asynchronous HTTP requests supports the specification. The json-server package that has been providing the RESTful web service for the examples supports CORS and will accept requests from any origin, which is why the examples have been working. If you want to see CORS in action, use the browser's F12 developer tools to watch the network requests that are made when you edit or create a product. You may see a request made using the OPTIONS verb, known as the *preflight request*, which the browser uses to check that it is allowed to make the POST or PUT request to the server. This request and the subsequent request that sends the data to the server will contain an Origin header, and the response will contain one or more Access-Control-Allow headers, through which the server sets out what it is willing to accept from the client.

All of this happens automatically, and the only configuration option is the withCredentials property that was described in Table 23-5. When this property is true, the browser will include authentication cookies, and headers from the origin will be included in the request to the server.

Using JSONP Requests

CORS is available only if the server to which the HTTP requests are sent supports it. For servers that don't implement CORS, Angular also provides support for JSONP, which allows a more limited form of cross-origin requests.

JSONP works by adding a script element to the Document Object Model that specifies the cross-origin server in its src attribute. The browser sends a GET request to the server, which returns JavaScript code that, when executed, provides the application with the data it requires. JSONP is, essentially, a hack that works around the browser's same-origin security policy. JSONP can be used only to make GET requests, and it presents greater security risks than CORS. As a consequence, JSONP should be used only when CORS isn't available.

The Angular support for JSONP is defined in a feature module called HttpClientJsonpModule, which is defined in the @angular/common/http JavaScript module. To enable JSONP, Listing 23-12 adds HttpClientJsonpModule to the set of imports for the model module.

Listing 23-12. Enabling JSONP in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { StaticDataSource } from "./static.datasource";
import { Model } from "./repository.model";
import { HttpClientJsonpModule, HttpClientModule } from "@angular/common/http";
import { RestDataSource, REST_URL } from "./rest.datasource";

@NgModule({
    imports: [HttpClientModule, HttpClientJsonpModule],
    providers: [Model, RestDataSource,
        { provide: REST_URL, useValue: `http://${location.hostname}:3500/products` }]
})
export class ModelModule { }
```

Angular provides support for JSONP through the HttpClient service, which takes care of managing the JSONP HTTP request and processing the response, which can otherwise be a tedious and error-prone process. Listing 23-13 shows the data source using JSONP to request the initial data for the application.

Listing 23-13. Making a JSONP Request in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {
    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.http.jsonp<Product[]>(this.url, "callback");
    }

    saveProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("POST", this.url, product);
    }

    updateProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("PUT",
            `${this.url}/${product.id}`, product);
    }

    deleteProduct(id: number): Observable<Product> {
        return this.sendRequest<Product>("DELETE", `${this.url}/${id}`);
    }

    private sendRequest<T>(verb: string, url: string, body?: Product)
            : Observable<T> {
        return this.http.request<T>(verb, url, {
            body: body
        });
    }
}
```

JSONP can be used only for GET requests, which are sent using the `HttpClient.jsonp` method. When you call this method, you must provide the URL for the request and the name for the callback parameter, which must be set to `callback`, like this:

```
...
return this.http.jsonp<Product[]>(this.url, "callback");
...
```

When Angular makes the HTTP request, it creates a URL with the name of a dynamically generated function. If you look at the network requests that the browser makes, you will see that the initial request is sent to a URL like this one:

```
http://localhost:3500/products?callback=ng_jsonp_callback_0
```

The server JavaScript function matches the name used in the URL and passes it the data received from the request. JSONP is a more limited way to make cross-origin requests, and, unlike CORS, it skirts around the browser's security policy, but it can be a useful fallback in a pinch.

Configuring Request Headers

If you are using a commercial RESTful web service, you will often have to set a request header to provide an API key so that the server can associate the request with your application for access control and billing. You can set this kind of header—or any other header—by configuring the configuration object that is passed to the request method, as shown in Listing 23-14. (This listing also returns to using the request method for all requests, rather than JSONP.)

Listing 23-14. Setting a Request Header in the rest.datasource.ts File in the src/app/model Folder

```typescript
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient, HttpHeaders } from "@angular/common/http";
import { Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {
    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.sendRequest<Product[]>("GET", this.url);
    }

    saveProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("POST", this.url, product);
    }

    updateProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("PUT",
            `${this.url}/${product.id}`, product);
    }

    deleteProduct(id: number): Observable<Product> {
        return this.sendRequest<Product>("DELETE", `${this.url}/${id}`);
    }

    private sendRequest<T>(verb: string, url: string, body?: Product)
            : Observable<T> {
        return this.http.request<T>(verb, url, {
            body: body,
```

```
        headers: new HttpHeaders({
            "Access-Key": "<secret>",
            "Application-Name": "exampleApp"
        })
    });
  }
}
```

The headers property is set to an HttpHeaders object, which can be created using a map object of properties that correspond to header names and the values that should be used for them. If you use the browser's F12 developer tools to inspect the asynchronous HTTP requests, you will see that the two headers specified in the listing are sent to the server along with the standard headers that the browser creates, like this:

```
...
Accept:*/*
Accept-Encoding:gzip, deflate, sdch, br
Accept-Language:en-US,en;q=0.8
access-key:<secret>
application-name:exampleApp
Connection:keep-alive
...
```

If you have more complex demands for request headers, then you can use the methods defined by the HttpHeaders class, as described in Table 23-7.

Table 23-7. *The HttpHeaders Methods*

Name	Description
keys()	Returns all the header names in the collection
get(name)	Returns the first value for the specified header
getAll(name)	Returns all the values for the specified header
has(name)	Returns true if the collection contains the specified header
set(header, value)	Returns a new HttpHeaders object that replaces all existing values for the specified header with a single value
set(header, values)	Returns a new HttpHeaders object that replaces all existing values for the specified header with an array of values
append(name, value)	Appends a value to the list of values for the specified header
delete(name)	Removes the specified header from the collection

HTTP headers can have multiple values, which is why there are methods that append values for headers or replace all the values in the collection. Listing 23-15 creates an empty HttpHeaders object and populates it with headers that have multiple values.

Listing 23-15. Setting Multiple Header Values in the rest.datasource.ts File in the src/app/model Folder

```
...
private sendRequest<T>(verb: string, url: string, body?: Product)
        : Observable<T> {

    let myHeaders = new HttpHeaders();
    myHeaders = myHeaders.set("Access-Key", "<secret>");
    myHeaders = myHeaders.set("Application-Names", ["exampleApp", "proAngular"]);

    return this.http.request<T>(verb, url, {
        body: body,
        headers: myHeaders
    });
}
...
```

When the browser sends requests to the server, they will include the following headers:

```
...
Accept:*/*
Accept-Encoding:gzip, deflate, sdch, br
Accept-Language:en-US,en;q=0.8
access-key:<secret>
application-names:exampleApp,proAngular
Connection:keep-alive
...
```

Handling Errors

At the moment, there is no error handling in the application, which means that Angular doesn't know what to do if there is a problem with an HTTP request. To make it easy to generate an error, I have added a button to the product table that will lead to an HTTP request to delete an object that doesn't exist at the server, as shown in Listing 23-16.

Listing 23-16. Adding an Error Button in the table.component.html File in the src/app/core Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
      <tr>
          <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
          <th>Details</th><th></th>
      </tr>
    </thead>
    <tbody>
      <tr *ngFor="let item of getProducts()">
          <td>{{item.id}}</td>
          <td>{{item.name}}</td>
          <td>{{item.category}}</td>
          <td>{{item.price | currency:"USD" }}</td>
```

```
        <td>
            <ng-container *ngIf="item.details else empty">
              {{ item.details?.supplier }}, {{ item.details?.keywords}}
            </ng-container>
            <ng-template #empty>(None)</ng-template>
        </td>
        <td class="text-center">
            <button class="btn btn-danger btn-sm m-1"
                    (click)="deleteProduct(item.id)">
                Delete
            </button>
            <button class="btn btn-warning btn-sm" (click)="editProduct(item.id)">
                Edit
            </button>
        </td>
      </tr>
    </tbody>
</table>
<button class="btn btn-primary m-1" (click)="createProduct()">
    Create New Product
</button>
<button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
    Generate HTTP Error
</button>
```

The button element invokes the component's deleteProduct method with an argument of -1. The component will ask the repository to delete this object, which will lead to an HTTP DELETE request being sent to /products/-1, which does not exist. If you open the browser's JavaScript console and click the Generate HTTP Error button, you will see the response from the server displayed, like this:

```
DELETE http://localhost:3500/products/-1 404 (Not Found)
```

Improving this situation means detecting this kind of error when one occurs and notifying the user, who won't typically be looking at the JavaScript console. A real application might also respond to errors by logging them so they can be analyzed later, but I am going to keep things simple and just display an error message.

Generating User-Ready Messages

The first step in handling errors is to convert the HTTP exception into something that can be displayed to the user. The default error message, which is the one written to the JavaScript console, contains too much information to display to the user. Users don't need to know the URL that the request was sent to; just having a sense of the kind of problem that has occurred will be enough.

The best way to transform error messages is to use the catchError method. The catchError method is used with the pipe method to receive any errors that occur within an Observable sequence, as shown in Listing 23-17.

Listing 23-17. Transforming Errors in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient, HttpHeaders } from "@angular/common/http";
import { catchError, Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {
    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.sendRequest<Product[]>("GET", this.url);
    }

    saveProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("POST", this.url, product);
    }

    updateProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("PUT",
            `${this.url}/${product.id}`, product);
    }

    deleteProduct(id: number): Observable<Product> {
        return this.sendRequest<Product>("DELETE", `${this.url}/${id}`);
    }

    private sendRequest<T>(verb: string, url: string, body?: Product)
        : Observable<T> {

        let myHeaders = new HttpHeaders();
        myHeaders = myHeaders.set("Access-Key", "<secret>");
        myHeaders = myHeaders.set("Application-Names", ["exampleApp", "proAngular"]);

        return this.http.request<T>(verb, url, {
            body: body,
            headers: myHeaders
        }).pipe(catchError((error: Response) => {
            throw(`Network Error: ${error.statusText} (${error.status})`)
        }));
    }
}
```

The function passed to the catchError method is invoked when there is an error and receives the Response object that describes the outcome, which in this case is used to generate an error message that contains the HTTP status code and status text from the response.

If you save the changes and then click the Generate HTTP Error button again, the error message will still be written to the browser's JavaScript console but will have changed to the format produced by the `catchError` method.

```
EXCEPTION: Network Error: Not Found (404)
```

Handling the Errors

The errors have been transformed but not handled, which is why they are still being reported as exceptions in the browser's JavaScript console. There are two ways in which the errors can be handled. The first is to provide an error-handling function to the `subscribe` method for the `Observable` objects created by the `HttpClient` object. This is a useful way to localize the error and provide the repository with the opportunity to retry the operation or try to recover in some other way.

The second approach is to replace the built-in Angular error-handling feature, which responds to any unhandled errors in the application and, by default, writes them to the console. It is this feature that writes out the messages shown in the previous sections.

For the example application, I want to override the default error handler with one that uses the message service. I created a file called `errorHandler.ts` in the `src/app/messages` folder and used it to define the class shown in Listing 23-18.

Listing 23-18. The Contents of the errorHandler.ts File in the src/app/messages Folder

```
import { ErrorHandler, Injectable, NgZone } from "@angular/core";
import { MessageService } from "./message.service";
import { Message } from "./message.model";

@Injectable()
export class MessageErrorHandler implements ErrorHandler {

    constructor(private messageService: MessageService, private ngZone: NgZone) {
    }

    handleError(error: any) {
        let msg = error instanceof Error ? error.message : error.toString();
        this.ngZone.run(() => this.messageService
            .reportMessage(new Message(msg, true)), 0);
    }
}
```

The `ErrorHandler` class is defined in the `@angular/core` module and responds to errors through a `handleError` method. The class shown in the listing replaces the default implementation of this method with one that uses the `MessageService` to report an error.

Redefining the error handler presents a problem. I want to display a message to the user, which requires the Angular change detection process to be triggered. But the message is produced by a service, and Angular doesn't keep track of the state of services as it does for components and directives. To resolve this issue, I defined an `NgZone` constructor parameter and used its `run` method to create the error message:

```
...
this.ngZone.run(() => this.messageService.reportMessage(new Message(msg, true)), 0);
...
```

The `run` method executes the function it receives and then triggers the Angular change detection process. For this example, the result is that the new message will be displayed to the user. Without the use of the `NgZone` object, the error message would be created but would not be displayed to the user until the next time the Angular detection process runs, which is usually in response to user interaction.

To replace the default `ErrorHandler`, I used a class provider in the message module, as shown in Listing 23-19.

Listing 23-19. Configuring an Error Handler in the message.module.ts File in the src/app/messages Folder

```
import { NgModule, ErrorHandler } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { MessageComponent } from "./message.component";
import { MessageService } from "./message.service";
import { MessageErrorHandler } from "./errorHandler";

@NgModule({
    imports: [BrowserModule],
    declarations: [MessageComponent],
    exports: [MessageComponent],
    providers: [MessageService,
        { provide: ErrorHandler, useClass: MessageErrorHandler }]
})
export class MessageModule { }
```

The error handling function uses the `MessageService` to report an error message to the user. Once these changes have been saved, clicking the Generate HTTP Error button produces an error that the user can see, as shown in Figure 23-4.

Figure 23-4. *Handling an HTTP error*

Summary

In this chapter, I explained how to make asynchronous HTTP requests in Angular applications. I introduced RESTful web services and the methods provided by the Angular `HttpClient` class that can be used to interact with them. I explained how the browser restricts requests to different origins and how Angular supports CORS and JSONP to make requests outside of the application's origin. In the next chapter, I introduce the URL routing feature, which allows for navigating complex applications.

CHAPTER 24

■ ■ ■

Routing and Navigation: Part 1

The Angular routing feature allows applications to change the components and templates that are displayed to the user by responding to changes to the browser's URL. This allows complex applications to be created that adapt the content they present openly and flexibly, with minimal coding. To support this feature, data bindings and services can be used to change the browser's URL, allowing the user to navigate around the application.

Routing is useful as the complexity of a project increases because it allows the structure of an application to be defined separately from the components and directives, meaning that changes to the structure can be made in the routing configuration and do not have to be applied to the individual components.

In this chapter, I demonstrate how the basic routing system works and apply it to the example application. In Chapters 25 and 26, I explain the more advanced routing features. Table 24-1 puts routing in context.

Table 24-1. *Putting Routing and Navigation in Context*

Question	Answer
What is it?	Routing uses the browser's URL to manage the content displayed to the user.
Why is it useful?	Routing allows the structure of an application to be kept apart from the components and templates in the application. Changes to the structure of the application are made in the routing configuration rather than in individual components and directives.
How is it used?	The routing configuration is defined as a set of fragments that are used to match the browser's URL and to select a component whose template is displayed as the content of an HTML element called `router-outlet`.
Are there any pitfalls or limitations?	The routing configuration can become unmanageable, especially if the URL schema is being defined gradually on an ad hoc basis.
Are there any alternatives?	You don't have to use the routing feature. You could achieve similar results by creating a component whose view selects the content to display to the user with the `ngIf` or `ngSwitch` directive, although this approach becomes more difficult than using routing as the size and complexity of an application increases.

Table 24-2 summarizes the chapter.

Table 24-2. *Chapter Summary*

Problem	Solution	Listing
Using URL navigation to select the content shown to users	Use URL routing	1–4
Navigating using an HTML element	Apply the `routerLink` attribute	5–7
Responding to route changes	Use the routing services to receive notifications	8
Including information in URLs	Use route parameters	9–17
Navigating using code	Use the `Router` service	18
Receiving notifications of routing activity	Handle the routing events	19–22

Preparing the Example Project

This chapter uses the exampleApp project created in Chapter 23. No changes are required for this chapter.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the server that provides the RESTful web server:

```
npm run json
```

Open a separate command prompt, navigate to the exampleApp folder, and run the following command to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to `http://localhost:4200` to see the content shown in Figure 24-1.

Figure 24-1. *Running the example application*

Getting Started with Routing

At the moment, all the content in the application is visible to the user all of the time. For the example application, this means that both the table and the form are always visible, and it is up to the user to keep track of which part of the application they are using for the task at hand.

That's fine for a simple application, but it becomes unmanageable in a complex project, which can have many areas of functionality that would be overwhelming if they were all displayed at once.

URL routing adds structure to an application using a natural and well-understood aspect of web applications: the URL. In this section, I am going to introduce URL routing by applying it to the example application so that either the table or the form is visible, with the active component being chosen based on the user's actions. This will provide a good basis for explaining how routing works and set the foundation for more advanced features.

Creating a Routing Configuration

The first step when applying routing is to define the *routes*, which are mappings between URLs and the components that will be displayed to the user. Routing configurations are conventionally defined in a file called app.routing.ts, defined in the src/app folder. I created this file and added the statements shown in Listing 24-1.

Listing 24-1. The Contents of the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";

const routes: Routes = [
    { path: "form/edit", component: FormComponent },
    { path: "form/create", component: FormComponent },
    { path: "", component: TableComponent }]

export const routing = RouterModule.forRoot(routes);
```

The Routes class defines a collection of routes, each of which tells Angular how to handle a specific URL. This example uses the most basic properties, where the path specifies the URL and the component property specifies the component that will be displayed to the user.

The path property is specified relative to the rest of the application, which means that the configuration in Listing 24-1 sets up the routes shown in Table 24-3.

Table 24-3. *The Routes Created in the Example*

URL	Displayed Component
http://localhost:4200/form/edit	FormComponent
http://localhost:4200/form/create	FormComponent
http://localhost:4200/	TableComponent

The routes are packaged into a module using the RouterModule.forRoot method. The forRoot method produces a module that includes the routing service. There is also a forChild method that doesn't include the service and that is demonstrated in Chapter 25, where I explain how to create routes for feature modules.

Although the path and component properties are the most commonly used when defining routes, there is a range of additional properties that can be used to define routes with advanced features. These properties are described in Table 24-4, along with details of where they are described.

Table 24-4. *The Routes Properties Used to Define Routes*

Name	Description
path	This property specifies the path for the route.
component	This property specifies the component that will be selected when the active URL matches the path.
pathMatch	This property tells Angular how to match the current URL to the path property. There are two allowed values: full, which requires the path value to completely match the URL, and prefix, which allows the path value to match the URL, even if the URL contains additional segments that are not part of the path value. This property is required when using the redirectTo property, as demonstrated in Chapter 25.
redirectTo	This property is used to create a route that redirects the browser to a different URL when activated. See Chapter 25 for details.
children	This property is used to specify child routes, which display additional components in nested router-outlet elements contained in the template of the active component, as demonstrated in Chapter 25.
outlet	This property is used to support multiple outlet elements, as described in Chapter 26.
resolve	This property is used to define work that must be completed before a route can be activated, as described in Chapter 26.
canActivate	This property is used to control when a route can be activated, as described in Chapter 26.
canActivateChild	This property is used to control when a child route can be activated, as described in Chapter 26.
canDeactivate	This property is used to control when a route can be deactivated so that a new route can be activated, as described in Chapter 26.
loadChildren	This property is used to configure a module that is loaded only when it is needed, as described in Chapter 26.
canLoad	This property is used to control when an on-demand module can be loaded.

UNDERSTANDING ROUTE ORDERING

The order in which routes are defined is significant. Angular compares the URL to which the browser has navigated with the path property of each route in turn until it finds a match. This means that the most specific routes should be defined first, with the routes that follow decreasing in specificity. This isn't a big deal for the routes in Listing 24-1, but it becomes significant when using route parameters (described in the "Using Route Parameters" section of this chapter) or adding child routes (described in Chapter 25).

If you find that your routing configuration doesn't result in the behavior you expect, then the order in which the routes have been defined is the first thing to check.

Creating the Routing Component

When using routing, the root component is dedicated to managing the navigation between different parts of the application. This is the typical purpose of the `app.component.ts` file that was added to the project by the `ng new` command when it was created. This component is a vehicle for its template, which is the `app.component.html` file in the `src/app` folder. In Listing 24-2, I have replaced the default contents.

Listing 24-2. Replacing the Contents of the app.component.html File in the src/app File

```
<paMessages></paMessages>
<router-outlet></router-outlet>
```

The `paMessages` element displays any messages and errors in the application. For the purposes of routing, it is the `router-outlet` element—known as the *outlet*—that is important because it tells Angular that this is where the component matched by the routing configuration should be displayed.

Updating the Root Module

The next step is to update the root module so that the new root component is used to bootstrap the application, as shown in Listing 24-3, which also imports the module that contains the routing configuration.

Listing 24-3. Enabling Routing in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';
import { ModelModule } from "./model/model.module";
import { CoreModule } from "./core/core.module";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { MessageModule } from "./messages/message.module";
import { MessageComponent } from "./messages/message.component";
import { AppComponent } from './app.component';
import { routing } from "./app.routing";

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, ModelModule, CoreModule, MessageModule, routing],
  providers: [],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

Completing the Configuration

The final step is to update the `index.html` file, as shown in Listing 24-4.

Listing 24-4. Configuring Routing in the index.html File in the src Folder

```
<!doctype html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <title>ExampleApp</title>
    <base href="/">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <link rel="icon" type="image/x-icon" href="favicon.ico">
</head>
<body class="m-1">
    <app-root></app-root>
</body>
</html>
```

The app element applies the new root component, whose template contains the router-outlet element. When you save the changes and the browser reloads the application, you will see just the product table, as illustrated by Figure 24-2. The default URL for the application corresponds to the route that shows the product table.

■ **Tip**   You may need to stop the Angular development tools, start them again using the ng serve command, and then reload the browser for this example.

Figure 24-2. Using routing to display components to the user

Adding Navigation Links

The basic routing configuration is in place, but there is no way to navigate around the application: nothing happens when you click the Create New Product or Edit button.

The next step is to add links to the application that will change the browser's URL and, in doing so, trigger a routing change that will display a different component to the user. Listing 24-5 adds these links to the table component's template.

Listing 24-5. Adding Navigation Links in the table.component.html File in the src/app/core Folder

```html
<table class="table table-sm table-bordered table-striped">
    <thead>
      <tr>
          <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
          <th>Details</th><th></th>
      </tr>
    </thead>
    <tbody>
      <tr *ngFor="let item of getProducts()">
          <td>{{item.id}}</td>
          <td>{{item.name}}</td>
          <td>{{item.category}}</td>
          <td>{{item.price | currency:"USD" }}</td>
          <td>
              <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
              </ng-container>
              <ng-template #empty>(None)</ng-template>
          </td>
          <td class="text-center">
              <button class="btn btn-danger btn-sm m-1"
                      (click)="deleteProduct(item.id)">
                  Delete
              </button>
              <button class="btn btn-warning btn-sm" (click)="editProduct(item.id)"
                      routerLink="/form/edit">
                  Edit
              </button>
          </td>
      </tr>
    </tbody>
</table>
<button class="btn btn-primary m-1" (click)="createProduct()"
        routerLink="/form/create">
    Create New Product
</button>
<button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
    Generate HTTP Error
</button>
```

The `routerLink` attribute applies a directive from the routing package that performs the navigation change. This directive can be applied to any element, although it is typically applied to `button` and anchor (`a`) elements. The expression for the `routerLink` directive applied to the Edit buttons tells Angular to target the `/form/edit` route.

```
...
<button class="btn btn-warning btn-sm" (click)="editProduct(item.id)"
        routerLink="/form/edit">
    Edit
</button>
...
```

The same directive applied to the Create New Product button tells Angular to target the `/create` route.

```
...
<button class="btn btn-primary m-1" (click)="createProduct()"
        routerLink="/form/create">
    Create New Product
</button>
...
```

The routing links added to the table component's template will allow the user to navigate to the form. The addition to the form component's template shown in Listing 24-6 will allow the user to navigate back again using the Cancel button.

Listing 24-6. Adding a Navigation Link in the form.component.html File in the src/app/core Folder

```
...
<div class="mt-2">
    <button type="submit" class="btn btn-primary"
            [class.btn-warning]="editing"
            [disabled]="form.invalid">
        {{editing ? "Save" : "Create"}}
    </button>
    <button type="reset" class="btn btn-secondary m-1" routerLink="/">
        Cancel
    </button>
</div>
...
```

The value assigned to the `routerLink` attribute targets the route that displays the product table. Listing 24-7 updates the feature module that contains the template so that it imports the `RouterModule`, which is the Angular module that contains the directive that selects the `routerLink` attribute.

Listing 24-7. Enabling the Routing Directive in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
```

```
import { FormComponent } from "./form.component";
import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";
import { RouterModule } from "@angular/router";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule,
        RouterModule],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [SharedState]
})
export class CoreModule { }
```

Understanding the Effect of Routing

Restart the Angular development tools, and you will be able to navigate around the application using the Edit, Create New Product, and Cancel buttons, as shown in Figure 24-3.

Figure 24-3. *Using routes to navigate around the application*

Not all the features in the application work yet, but this is a good time to explore the effect of adding routing to the application. Enter the root URL for the application (`http://localhost:4200`) and then click the Create New Product button. When you clicked the button, the Angular routing system changed the URL that the browser displays to this:

```
http://localhost:4200/form/create
```

If you watch the requests made by the application in the F12 development tools during the transition, you will notice that no requests are sent to the server for new content. This change is done entirely within the Angular application and does not produce any new HTTP requests.

The new URL is processed by the Angular routing system, which can match the new URL to this route from the `app.routing.ts` file.

```
{ path: "form/create", component: FormComponent },
```

The routing system takes into account the `base` element in the `index.html` file when it matches the URL to a route. The `base` element is configured with an `href` value of `/` that is combined with the `path` in the route to make a match when the URL is `/form/create`.

The `component` property tells the Angular routing system that it should display the `FormComponent` to the user. A new instance of the `FormComponent` class is created, and its template content is used as the content for the `router-outlet` element in the root component's template.

If you click the Cancel button below the form, then the process is repeated, but this time, the browser returns to the root URL for the application, which is matched by the route whose path component is the empty string.

```
{ path: "", component: TableComponent }
```

This route tells Angular to display the `TableComponent` to the user. A new instance of the `TableComponent` class is created, and its template is used as the content of the `router-outlet` element, displaying the model data to the user.

This is the essence of routing: the browser's URL changes, which causes the routing system to consult its configuration to determine which component should be displayed to the user. Lots of options and features are available, but this is the core purpose of routing, and you won't go too far wrong if you keep this in mind.

THE PERILS OF CHANGING THE URL MANUALLY

The `routerLink` directive sets the URL using a JavaScript API that tells the browser that this is a change relative to the current document and not a change that requires an HTTP request to the server.

If you enter a URL that matches the routing system into the browser window, you will see an effect that looks like the expected change but is actually something else entirely. Keep an eye on the network requests in the F12 development tools while manually entering the following URL into the browser:

```
http://localhost:4200/form/create
```

Rather than handling the change within the Angular application, the browser sends an HTTP request to the server, which reloads the application. Once the application is loaded, the routing system inspects the browser's URL, matches one of the routes in the configuration, and then displays the `FormComponent`.

The reason this works is that the development HTTP server will return the contents of the `index.html` file for URLs that don't correspond to files on the disk. As an example, request this URL:

`http://localhost:4200/this/does/not/exist`

The browser will display an error because the request has provided the browser with the contents of the `index.html` file, which it has used to load and start the example Angular application. When the routing system inspects the URL, it finds no matching route and creates an error.

There are two important points to note. The first is that when you test your application's routing configuration, you should check the HTTP requests that the browser is making because you will sometimes see the right result for the wrong reasons. On a fast machine, you may not even realize that the application has been reloaded and restarted by the browser.

Second, you must remember that the URL must be changed using the `routerLink` directive (or one of the similar features provided by the router module) and not manually, using the browser's URL bar.

Finally, since users won't know about the difference between programmatic and manual URL changes, your routing configuration should be able to deal with URLs that don't correspond to routes, as described in Chapter 25.

Completing the Routing Implementation

Adding routing to the application is a good start, but a lot of the application features just don't work. For example, clicking an Edit button displays the form, but it isn't populated, and it doesn't show the color cue that indicates editing. In the sections that follow, I use features provided by the routing system to finish wiring up the application so that everything works as expected.

Handling Route Changes in Components

The form component isn't working properly because it isn't being notified that the user has clicked a button to edit a product. This problem occurs because the routing system creates new instances of component classes only when it needs them, which means the `FormComponent` object is created only after the Edit button is clicked. If you click the Cancel button under the form and then click an Edit button in this table again, a second instance of the `FormComponent` will be created.

This leads to a timing issue in the way that the product component and the table component communicate, via a Reactive Extensions `Subject`. A `Subject` only passes events to subscribers that arrive after the `subscribe` method has been called. The introduction of routing means that the `FormComponent` object is created after the event describing the edit operation has already been sent.

This problem could be solved by replacing the `Subject` with a `BehaviorSubject`, which sends the most recent event to subscribers when they call the subscribe method. But a more elegant approach—especially since this is a chapter on the routing system—is to use the URL to collaborate between components.

Angular provides a service that components can receive to get details of the current route. The relationship between the service and the types that it provides access to may seem complicated at first, but it will make sense as you see how the examples unfold and some of the different ways that routing can be used.

The class on which components declare a dependency is called `ActivatedRoute`. For this section, it defines one important property, which is described in Table 24-5. There are other properties, too, which are described later in the chapter but which you can ignore for the moment.

Table 24-5. *The ActivatedRoute Property*

Name	Description
snapshot	This property returns an `ActivatedRouteSnapshot` object that describes the current route.

The `snapshot` property returns an instance of the `ActivatedRouteSnapshot` class, which provides information about the route that led to the current component being displayed to the user using the properties described in Table 24-6.

Table 24-6. *The Basic ActivatedRouteSnapshot Properties*

Name	Description
url	This property returns an array of `UrlSegment` objects, each of which describes a single segment in the URL that matched the current route.
params	This property returns a `Params` object, which describes the URL parameters, indexed by name.
queryParams	This property returns a `Params` object, which describes the URL query parameters, indexed by name.
fragment	This property returns a `string` containing the URL fragment.

The `url` property is the one that is most important for this example because it allows the component to inspect the segments of the current URL and extract the information from them that is required to perform an operation. The `url` property returns an array of `UrlSegment` objects, which provide the properties described in Table 24-7.

Table 24-7. *The URLSegment Properties*

Name	Description
path	This property returns a string that contains the segment value.
parameters	This property returns an indexed collection of parameters, as described in the "Using Route Parameters" section.

To determine what route has been activated by the user, the form component can declare a dependency on `ActivatedRoute` and then use the object it receives to inspect the segments of the URL, as shown in Listing 24-8.

Listing 24-8. Inspecting the Active Route in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
```

```
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";
import { UniqueValidator } from "../validation/unique";
import { ProhibitedValidator } from "../validation/prohibited";
import { ActivatedRoute } from "@angular/router";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    // ...form structure omitted for brevity...

    constructor(private model: Model, activeRoute: ActivatedRoute) {
        this.editing = activeRoute.snapshot.url[1].path == "edit";
    }

    // handleStateChange(newState: StateUpdate) {
    //     this.editing = newState.mode == MODES.EDIT;
    //     this.keywordGroup.clear();
    //     if (this.editing && newState.id) {
    //         Object.assign(this.product, this.model.getProduct(newState.id)
    //             ?? new Product());
    //         this.messageService.reportMessage(
    //             new Message(`Editing ${this.product.name}`));
    //         this.product.details?.keywords?.forEach(val => {
    //             this.keywordGroup.push(this.createKeywordFormControl());
    //         })
    //     } else {
    //         this.product = new Product();
    //         this.messageService.reportMessage(new Message("Creating New Product"));
    //     }
    //     if (this.keywordGroup.length == 0) {
    //         this.keywordGroup.push(this.createKeywordFormControl());
    //     }
    //     this.productForm.reset(this.product);
    // }

    // ...other methods omitted for brevity...
}
```

The component no longer uses the shared state service to receive events. Instead, it inspects the second segment of the active route's URL to set the value of the editing property, which determines whether it should display its create or edit mode. If you click an Edit button in the table, you will now see the correct coloring displayed, as shown in Figure 24-4, although the fields are not yet populated with data.

Figure 24-4. *Using the active route in a component*

Using Route Parameters

When I set up the routing configuration for the application, I defined two routes that targeted the form component, like this:

```
...
{ path: "form/edit", component: FormComponent },
{ path: "form/create", component: FormComponent },
...
```

When Angular is trying to match a route to a URL, it looks at each segment in turn and checks to see that it matches the URL that is being navigated to. Both of these URLs are made up of *static segments*, which means they have to match the navigated URL exactly before Angular will activate the route.

705

Angular routes can be more flexible and include *route parameters*, which allow any value for a segment to match the corresponding segment in the navigated URL. This means routes that target the same component with similar URLs can be consolidated into a single route, as shown in Listing 24-9.

Listing 24-9. Consolidating Routes in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";

const routes: Routes = [
    // { path: "form/edit", component: FormComponent },
    // { path: "form/create", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "", component: TableComponent }]

export const routing = RouterModule.forRoot(routes);
```

The second segment of the modified URL defines a route parameter, denoted by the colon (the : character) followed by a name. In this case, the route parameter is called mode. This route will match any URL that has two segments where the first segment is form, as summarized in Table 24-8. The content of the second segment will be assigned to a parameter called mode.

Table 24-8. *URL Matching with the Route Parameter*

URL	Result
http://localhost:4200/form	No match—too few segments
http://localhost:4200/form/create	Matches, with create assigned to the mode parameter
http://localhost:4200/form/london	Matches, with london assigned to the mode parameter
http://localhost:4200/product/edit	No match—the first segment is not form
http://localhost:4200/form/edit/1	No match—too many segments

Using route parameters makes it simpler to handle routes programmatically because the value of the parameter can be obtained using its name, as shown in Listing 24-10.

Listing 24-10. Reading a Route Parameter in the form.component.ts File in the src/app/core Folder

```
...
constructor(private model: Model, activeRoute: ActivatedRoute) {
    this.editing = activeRoute.snapshot.params["mode"] == "edit";
}
...
```

The component doesn't need to know the structure of the URL to get the information it needs. Instead, it can use the params property provided by the ActivatedRouteSnapshot class to get a collection of the parameter values, indexed by name. The component gets the value of the mode parameter and uses it to set the editing property.

Using Multiple Route Parameters

To tell the form component which product has been selected when the user clicks an Edit button, I need to use a second route parameter. Since Angular matches URLs based on the number of segments they contain, this means I need to split up the routes that target the form component again, as shown in Listing 24-11. This cycle of consolidating and then expanding routes is typical of most development projects as you increase the amount of information that is included in routed URLs to add functionality to the application.

Listing 24-11. Adding a Route in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "", component: TableComponent }]

export const routing = RouterModule.forRoot(routes);
```

The new route will match any URL that has three segments where the first segment is form. To create URLs that target this route, I need to use a different approach for the routerLink expressions in the template because I need to generate the third segment dynamically for each Edit button in the product table, as shown in Listing 24-12.

Listing 24-12. Generating Dynamic URLs in the table.component.html File in the src/app/core Folder

```
...
<td class="text-center">
    <button class="btn btn-danger btn-sm m-1"
            (click)="deleteProduct(item.id)">
        Delete
    </button>
    <button class="btn btn-warning btn-sm" (click)="editProduct(item.id)"
            [routerLink]="['/form', 'edit', item.id]">
        Edit
    </button>
</td>
...
```

The routerLink attribute is now enclosed in square brackets, telling Angular that it should treat the attribute value as a data binding expression. The expression is set out as an array, with each element containing the value for one segment. The first two segments are literal strings and will be included in the target URL without modification. The third segment will be evaluated to include the id property value for the current Product object being processed by the ngIf directive, just like the other expressions in the template. The routerLink directive will combine the individual segments to create a URL such as /form/edit/2.

Listing 24-13 shows how the form component gets the value of the new route parameter and uses it to select the product that is to be edited.

707

Listing 24-13. Using the New Route Parameter in the form.component.ts File in the src/app/core Folder

```
...
constructor(private model: Model, activeRoute: ActivatedRoute) {
    this.editing = activeRoute.snapshot.params["mode"] == "edit";
    let id = activeRoute.snapshot.params["id"];
    if (id != null) {
        Object.assign(this.product, model.getProduct(id) || new Product());
        this.productForm.patchValue(this.product);
    }
}
...
```

When the user clicks an Edit button, the routing URL that is activated tells the form component that an edit operation is required and specifies the product is to be modified, allowing the form to be populated correctly, as shown in Figure 24-5.

Figure 24-5. *Using URLs segments to provide information*

Dealing with Direct Data Access

The introduction of routing has revealed a problem with the way that data is obtained from the web service. If the user starts by requesting `http://localhost:4200` and clicks one of the Edit buttons, then the application works as expected and the form is correctly populated with data.

But if the user navigates directly to the URL for editing a product, such as `http://localhost:4200/form/edit/2`, then the form is never populated with data. This is because the `RestDataSource` class has been written to assume that individual `Product` objects will be accessed only by clicking an Edit button, which can be done only once the data has been received from the web service.

In Chapter 26, I explain how you can stop routes from being activated until a specific condition is true, such as the arrival of the data, but another approach is to use observables to ensure that data values can be requested directly. The first step is to enhance the repository, as shown in Listing 24-14.

Listing 24-14. Using Observables in the repository.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";
import { Observable, ReplaySubject } from "rxjs";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class Model {
    private products: Product[];
    private locator = (p: Product, id?: number) => p.id == id;
    private replaySubject: ReplaySubject<Product[]>;

    constructor(private dataSource: RestDataSource) {
        this.products = new Array<Product>();
        this.replaySubject = new ReplaySubject<Product[]>(1);
        this.dataSource.getData().subscribe(data => {
            this.products = data
            this.replaySubject.next(data);
            this.replaySubject.complete();
        });
    }

    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }
```

```
    getProductObservable(id: number): Observable<Product | undefined> {
        let subject = new ReplaySubject<Product | undefined>(1);
        this.replaySubject.subscribe(products => {
            subject.next(products.find(p => this.locator(p, id)));
            subject.complete();
        });
        return subject;
    }

    // ...other methods omitted for brevity...
}
```

The changes rely on the ReplaySubject class to ensure that individual Product objects can be received even if the call to the new getProductObservable method is made before the data requested by the constructor has arrived. The ReplaySubject is useful for this problem because it allows subsequent calls to the getProductObservable method to benefit from the data already produced. Listing 24-15 updates the form component to use the new repository method.

Listing 24-15. Supporting Direct Access in the form.component.ts File in the src/app/core Folder

```
...
constructor(private model: Model, activeRoute: ActivatedRoute) {
    this.editing = activeRoute.snapshot.params["mode"] == "edit";
    let id = activeRoute.snapshot.params["id"];
    if (id != null) {
        model.getProductObservable(id).subscribe(p => {
            Object.assign(this.product, p || new Product());
            this.productForm.patchValue(this.product);
        });
    }
}
...
```

The use of multiple observables is a little awkward, but the effect is that the user can request a URL such as http://localhost:4200/form/edit/2 directly and see the data they expect, as shown in Figure 24-6.

Figure 24-6. *Providing direct access to data*

Using Optional Route Parameters

Optional route parameters allow URLs to include information to provide hints or guidance to the rest of the application, but this is not essential for the application to work.

This type of route parameter is expressed using URL matrix notation, which isn't part of the specification for URLs but which browsers support nonetheless. Here is an example of a URL that has optional route parameters:

```
http://localhost:4200/form/edit/2;name=Lifejacket;price=48.95
```

The optional route parameters are separated by semicolons (the `;` character), and this URL includes optional parameters called `name` and `price`.

As a demonstration of how to use optional parameters, Listing 24-16 shows the addition of an optional route parameter that includes the object to be edited as part of the URL.

Listing 24-16. An Optional Route Parameter in the table.component.html File in the src/app/core Folder

```
...
<button class="btn btn-warning btn-sm" (click)="editProduct(item.id)"
        [routerLink]="['/form', 'edit', item.id,
        {name: item.name, category: item.category, price: item.price}]">
    Edit
</button>
...
```

The optional values are expressed as literal objects, where property names identify the optional parameter. In this example, there are name, category, and price properties, and their values are set.

Listing 24-17 shows how the form component checks to see whether the optional parameters are present. If they have been included in the URL, then the parameter values are used to avoid a request to the data model.

Listing 24-17. Receiving Optional Parameters in the form.component.ts File in the src/app/core Folder

```
...
constructor(private model: Model, activeRoute: ActivatedRoute) {
    this.editing = activeRoute.snapshot.params["mode"] == "edit";
    let id = activeRoute.snapshot.params["id"];
    if (id != null) {
        model.getProductObservable(id).subscribe(p => {
            Object.assign(this.product, p || new Product());
            this.product.name = activeRoute.snapshot.params["name"]
                ?? this.product.name;
            this.product.category = activeRoute.snapshot.params["category"]
                ?? this.product.category;
            let price = activeRoute.snapshot.params["price"];
            if (price != null) {
                this.product.price == Number.parseFloat(price);
            }
            this.productForm.patchValue(this.product);
        });
    }
}
...
```

The optional parameters in Listing 24-16 will produce a URL like this one for the Edit buttons:

```
http://localhost:4200/form/edit/5;name=Stadium;category=Soccer;price=79500
```

Optional route parameters are accessed in the same way as required parameters, and it is the responsibility of the component to check to see whether they are present and to proceed anyway if they are not part of the URL. In this case, the component uses the optional parameter values to override the values from the repository, which you can see by requesting this URL:

```
http://localhost:4200/form/edit/5;category=Football
```

The supplied value for the category parameter overrides the value provided by the repository, as shown in Figure 24-7.

Figure 24-7. *Using optional route parameters*

Navigating in Code

Using the routerLink attribute makes it easy to set up navigation in templates, but applications will often need to initiate navigation on behalf of the user within a component or directive.

To give access to the routing system to building blocks such as directives and components, Angular provides the Router class, which is available as a service through dependency injection and whose most useful methods and properties are described in Table 24-9.

Table 24-9. *Selected Router Methods and Properties*

Name	Description
navigated	This boolean property returns true if there has been at least one navigation event and false otherwise.
url	This property returns the active URL.
isActive(url, exact)	This method returns true if the specified URL is the URL defined by the active route. The exact argument specified whether all the segments in the specified URL must match the current URL for the method to return true.
events	This property returns an Observable<Event> that can be used to monitor navigation changes. See the "Receiving Navigation Events" section for details.
navigateByUrl (url, extras)	This method navigates to the specified URL. The result of the method is a Promise, which resolves with true when the navigation is successful and false when it is not, and which is rejected when there is an error.
navigate(commands, extras)	This method navigates using an array of segments. The extras object can be used to specify whether the change of URL is relative to the current route. The result of the method is a Promise, which resolves with true when the navigation is successful and false when it is not, and which is rejected when there is an error.

The navigate and navigateByUrl methods make it easy to perform navigation inside a building block such as a component. Listing 24-18 shows the use of the Router in the form component to redirect the application back to the table after a product has been created or updated.

Listing 24-18. Navigating Programmatically in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";
import { UniqueValidator } from "../validation/unique";
import { ProhibitedValidator } from "../validation/prohibited";
import { ActivatedRoute, Router } from "@angular/router";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;
```

```
    // ...form structure omitted for brevity...

    constructor(private model: Model, activeRoute: ActivatedRoute,
            private router: Router) {
        this.editing = activeRoute.snapshot.params["mode"] == "edit";
        let id = activeRoute.snapshot.params["id"];
        if (id != null) {
            model.getProductObservable(id).subscribe(p => {
                Object.assign(this.product, p || new Product());
                this.product.name = activeRoute.snapshot.params["name"]
                    ?? this.product.name;
                this.product.category = activeRoute.snapshot.params["category"]
                    ?? this.product.category;
                let price = activeRoute.snapshot.params["price"];
                if (price != null) {
                    this.product.price == Number.parseFloat(price);
                }
                this.productForm.patchValue(this.product);
            });
        }
    }

    submitForm() {
        if (this.productForm.valid) {
            Object.assign(this.product, this.productForm.value);
            this.model.saveProduct(this.product);
            // this.product = new Product();
            // this.keywordGroup.clear();
            // this.keywordGroup.push(this.createKeywordFormControl());
            // this.productForm.reset();
            this.router.navigateByUrl("/");
        }
    }

    // ...methods omitted for brevity...
}
```

The component receives the Router object as a constructor argument and uses it in the submitForm method to navigate back to the application's root URL. The statements that have been commented out in the submitForm method are no longer required because the routing system will destroy the form component once it is no longer on display, which means that resetting the form's state is not required.

The result is that clicking the Save or Create button in the form will cause the application to display the product table, as shown in Figure 24-8.

Figure 24-8. *Navigating programmatically*

Receiving Navigation Events

In many applications, there will be components or directives that are not directly involved in the application's navigation but that still need to know when navigation occurs. The example application contains an example in the message component, which displays notifications and errors to the user. This component always displays the most recent message, even when that information is stale and unlikely to be helpful to the user. To see the problem, click the Generate HTTP Error button and then click the Create New Product button or one of the Edit buttons; the error message remains on display even though you have navigated elsewhere in the application, as shown in Figure 24-9.

Figure 24-9. *An outdated error message*

The `events` property defined by the `Router` class returns an `Observable<Event>`, which emits a sequence of `Event` objects describing changes from the routing system. Table 24-10 describes the most useful events.

Table 24-10. *Useful Events Provided by the Router Observer*

Name	Description
NavigationStart	This event is sent when the navigation process starts.
RoutesRecognized	This event is sent when the routing system matches the URL to a route.
NavigationEnd	This event is sent when the navigation process completes successfully.
NavigationError	This event is sent when the navigation process produces an error.
NavigationCancel	This event is sent when the navigation process is canceled.
NavigationError	This event is sent when an error arises during navigation.

All the event classes define an `id` property, which returns a number that is incremented for each navigation, and a `url` property, which returns the target URL. The `RoutesRecognized` and `NavigationEnd` events also define a `urlAfterRedirects` property, which returns the URL that has been navigated to.

To address the issue with the messaging system, Listing 24-19 subscribes to the `Observer` provided by the `Router.events` property and clears the message displayed to the user when the `NavigationEnd` or `NavigationCancel` event is received.

Listing 24-19. Responding to Events in the message.component.ts File in the src/app/messages Folder

```
import { Component } from "@angular/core";
import { MessageService } from "./message.service";
import { Message } from "./message.model";
import { Router, NavigationEnd, NavigationCancel } from "@angular/router";
```

```
@Component({
    selector: "paMessages",
    templateUrl: "message.component.html",
})
export class MessageComponent {
    lastMessage?: Message;

    constructor(messageService: MessageService, router: Router) {
        messageService.messages.subscribe(msg => this.lastMessage = msg);
        router.events.subscribe(e => {
            if (e instanceof NavigationEnd || e instanceof NavigationCancel) {
                this.lastMessage = undefined;
            }
        })
    }
}
```

The result of these changes is that messages are shown to the user only until the next navigation event, as shown in Figure 24-10.

Figure 24-10. Responding to navigation events

Removing the Event Bindings and Supporting Code

One of the benefits of using the routing system is that it can simplify applications, replacing event bindings and the methods they invoke with navigation changes. The final change to complete the routing implementation is to remove the last traces of the previous mechanism that was used to coordinate between components. Listing 24-20 removes the event bindings from the table component's template, which were used to respond when the user clicked the Create New Product or Edit button. (The event binding for the Delete buttons is still required because this feature does not relate to navigation.)

Listing 24-20. Removing Event Bindings in the table.component.html File in the src/app/core Folder

```html
<table class="table table-sm table-bordered table-striped">
    <thead>
      <tr>
          <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
          <th>Details</th><th></th>
      </tr>
    </thead>
    <tbody>
      <tr *ngFor="let item of getProducts()">
          <td>{{item.id}}</td>
          <td>{{item.name}}</td>
          <td>{{item.category}}</td>
          <td>{{item.price | currency:"USD" }}</td>
          <td>
              <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
              </ng-container>
              <ng-template #empty>(None)</ng-template>
          </td>
          <td class="text-center">
              <button class="btn btn-danger btn-sm m-1"
                      (click)="deleteProduct(item.id)">
                  Delete
              </button>
              <button class="btn btn-warning btn-sm"
                      [routerLink]="['/form', 'edit', item.id]">
                  Edit
              </button>
          </td>
      </tr>
    </tbody>
</table>
<button class="btn btn-primary m-1" routerLink="/form/create">
    Create New Product
</button>
<button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
    Generate HTTP Error
</button>
```

Listing 24-21 shows the corresponding changes in the component, which remove the methods that the event bindings invoked and remove the dependency on the service that was used to signal when a product should be edited or created.

Listing 24-21. Removing Event Handling Code in the table.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
//import { MODES, SharedState } from "./sharedState.service";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html"
})
export class TableComponent {

    constructor(private model: Model) { }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts();
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    // editProduct(key?: number) {
    //     this.state.update(MODES.EDIT, key)
    // }

    // createProduct() {
    //     this.state.update(MODES.CREATE);
    // }
}
```

The service used for coordination by the components is no longer required, and Listing 24-22 disables it from the core module.

Listing 24-22. Removing the Shared State Service in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
```

```
import { FormComponent } from "./form.component";
//import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";
import { RouterModule } from "@angular/router";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule,
        RouterModule],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective],
    exports: [ModelModule, TableComponent, FormComponent],
    //providers: [SharedState]
})
export class CoreModule { }
```

The result is that the coordination between the table and form components is handled entirely through the routing system, which is now responsible for displaying the components and managing the navigation between them.

Summary

In this chapter, I introduced the Angular routing feature and demonstrated how to navigate to a URL in an application to select the content that is displayed to the user. I showed you how to create navigation links in templates, how to perform navigation in a component or directive, and how to respond to navigation changes programmatically. In the next chapter, I continue to describe the Angular routing system.

CHAPTER 25

■ ■ ■

Routing and Navigation: Part 2

In the previous chapter, I introduced the Angular URL routing system and explained how it can be used to control the components that are displayed to the user. The routing system has a lot of features, which I continue to describe in this chapter and Chapter 26. This emphasis in this chapter is about creating more complex routes, including routes that will match any URL, routes that redirect the browser to other URLs, routes that navigate within a component, and routes that select multiple components. Table 25-1 summarizes the chapter.

Table 25-1. *Chapter Summary*

Problem	Solution	Listing
Matching multiple URLs with a single route	Use routing wildcards	1–8
Redirecting one URL to another	Use a redirection route	9
Navigating within a component	Use a relative URL	10
Receiving notifications when the activated URL changes	Use the Observable objects provided by the ActivatedRoute class	11
Styling an element when a specific route is active	Use the routerLinkActive attribute	12–15
Using the routing system to display nested components	Define child routes and use the router-outlet element	16–20

Preparing the Example Project

For this chapter, I will continue using the exampleApp project that was created in Chapter 20 and has been modified in each subsequent chapter. To prepare for this chapter, I have added two methods to the repository class, as shown in Listing 25-1.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 25-1. Adding Methods in the repository.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";
import { Observable, ReplaySubject } from "rxjs";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class Model {
    private products: Product[];
    private locator = (p: Product, id?: number) => p.id == id;
    private replaySubject: ReplaySubject<Product[]>;

    constructor(private dataSource: RestDataSource) {
        this.products = new Array<Product>();
        this.replaySubject = new ReplaySubject<Product[]>(1);
        this.dataSource.getData().subscribe(data => {
            this.products = data
            this.replaySubject.next(data);
            this.replaySubject.complete();
        });
    }

    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }

    getProductObservable(id: number): Observable<Product | undefined> {
        let subject = new ReplaySubject<Product | undefined>(1);
        this.replaySubject.subscribe(products => {
            subject.next(products.find(p => this.locator(p, id)));
            subject.complete();
        });
        return subject;
    }

    getNextProductId(id?: number): Observable<number> {
        let subject = new ReplaySubject<number>(1);
        this.replaySubject.subscribe(products => {
            let nextId = 0;
            let index = products.findIndex(p => this.locator(p, id));
            if (index > -1) {
                nextId = products[products.length > index + 1
                    ? index + 1 : 0].id ?? 0;
            } else {
                nextId = id || 0;
            }
```

```
            subject.next(nextId);
            subject.complete();
        });
        return subject;
    }

    getPreviousProductid(id?: number): Observable<number> {
        let subject = new ReplaySubject<number>(1);
        this.replaySubject.subscribe(products => {
            let nextId = 0;
            let index = products.findIndex(p => this.locator(p, id));
            if (index > -1) {
                nextId = products[index > 0
                    ? index - 1 : products.length - 1].id ?? 0;
            } else {
                nextId = id || 0;
            }
            subject.next(nextId);
            subject.complete();
        });
        return subject;
    }

    saveProduct(product: Product) {
        if (product.id == 0 || product.id == null) {
            this.dataSource.saveProduct(product)
                .subscribe(p => this.products.push(p));
        } else {
            this.dataSource.updateProduct(product).subscribe(p => {
                let index = this.products
                    .findIndex(item => this.locator(item, p.id));
                this.products.splice(index, 1, p);
            });
        }
    }

    deleteProduct(id: number) {
        this.dataSource.deleteProduct(id).subscribe(() => {
            let index = this.products.findIndex(p => this.locator(p, id));
            if (index > -1) {
                this.products.splice(index, 1);
            }
        });
    }
}
```

The new methods accept an ID value, locate the corresponding product, and then return observables that produce the IDs of the next and previous objects in the array that the repository uses to collect the data model objects. I will use this feature later in the chapter to allow the user to page through the set of objects in the data model.

To simplify the example, Listing 25-2 removes the statements in the form component that receive the details of the product to edit using optional route parameters. I also changed the access level for the constructor parameters so I can use them directly in the component's template.

Listing 25-2. Removing Optional Parameters in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message  } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";
import { UniqueValidator } from "../validation/unique";
import { ProhibitedValidator } from "../validation/prohibited";
import { ActivatedRoute, Router } from "@angular/router";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FilteredFormArray([
        this.createKeywordFormControl(),
    ], {
        validators: UniqueValidator.unique()
    })

    productForm: FormGroup = new FormGroup({
        name:  new FormControl("", {
            validators: [
                Validators.required,
                Validators.minLength(3),
                Validators.pattern("^[A-Za-z ]+$")
            ],
            updateOn: "change"
        }),
        category: new FormControl("", {
            validators: Validators.required,
            asyncValidators: ProhibitedValidator.prohibited()
        }),
        price: new FormControl("", {
            validators: [
                Validators.required, Validators.pattern("^[0-9\.]+$"),
                LimitValidator.Limit(300)
```

```
            ]
        }),
        details: new FormGroup({
            supplier: new FormControl("", { validators: Validators.required }),
            keywords: this.keywordGroup
        })
    });

    constructor(public model: Model, activeRoute: ActivatedRoute,
            public router: Router) {
        this.editing = activeRoute.snapshot.params["mode"] == "edit";
        let id = activeRoute.snapshot.params["id"];
        if (id != null) {
            model.getProductObservable(id).subscribe(p => {
                Object.assign(this.product, p || new Product());
                // this.product.name = activeRoute.snapshot.params["name"]
                //      ?? this.product.name;
                // this.product.category = activeRoute.snapshot.params["category"]
                //      ?? this.product.category;
                // let price = activeRoute.snapshot.params["price"];
                // if (price != null) {
                //      this.product.price == Number.parseFloat(price);
                // }
                this.productForm.patchValue(this.product);
            });
        }
    }

    submitForm() {
        if (this.productForm.valid) {
            Object.assign(this.product, this.productForm.value);
            this.model.saveProduct(this.product);
            this.router.navigateByUrl("/");
        }
    }

    resetForm() {
        this.keywordGroup.clear();
        this.keywordGroup.push(this.createKeywordFormControl());
        this.editing = true;
        this.product = new Product();
        this.productForm.reset();
    }

    createKeywordFormControl(): FormControl {
        return new FormControl("", { validators:
            Validators.pattern("^[A-Za-z ]+$") });
    }

    addKeywordControl() {
        this.keywordGroup.push(this.createKeywordFormControl());
    }
```

```
    removeKeywordControl(index: number) {
        this.keywordGroup.removeAt(index);
    }
}
```

Adding Components to the Project

I need to add some components to the application to demonstrate some of the features covered in this chapter. These components are simple because I am focusing on the routing system, rather than adding useful features to the application. I created a file called `productCount.component.ts` in the `src/app/core` folder and used it to define the component shown in Listing 25-3.

■ **Tip**   You can omit the `selector` attribute from the `@Component` decorator if a component is going to be displayed only through the routing system. I tend to add it anyway so that I can apply the component using an HTML element as well.

Listing 25-3. The Contents of the productCount.component.ts File in the src/app/core Folder

```
import {
    Component, KeyValueDiffer, KeyValueDiffers, ChangeDetectorRef
} from "@angular/core";
import { Model } from "../model/repository.model";

@Component({
    selector: "paProductCount",
    template: `<div class="bg-info text-white p-2">There are
                    {{count}} products
                </div>`
})
export class ProductCountComponent {
    private differ?: KeyValueDiffer<any, any>;
    count: number = 0;

    constructor(private model: Model,
        private keyValueDiffers: KeyValueDiffers,
        private changeDetector: ChangeDetectorRef) { }

    ngOnInit() {
        this.differ = this.keyValueDiffers
            .find(this.model.getProducts())
            .create();
    }

    ngDoCheck() {
        if (this.differ?.diff(this.model.getProducts()) != null) {
            this.updateCount();
        }
    }
```

```
    private updateCount() {
        this.count = this.model.getProducts().length;
    }
}
```

This `component` uses an inline template to display the number of products in the data model, which is updated when the data model changes. Next, I added a file called `categoryCount.component.ts` in the `src/app/core` folder and defined the component shown in Listing 25-4.

Listing 25-4. The Contents of the categoryCount.component.ts File in the src/app/core Folder

```
import {
    Component, KeyValueDiffer, KeyValueDiffers, ChangeDetectorRef
} from "@angular/core";
import { Model } from "../model/repository.model";

@Component({
    selector: "paCategoryCount",
    template: `<div class="bg-primary p-2 text-white">
                    There are {{count}} categories
               </div>`
})
export class CategoryCountComponent {
    private differ?: KeyValueDiffer<any, any>;
    count: number = 0;

    constructor(private model: Model,
        private keyValueDiffers: KeyValueDiffers,
        private changeDetector: ChangeDetectorRef) { }

    ngOnInit() {
        this.differ = this.keyValueDiffers
            .find(this.model.getProducts())
            .create();
    }

    ngDoCheck() {
        if (this.differ?.diff(this.model.getProducts()) != null) {
            this.count = this.model.getProducts()
                .map(p => p.category)
                .filter((category, index, array) => array.indexOf(category) == index)
                .length;
        }
    }
}
```

This component uses a differ to track changes in the data model and count the number of unique categories, which is displayed using a simple inline template. For the final component, I added a file called `notFound.component.ts` in the `src/app/core` folder and used it to define the component shown in Listing 25-5.

Listing 25-5. The notFound.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "paNotFound",
    template: `<h3 class="bg-danger text-white p-2">Sorry, something went wrong</h3>
                <button class="btn btn-primary" routerLink="/">Start Over</button>`
})
export class NotFoundComponent {}
```

This component displays a static message that will be shown when something goes wrong with the routing system. Listing 25-6 adds the new components to the core module.

Listing 25-6. Declaring Components in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
//import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";
import { RouterModule } from "@angular/router";
import { ProductCountComponent } from "./productCount.component";
import { CategoryCountComponent } from "./categoryCount.component";
import { NotFoundComponent } from "./notFound.component";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule,
        RouterModule],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective, ProductCountComponent,
        CategoryCountComponent, NotFoundComponent],
    exports: [ModelModule, TableComponent, FormComponent],
})
export class CoreModule { }
```

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the server that provides the RESTful web server:

```
npm run json
```

Open a separate command prompt, navigate to the exampleApp folder, and run the following command to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to `http://localhost:4200` to see the content shown in Figure 25-1.

Figure 25-1. *Running the example application*

Using Wildcards and Redirections

The routing configuration in an application can quickly become complex and contain redundancies and oddities to cater to the structure of an application. Angular provides two useful tools that can help simplify routes and also deal with problems when they arise, as described in the following sections.

Using Wildcards in Routes

The Angular routing system supports a special path, denoted by two asterisks (the ** characters), that allows routes to match any URL. The basic use of the wildcard path is to deal with navigation that would otherwise create a routing error. Listing 25-7 adds a button to the table component's template that navigates to a route that hasn't been defined by the application's routing configuration.

Listing 25-7. Adding a Button in the table.component.html File in the src/app/core Folder

```html
<table class="table table-sm table-bordered table-striped">
    <thead>
      <tr>
          <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
          <th>Details</th><th></th>
      </tr>
    </thead>
    <tbody>
      <tr *ngFor="let item of getProducts()">
          <td>{{item.id}}</td>
          <td>{{item.name}}</td>
          <td>{{item.category}}</td>
          <td>{{item.price | currency:"USD" }}</td>
          <td>
              <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
              </ng-container>
              <ng-template #empty>(None)</ng-template>
          </td>
          <td class="text-center">
              <button class="btn btn-danger btn-sm m-1"
                      (click)="deleteProduct(item.id)">
                  Delete
              </button>
              <button class="btn btn-warning btn-sm"
                  [routerLink]="['/form', 'edit', item.id]">
                  Edit
              </button>
          </td>
      </tr>
    </tbody>
</table>
<button class="btn btn-primary m-1" routerLink="/form/create">
    Create New Product
</button>
<button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
    Generate HTTP Error
</button>
<button class="btn btn-danger m-1" routerLink="/does/not/exist">
    Generate Routing Error
</button>
```

Clicking the button will ask the application to navigate to the URL /does/not/exist, for which there is no route configured. When a URL doesn't match a URL, an error is thrown, which is then picked up and processed by the error handling class, which leads to a warning being displayed by the message component, as shown in Figure 25-2.

Figure 25-2. *The default navigation error*

This isn't a useful way to deal with an unknown route because the user won't know what routes are and may not realize that the application was trying to navigate to the problem URL.

A better approach is to use the wildcard route to handle navigation for URLs that have not been defined and select a component that will present a more useful message to the user, as illustrated in Listing 25-8.

Listing 25-8. Adding a Wildcard Route in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "", component: TableComponent },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The new route in the listing uses the wildcard to select the NotFoundComponent, which displays the message shown in Figure 25-3 when the Generate Routing Error button is clicked.

Figure 25-3. *Using a wildcard route*

Clicking the Start Over button navigates to the / URL, which will select the table component for display.

Using Redirections in Routes

Routes do not have to select components; they can also be used as aliases that redirect the browser to a different URL. Redirections are defined using the redirectTo property in a route, as shown in Listing 25-9.

Listing 25-9. Using Route Redirection in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The redirectTo property is used to specify the URL that the browser will be redirected to. When defining redirections, the pathMatch property must also be specified, using one of the values described in Table 25-2.

Table 25-2. *The pathMatch Values*

Name	Description
prefix	This value configures the route so that it matches URLs that start with the specified path, ignoring any subsequent segments.
full	This value configures the route so that it matches only the URL specified by the path property.

The first route added in Listing 25-9 specifies a pathMatch value of prefix and a path of does, which means it will match any URL whose first segment is does, such as the /does/not/exist URL that is navigated to by the Generate Routing Error button. When the browser navigates to a URL that has this prefix, the routing system will redirect it to the /form/create URL, as shown in Figure 25-4.

Figure 25-4. *Performing a route redirection*

The other routes in Listing 25-9 redirect the empty path to the /table URL, which displays the table component. This is a common technique that makes the URL schema more obvious because it matches the default URL (http://localhost:4200/) and redirects it to something more meaningful and memorable to the user (http://localhost:4200/table). In this case, the pathMatch property value is full, although this has no effect since it has been applied to the empty path.

Navigating Within a Component

The examples in the previous chapter navigated between different components so that clicking a button in the table component navigates to the form component and vice versa.

This isn't the only kind of navigation that's possible; you can also navigate within a component. To demonstrate, Listing 25-10 adds buttons to the form component that allow the user to edit the previous or next data objects.

Listing 25-10. Adding Buttons to the form.component.html File in the src/app/core Folder

```
<div *ngIf="editing" class="p-2">
    <button class="btn btn-secondary m-1"
        [routerLink]="['/form', 'edit',
            model.getPreviousProductid(product.id) | async]">
        Previous
    </button>
    <button class="btn btn-secondary"
        [routerLink]="['/form', 'edit',
            model.getNextProductId(product.id) | async]">
        Next
    </button>
</div>

<form [formGroup]="productForm" #form="ngForm"
        (ngSubmit)="submitForm()" (reset)="resetForm()">

    <!-- ...elements omitted for brevity... -->

</form>
```

These buttons have bindings for the routerLink directive with expressions that target the previous and next objects in the data model, using the async pipe to get results from the observables returned added to the repository at the start of the chapter. This means that if you click the Edit button in the table for the lifejacket, for example, the Next button will navigate to the URL that edits the soccer ball, and the Previous button will navigate to the URL for the kayak.

Responding to Ongoing Routing Changes

Although the URL changes when the Previous and Next buttons are clicked, there is no change in the data displayed to the user. Angular tries to be efficient during navigation, and it knows that the URLs that the Previous and Next buttons navigate to are handled by the same component that is currently displayed to the user. Rather than create a new instance of the component, it simply tells the component that the selected route has changed.

This is a problem because the form component isn't set up to receive change notifications. Its constructor receives the ActivatedRoute object that Angular uses to provide details of the current route, but only its snapshot property is used. The component's constructor has long been executed by the time that Angular updates the values in the ActivatedRoute object, which means that it misses the notification. This worked when the configuration of the application meant that a new form component would be created each time the user wanted to create or edit a product, but it is no longer sufficient.

Fortunately, the ActivatedRoute class defines a set of properties allowing interested parties to receive notifications through Reactive Extensions Observable objects. These properties correspond to the ones provided by the ActivatedRouteSnapshot object returned by the snapshot property but send new events when there are any subsequent changes, as described in Table 25-3.

Table 25-3. *The Observable Properties of the ActivatedRoute Class*

Name	Description
url	This property returns an Observable<UrlSegment[]>, which provides the set of URL segments each time the route changes.
params	This property returns an Observable<Params>, which provides the URL parameters each time the route changes.
queryParams	This property returns an Observable<Params>, which provides the URL query parameters each time the route changes.
fragment	This property returns an Observable<string>, which provides the URL fragment each time the route changes.

These properties can be used by components that need to handle navigation changes that don't result in a different component being displayed to the user, as shown in Listing 25-11.

■ **Tip**   If you need to combine different data elements from the route, such as using both segments and parameters, then subscribe to the Observer for one data element and use the snapshot property to get the rest of the data you require.

Listing 25-11. Observing Route Changes in the form.component.ts File in the src/app/core Folder

```
...
constructor(public model: Model, activeRoute: ActivatedRoute,
        public router: Router) {

    activeRoute.params.subscribe(params => {
        this.editing = params["mode"] == "edit";
        let id = params["id"];
        if (id != null) {
            model.getProductObservable(id).subscribe(p => {
                Object.assign(this.product, p || new Product());
                this.productForm.patchValue(this.product);
            });
        }
    })
}
...
```

The component subscribes to the Observer<Params> that sends a new Params object to subscribers each time the active route changes. The Observer objects returned by the ActivatedRoute properties send details of the most recent route change when the subscribe method is called, ensuring that the component's constructor doesn't miss the initial navigation that led to it being called.

The result is that the component can react to route changes that don't cause Angular to create a new component, meaning that clicking the Next or Previous button changes the product that has been selected for editing, as shown in Figure 25-5.

■ **Tip** The effect of navigation is obvious when the activated route changes the component that is displayed to the user. It may not be so obvious when just the data changes. To help emphasize changes, Angular can apply animations that draw attention to the effects of navigation. See Chapter 27 for details.

Figure 25-5. *Responding to route changes*

Styling Links for Active Routes

A common use for the routing system is to display multiple navigation elements alongside the content that they select. To demonstrate, Listing 25-12 adds a new route to the application that will allow the table component to be targeted with a URL that contains a category filter.

Listing 25-12. Defining a Route in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table/:category", component: TableComponent },
    { path: "table", component: TableComponent },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

Listing 25-13 updates the TableComponent class so that it uses the routing system to get details of the active route and assigns the value of the category route parameter to a category property that can be accessed in the template. The category property is used in the getProducts method to filter the objects in the data model.

738

Listing 25-13. Adding Category Filter Support in the table.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html"
})
export class TableComponent {
    category: string | null = null;

    constructor(public model: Model, activeRoute: ActivatedRoute) {
        activeRoute.params.subscribe(params => {
            this.category = params["category"] || null;
        })
    }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts()
            .filter(p => this.category == null || p.category == this.category);
    }

    get categories(): (string) [] {
        return (this.model.getProducts()
            .map(p => p.category)
            .filter((c, index, array) => c != undefined
                && array.indexOf(c) == index)) as string[];
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }
}
```

There is also a new categories property that will be used in the template to generate the set of categories for filtering. The final step is to add the HTML elements to the template that will allow the user to apply a filter, as shown in Listing 25-14.

Listing 25-14. Adding Filter Elements in the table.component.html File in the src/app/core Folder

```html
<div class="container-fluid">
    <div class="row">
        <div class="col-auto">
            <div class="d-grid gap-2">
                <button class="btn btn-secondary"
                        routerLink="/" routerLinkActive="bg-primary">
                    All
                </button>
                <button *ngFor="let category of categories"
                        class="btn btn-secondary"
                        [routerLink]="['/table', category]"
                        routerLinkActive="bg-primary">
                    {{category}}
                </button>
            </div>
        </div>
        <div class="col">
            <table class="table table-sm table-bordered table-striped">
                <thead>
                <tr>
                    <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
                    <th>Details</th><th></th>
                </tr>
                </thead>
                <tbody>
                <tr *ngFor="let item of getProducts()">
                    <td>{{item.id}}</td>
                    <td>{{item.name}}</td>
                    <td>{{item.category}}</td>
                    <td>{{item.price | currency:"USD" }}</td>
                    <td>
                        <ng-container *ngIf="item.details else empty">
                            {{ item.details?.supplier }}, {{ item.details?.keywords}}
                        </ng-container>
                        <ng-template #empty>(None)</ng-template>
                    </td>
                    <td class="text-center">
                        <button class="btn btn-danger btn-sm m-1"
                                (click)="deleteProduct(item.id)">
                            Delete
                        </button>
                        <button class="btn btn-warning btn-sm"
                                [routerLink]="['/form', 'edit', item.id]">
                            Edit
                        </button>
                    </td>
                </tr>
                </tbody>
            </table>
        </div>
```
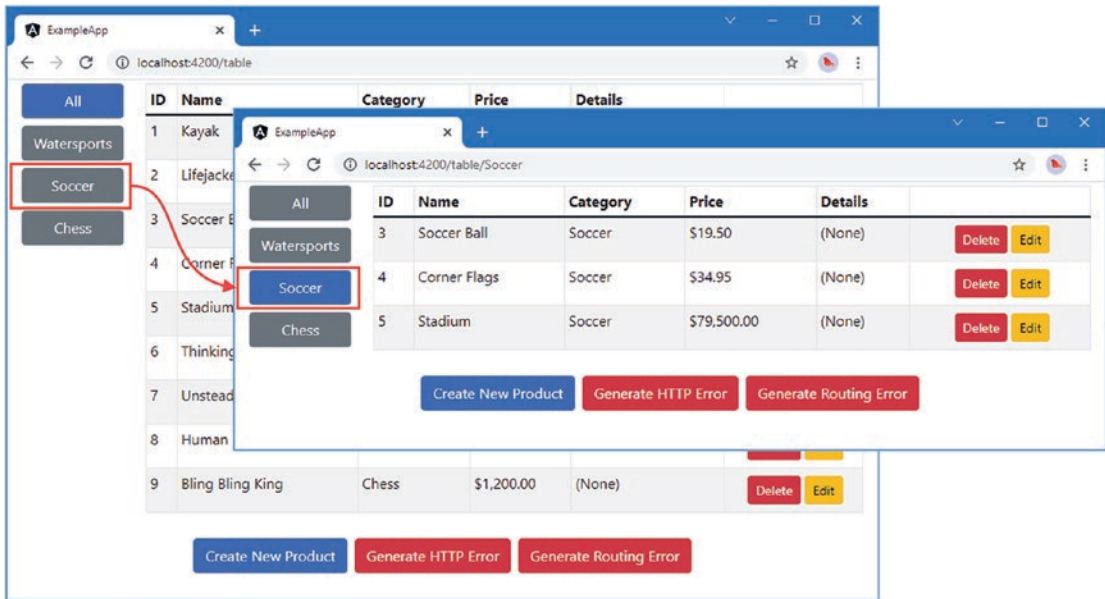

```
    </div>
</div>
<div class="p-2 text-center">
    <button class="btn btn-primary m-1" routerLink="/form/create">
        Create New Product
    </button>
    <button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
        Generate HTTP Error
    </button>
    <button class="btn btn-danger m-1" routerLink="/does/not/exist">
        Generate Routing Error
    </button>
</div>
```

The important part of this example is the use of the routerLinkActive attribute, which is used to specify a CSS class that the element will be assigned to when the URL specified by the routerLink attribute matches the active route.

The listing specifies a class called bg-primary, which changes the appearance of the button and makes the selected category more obvious. When combined with the functionality added to the component in Listing 25-13, the result is a set of buttons allowing the user to view products in a single category, as shown in Figure 25-6.

Figure 25-6. *Filtering products*

If you click the Soccer button, the application will navigate to the /table/Soccer URL, and the table will display only those products in the Soccer category. The Soccer button will also be highlighted since the routerLinkActive attribute means that Angular will add the button element to the Bootstrap bg-primary class.

Fixing the All Button

The navigation buttons reveal a common problem, which is that the All button is always added to the active class, even when the user has filtered the table to show a specific category.

This happens because the routerLinkActive attribute performs partial matches on the active URL by default. In the case of the example, the / URL will always cause the All button to be activated because it is at the start of all URLs. This problem can be fixed by configuring the routerLinkActive directive, as shown in Listing 25-15.

Listing 25-15. Configuring the Directive in the table.component.html File in the src/app/core Folder

```
...
<div class="d-grid gap-2">
    <button class="btn btn-secondary"
            routerLink="/table" routerLinkActive="bg-primary"
            [routerLinkActiveOptions]="{exact: true}">
        All
    </button>
    <button *ngFor="let category of categories"
            class="btn btn-secondary"
            [routerLink]="['/table', category]"
            routerLinkActive="bg-primary">
        {{category}}
    </button>
</div>
...
```

The configuration is performed using a binding on the routerLinkActiveOptions attribute, which accepts a literal object. The exact property is the only available configuration setting and is used to control matching the active route URL. Setting this property to true will add the element to the class specified by the routerLinkActive attribute only when there is an exact match with the active route's URL, which is changed to /table. With this change, the All button will be highlighted only when all of the products are shown, as illustrated by Figure 25-7.

Figure 25-7. *Fixing the All button problem*

Creating Child Routes

Child routes allow components to respond to part of the URL by embedding `router-outlet` elements in their templates, creating more complex arrangements of content. I am going to use the simple components I created at the start of the chapter to demonstrate how child routes work. These components will be displayed above the product table, and the component that is shown will be specified in the URLs shown in Table 25-4.

Table 25-4. *The URLs and the Components They Will Select*

URL	Component
/table/products	The `ProductCountComponent` will be displayed.
/table/categories	The `CategoryCountComponent` will be displayed.
/table	Neither component will be displayed.

Listing 25-16 shows the changes to the application's routing configuration to implement the routing strategy in the table.

Listing 25-16. Configuring Routes in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    {
        path: "table",
        component: TableComponent,
        children: [
            { path: "products", component: ProductCountComponent },
            { path: "categories", component: CategoryCountComponent }
        ]
    },
    { path: "table/:category", component: TableComponent },
    { path: "table", component: TableComponent },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

Child routes are defined using the `children` property, which is set to an array of routes defined in the same way as the top-level routes. When Angular uses the entire URL to match a route that has children, there

will be a match only if the URL to which the browser navigates contains segments that match both the top-level segment and the segments specified by one of the child routes.

■ **Tip**   Notice that I have added the new route before the one whose path is `table/:category`. Angular tries to match routes in the order in which they are defined. The `table/:category` path would match both the `/table/products` and `/table/categories` URLs and lead the table component to filter the products for nonexistent categories. By placing the more specific route first, the `/table/products` and `/table/categories` URLs will be matched before the `table/:category` path is considered.

Creating the Child Route Outlet

The components selected by child routes are displayed in a `router-outlet` element defined in the template of the component selected by the parent route. In the case of the example, this means the child routes will target an element in the table component's template, as shown in Listing 25-17, which also adds elements that will navigate to the new routes.

Listing 25-17. Adding an Outlet in the table.component.html File in the src/app/core Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="col-auto">
            <div class="d-grid gap-2">
                <button class="btn btn-secondary"
                        routerLink="/table" routerLinkActive="bg-primary"
                        [routerLinkActiveOptions]="{exact: true}">
                    All
                </button>
                <button *ngFor="let category of categories"
                        class="btn btn-secondary"
                        [routerLink]="['/table', category]"
                        routerLinkActive="bg-primary">
                    {{category}}
                </button>
            </div>
        </div>
        <div class="col">

            <button class="btn btn-info mx-1" routerLink="/table/products">
                Count Products
            </button>
            <button class="btn btn-primary mx-1" routerLink="/table/categories">
                Count Categories
            </button>
            <button class="btn btn-secondary mx-1" routerLink="/table">
                Count Neither
            </button>
```

```
        <div class="my-2">
            <router-outlet></router-outlet>
        </div>

        <table class="table table-sm table-bordered table-striped">
            <thead>
            <tr>
                <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
                <th>Details</th><th></th>
            </tr>
            </thead>
            <tbody>
            <tr *ngFor="let item of getProducts()">
                <td>{{item.id}}</td>
                <td>{{item.name}}</td>
                <td>{{item.category}}</td>
                <td>{{item.price | currency:"USD" }}</td>
                <td>
                    <ng-container *ngIf="item.details else empty">
                        {{ item.details?.supplier }}, {{ item.details?.keywords}}
                    </ng-container>
                    <ng-template #empty>(None)</ng-template>
                </td>
                <td class="text-center">
                    <button class="btn btn-danger btn-sm m-1"
                            (click)="deleteProduct(item.id)">
                        Delete
                    </button>
                    <button class="btn btn-warning btn-sm"
                            [routerLink]="['/form', 'edit', item.id]">
                        Edit
                    </button>
                </td>
            </tr>
            </tbody>
        </table>
    </div>
  </div>
</div>
<div class="p-2 text-center">
    <button class="btn btn-primary m-1" routerLink="/form/create">
        Create New Product
    </button>
    <button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
        Generate HTTP Error
    </button>
    <button class="btn btn-danger m-1" routerLink="/does/not/exist">
        Generate Routing Error
    </button>
</div>
```

The button elements have routerLink attributes that specify the URLs listed in Table 25-4, and there is also a router-outlet element, which will be used to display the selected component, as shown in Figure 25-8, or no component if the browser navigates to the /table URL.

Figure 25-8. *Using child routes*

Accessing Parameters from Child Routes

Child routes can use all the features available to the top-level routes, including defining route parameters and even having their own child routes. Route parameters are worth special attention in child routes because of the way that Angular isolates children from their parents. For this section, I am going to add support for the URLs described in Table 25-5.

Table 25-5. *The New URLs Supported by the Example Application*

Name	Description
/table/:category/products	This route will filter the contents of the table and select the ProductCountComponent.
/table/:category/categories	This route will filter the contents of the table and select the CategoryCountComponent.

Listing 25-18 defines the routes that support the URLs shown in the table.

Listing 25-18. Adding Routes in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
```

```
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";

const childRoutes: Routes = [
    { path: "products", component: ProductCountComponent },
    { path: "categories", component: CategoryCountComponent },
    { path: "", component: ProductCountComponent }
];

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    // {
    //     path: "table",
    //     component: TableComponent,
    //     children: [
    //         { path: "products", component: ProductCountComponent },
    //         { path: "categories", component: CategoryCountComponent }
    //     ]
    // },
    // { path: "table/:category", component: TableComponent },
    // { path: "table", component: TableComponent },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The type of the children property is a Routes object, which makes it easy to minimize duplication in the route configuration when you need to apply the same set of child routes in different parts of the URL schema. In the listing, I have defined the child routes in a Routes object called childRoutes and used it as the value for the children property in two different top-level routes.

To make it possible to target these new routes, Listing 25-19 changes the targets of the buttons that appear above the table so they navigate relative to the current URL. I have removed the Count Neither button since the ProductCountComponent will be shown when the empty path child route matches the URL.

Listing 25-19. Using Relative URLs in the table.component.html File in the src/app/core Folder

```
...
<div class="col">
    <button class="btn btn-info mx-1" routerLink="products">
        Count Products
    </button>
    <button class="btn btn-primary mx-1" routerLink="categories">
        Count Categories
```

```
    </button>
    <button class="btn btn-secondary mx-1" routerLink="/table">
        Count Neither
    </button>
    <div class="my-2">
        <router-outlet></router-outlet>
    </div>

    <table class="table table-sm table-bordered table-striped">
...
```

When Angular matches routes, the information it provides to the components that are selected through the ActivatedRoute object is segregated so that each component receives details of only the part of the route that selected it.

In the case of the routes added in Listing 25-19, this means the ProductCountComponent and CategoryCountComponent receive an ActivatedRoute object that describes only the child route that selected them, with the single segment of /products or /categories. Equally, the TableComponent component receives an ActivatedRoute object that doesn't contain the segment that was used to match the child route.

Fortunately, the ActivatedRoute class provides some properties that offer access to the rest of the route, allowing parents and children to access the rest of the routing information, as described in Table 25-6.

Table 25-6. *The ActivatedRoute Properties for Child-Parent Route Information*

Name	Description
pathFromRoot	This property returns an array of ActivatedRoute objects representing all the routes used to match the current URL.
parent	This property returns an ActivatedRoute representing the parent of the route that selected the component.
firstChild	This property returns an ActivatedRoute representing the first child route used to match the current URL.
children	This property returns an array of ActivatedRoute objects representing all the child routes used to match the current URL.

Listing 25-20 shows how the ProductCountComponent component can access the wider set of routes used to match the current URL to get a value for the category route parameter and adapt its output when the contents of the table are filtered for a single category.

Listing 25-20. Ancestor Routes in the productCount.component.ts File in the src/app/core Folder

```
import {
    Component, KeyValueDiffer, KeyValueDiffers, ChangeDetectorRef
} from "@angular/core";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";

@Component({
    selector: "paProductCount",
```

```
    template: `<div class="bg-info text-white p-2">There are
                {{count}} products
            </div>`
})
export class ProductCountComponent {
    private differ?: KeyValueDiffer<any, any>;
    count: number = 0;
    private category?: string;

    constructor(private model: Model,
            private keyValueDiffers: KeyValueDiffers,
            private changeDetector: ChangeDetectorRef,
            activeRoute: ActivatedRoute) {
        activeRoute.pathFromRoot.forEach(route => route.params.subscribe(params => {
            if (params["category"] != null) {
                this.category = params["category"];
                this.updateCount();
            }
        }))
    }

    ngOnInit() {
        this.differ = this.keyValueDiffers
            .find(this.model.getProducts())
            .create();
    }

    ngDoCheck() {
        if (this.differ?.diff(this.model.getProducts()) != null) {
            this.updateCount();
        }
    }

    private updateCount() {
        this.count = this.model.getProducts()
            .filter(p => this.category == null || p.category == this.category)
            .length;
    }
}
```

The pathFromRoot property is especially useful because it allows a component to inspect all the routes that have been used to match the URL. Angular minimizes the routing updates required to handle navigation, which means that a component that has been selected by a child route won't receive a change notification through its ActivatedRoute object if only its parent has changed. It is for this reason that I have subscribed to updates from all the ActivatedRoute objects returned by the pathFromRoot property, ensuring that the component will always detect changes in the value of the category route parameter.

To see the result, save the changes, click the Watersports button to filter the contents of the table, and then click the Count Products button, which selects the ProductCountComponent. This number of products reported by the component will correspond to the number of rows in the table, as shown in Figure 25-9.

Figure 25-9. *Accessing the other routes used to match a URL*

Summary

In this chapter, I continued to describe the features provided by the Angular URL routing system, going beyond the basic features described in the previous chapter. I explained how to create wildcard and redirection routes, how to create routes that navigate relative to the current URL, and how to create child routes to display nested components. In the next chapter, I finish describing the URL routing system, focusing on the most advanced features.

CHAPTER 26

■ ■ ■

Routing and Navigation: Part 3

In this chapter, I continue to describe the Angular URL routing system, focusing on the most advanced features. I explain how to control route activation, how to load feature modules dynamically, and how to use multiple outlet elements in a template. Table 26-1 summarizes the chapter.

Table 26-1. *Chapter Summary*

Problem	Solution	Listing
Delaying navigation until a task is complete	Use a route resolver	1–6
Preventing route activation	Use an activation guard	7–13
Preventing the user from navigating away from the current content	Use a deactivation guard	14–18
Deferring loading a feature module until it is required	Create a dynamically loaded module	19–24
Controlling when a dynamically loaded module is used	Use a loading guard	25–27
Using routing to manage multiple router outlets	Use named outlets in the same template	28–33

Preparing the Example Project

For this chapter, I will continue using the exampleApp project that was created in Chapter 20 and has been modified in each subsequent chapter. No changes are required for this chapter.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the server that provides the RESTful web server:

```
npm run json
```

Open a separate command prompt, navigate to the exampleApp folder, and run the following command to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to `http://localhost:4200` to see the content shown in Figure 26-1.

Figure 26-1. *Running the example application*

Guarding Routes

At the moment, the user can navigate anywhere in the application at any time. This isn't always a good idea, either because some parts of the application may not always be ready or because some parts of the application are restricted until specific actions are performed. To control the use of navigation, Angular supports *guards*, which are specified as part of the route configuration using the properties defined by the Routes class, described in Table 26-2.

Table 26-2. *The Routes Properties for Guards*

Name	Description
resolve	This property is used to specify guards that will delay route activation until some operation has been completed, such as loading data from a server.
canActivate	This property is used to specify the guards that will be used to determine whether a route can be activated.
canActivateChild	This property is used to specify the guards that will be used to determine whether a child route can be activated.
canDeactivate	This property is used to specify the guards that will be used to determine whether a route can be deactivated.
canLoad	This property is used to guard routes that load feature modules dynamically, as described in the "Loading Feature Modules Dynamically" section.

Delaying Navigation with a Resolver

A common reason for guarding routes is to ensure that the application has received the data that it requires before a route is activated. The example application loads data from the RESTful web service asynchronously, which means there can be a delay between the moment at which the browser is asked to send the HTTP request and the moment at which the response is received and the data is processed. You may not have noticed this delay as you followed the examples because the browser and the web service are running on the same machine. In a deployed application, there is a much greater prospect of there being a delay, caused by network congestion, a high server load, or a dozen other factors.

To simulate network congestion, Listing 26-1 modifies the RESTful data source class to introduce a delay after the response is received from the web service.

Listing 26-1. Adding a Delay in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient, HttpHeaders } from "@angular/common/http";
import { catchError, delay, Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {
    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.sendRequest<Product[]>("GET", this.url).pipe(delay(5000));
    }

    saveProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("POST", this.url, product);
    }
```

```
updateProduct(product: Product): Observable<Product> {
    return this.sendRequest<Product>("PUT",
        `${this.url}/${product.id}`, product);
}

deleteProduct(id: number): Observable<Product> {
    return this.sendRequest<Product>("DELETE", `${this.url}/${id}`);
}

private sendRequest<T>(verb: string, url: string, body?: Product)
    : Observable<T> {

    let myHeaders = new HttpHeaders();
    myHeaders = myHeaders.set("Access-Key", "<secret>");
    myHeaders = myHeaders.set("Application-Names", ["exampleApp", "proAngular"]);

    return this.http.request<T>(verb, url, {
        body: body,
        headers: myHeaders
    }).pipe(catchError((error: Response) => {
        throw(`Network Error: ${error.statusText} (${error.status})`)
    }));
}
}
```

The delay is added using the Reactive Extensions delay method and is applied to create a five-second delay, which is long enough to create a noticeable pause without being too painful to wait for every time the application is reloaded. To change the delay, increase or decrease the argument for the delay method, which is expressed in milliseconds.

The effect of the delay is that the user is presented with an incomplete and confusing layout while the application is waiting for the data to load, as shown in Figure 26-2.

Figure 26-2. *Waiting for data*

Creating a Resolver Service

A *resolver* is used to ensure that a task is performed before a route can be activated. To create a resolver, I added a file called model.resolver.ts in the src/app/model folder and defined the class shown in Listing 26-2.

Listing 26-2. The Contents of the model.resolver.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { ActivatedRouteSnapshot, RouterStateSnapshot } from "@angular/router";
import { Observable } from "rxjs";
import { Model } from "./repository.model"
import { Product } from "./product.model";

@Injectable()
export class ModelResolver {

    constructor(private model: Model) { }

    resolve(route: ActivatedRouteSnapshot,
            state: RouterStateSnapshot): Observable<Product | undefined> {

        return this.model.getProductObservable(1);
    }
}
```

Resolvers are classes that define a resolve method that accepts two arguments. The first argument is an ActivatedRouteSnapshot object, which describes the route that is being navigated to using the properties described in Chapter 24. The second argument is a RouterStateSnapshot object, which describes the current route through a single property called url. These arguments can be used to adapt the resolver to the navigation that is about to be performed, although neither is required by the resolver in the listing, which uses the same behavior regardless of the routes that are being navigated to and from.

■ **Note** All of the guards described in this chapter can implement interfaces defined in the @angular/router module. For example, resolvers can implement an interface called Resolve. These interfaces are optional, and I have not used them in this chapter.

The resolve method can return three different types of result, as described in Table 26-3.

Table 26-3. The Result Types Allowed by the resolve Method

Result Type	Description
Observable<any>	The browser will activate the new route when the Observer emits an event.
Promise<any>	The browser will activate the new route when the Promise resolves.
Any other result	The browser will activate the new route as soon as the method produces a result.

The `Observable` and `Promise` results are useful when dealing with asynchronous operations, such as requesting data using an HTTP request. Angular waits until the asynchronous operation is complete before activating the new route. Any other result is interpreted as the result of a synchronous operation, and Angular will activate the new route immediately.

The resolver in Listing 26-2 uses its constructor to receive a `Model` object via dependency injection. When the `resolve` method is called, it calls the `getProductObservable` method, which returns an observable that will emit a result only once data has been received. Angular will subscribe to the `Observable` and delay activating the new route until it emits an event.

The observable returned by the `getProductObservable` method will emit an event immediately once data has been received, which is important because Angular will call the guard's `resolve` method every time that the application tries to navigate to a route to which the resolver has been applied.

Notice that I don't care about the data produced by the repository through the observable. All that matters from the perspective of the guard is that the observable returned by the `getProductObservable` method will emit an event that indicates data has been received.

Registering the Resolver Service

The next step is to register the resolver as a service in its feature module, as shown in Listing 26-3.

Listing 26-3. Registering the Resolver in the model.module.ts File in the src/app/model Folder

```
import { NgModule } from "@angular/core";
import { StaticDataSource } from "./static.datasource";
import { Model } from "./repository.model";
import { HttpClientJsonpModule, HttpClientModule } from "@angular/common/http";
import { RestDataSource, REST_URL } from "./rest.datasource";
import { ModelResolver } from "./model.resolver";

@NgModule({
    imports: [HttpClientModule, HttpClientJsonpModule],
    providers: [Model, RestDataSource,
        { provide: REST_URL, useValue: `http://${location.hostname}:3500/products` },
        ModelResolver]
})
export class ModelModule { }
```

Applying the Resolver

The resolver is applied to routes using the `resolve` property, as shown in Listing 26-4.

Listing 26-4. Applying a Resolver in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";
```

```
const childRoutes: Routes = [
    {   path: "",
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];

const routes: Routes = [
    { path: "form/:mode/:id", component: FormComponent },
    { path: "form/:mode", component: FormComponent },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The resolve property accepts a map object whose property values are the resolver classes that will be applied to the route. (The property names do not matter.) I want to apply the resolver to all the views that display the product table, so to avoid duplication, I created a route with the resolve property and used it as the parent for the existing child routes.

The effect is that the user will see no content until the data has been received from the web service and processed by the application, as shown in Figure 26-3.

Figure 26-3. *Using a route guard*

Displaying Placeholder Content

Angular uses the resolver before activating any of the routes to which it has been applied, which prevents the user from seeing the product table until the model has been populated with the data from the RESTful web service. Sadly, that just means the user sees an empty window while the browser is waiting for the server to respond. To address this, Listing 26-5 enhances the resolver to use the message service to tell the user what is happening when the data is being loaded.

Listing 26-5. Displaying a Message in the model.resolver.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { ActivatedRouteSnapshot, RouterStateSnapshot } from "@angular/router";
import { Observable } from "rxjs";
import { Model } from "./repository.model"
import { Product } from "./product.model";
import { MessageService } from "../messages/message.service";
import { Message } from "../messages/message.model";

@Injectable()
export class ModelResolver {

    constructor(private model: Model,
        private messages: MessageService) { }

    resolve(route: ActivatedRouteSnapshot,
            state: RouterStateSnapshot): Observable<Product | undefined> {
        this.messages.reportMessage(new Message("Loading data..."));
        return this.model.getProductObservable(1);
    }
}
```

The guard uses the message service to give the user an indication that something is happening and relies on the way that the service removes messages when navigation events are received. The result is that the user sees a loading message until data is received, as shown in Figure 26-4.

Figure 26-4. *Displaying a loading message*

Using a Resolver to Prevent URL Entry Problems

A resolver can be applied more broadly so that it protects multiple routes, which extends the loading message when the user navigates directly to a URL for a specific product, as shown in Listing 26-6.

Listing 26-6. Applying the Resolver to Other Routes in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";

const childRoutes: Routes = [
    {   path: "",
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];

const routes: Routes = [
    {
        path: "form/:mode/:id", component: FormComponent,
        resolve: { model: ModelResolver }
    },
    {
        path: "form/:mode", component: FormComponent,
        resolve: { model: ModelResolver }
    },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

Applying the ModelResolver class to the routes that target FormComponent ensures that the user is shown the placeholder message while the data is loaded, as shown in Figure 26-5.

Figure 26-5. *Expanding the use of a resolver*

Preventing Navigation with Guards

Resolvers are used to delay navigation while the application performs some prerequisite work, such as loading data. The other guards that Angular provides are used to control whether navigation can occur at all, which can be useful when you want to alert the user to prevent potentially unwanted operations (such as abandoning data edits) or limit access to parts of the application unless the application is in a specific state, such as when a user has been authenticated.

    Many uses for route guards introduce an additional interaction with the user, either to gain explicit approval to perform an operation or to obtain additional data, such as authentication credentials. For this chapter, I am going to handle this kind of interaction by extending the message service so that messages can require user input. In Listing 26-7, I have added an optional `responses` constructor argument/property to the `Message` model class, which will allow messages to contain prompts to the user and callbacks that will be invoked when they are selected. The `responses` property is an array of TypeScript tuples, where the first value is the name of the response, which will be presented to the user, and the second value is the callback function, which will be passed the name as its argument.

Listing 26-7. Adding Responses in the message.model.ts File in the src/app/messages Folder

```
export class Message {

    constructor(public text: string,
        public error: boolean = false,
        public responses?: [string, (r: string) => void][]) { }
}
```

    The only other change required to implement this feature is to present the response options to the user. Listing 26-8 adds `button` elements below the message text for each `response`. Clicking the buttons will invoke the callback function.

Listing 26-8. Presenting Responses in the message.component.html File in the src/app/core Folder

```
<div *ngIf="lastMessage"
     class="bg-primary text-white p-2 text-center"
     [class.bg-danger]="lastMessage.error">
        <h4>{{lastMessage.text}}</h4>
</div>
<div class="text-center my-2">
    <button *ngFor="let resp of lastMessage?.responses; let i = index"
            (click)="resp[1](resp[0])"
            class="btn btn-primary m-2" [class.btn-secondary]="i > 0">
        {{resp[0]}}
    </button>
</div>
```

Preventing Route Activation

Guards can be used to prevent a route from being activated, helping to protect the application from entering an unwanted state or warning the user about the impact of performing an operation. To demonstrate, I am going to guard the /form/create URL to prevent the user from starting the process of creating a new product unless the user agrees to the application's terms and conditions.

Guards for route activation are classes that define a method called canActivate, which receives the same ActivatedRouteSnapshot and RouterStateSnapshot arguments as resolvers. The canActivate method can be implemented to return three different result types, as described in Table 26-4.

Table 26-4. The Result Types Allowed by the canActivate Method

Result Type	Description
boolean	This type of result is useful when performing synchronous checks to see whether the route can be activated. A true result will activate the route, and a result of false will not, effectively ignoring the navigation request.
Observable<boolean>	This type of result is useful when performing asynchronous checks to see whether the route can be activated. Angular will wait until the Observable emits a value, which will be used to determine whether the route is activated. When using this kind of result, it is important to terminate the Observable by calling the complete method; otherwise, Angular will just keep waiting.
Promise<boolean>	This type of result is useful when performing asynchronous checks to see whether the route can be activated. Angular will wait until the Promise is resolved and activate the route if it yields true. If the Promise yields false, then the route will not be activated, effectively ignoring the navigation request.

To get started, I added a file called terms.guard.ts to the src/app folder and defined the class shown in Listing 26-9.

Listing 26-9. The Contents of the terms.guard.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";
import {
    ActivatedRouteSnapshot, RouterStateSnapshot,
    Router
} from "@angular/router";
import { MessageService } from "./messages/message.service";
import { Message } from "./messages/message.model";

@Injectable()
export class TermsGuard {

    constructor(private messages: MessageService,
                private router: Router) { }

    canActivate(route: ActivatedRouteSnapshot, state: RouterStateSnapshot):
        Promise<boolean> | boolean {

        if (route.params["mode"] == "create") {

            return new Promise<boolean>((resolve) => {
                let responses: [string, () => void][]
                    = [["Yes", () => resolve(true)], ["No",  () => resolve(false)]];
                this.messages.reportMessage(
                    new Message("Do you accept the terms & conditions?",
                        false, responses));
            });
        } else {
            return true;
        }
    }
}
```

The `canActivate` method can return two different types of results. The first type is a `boolean`, which allows the guard to respond immediately for routes that it doesn't need to protect, which in this case is any that lacks a parameter called `mode` whose value is `create`. If the URL matched by the route doesn't contain this parameter, the `canActivate` method returns `true`, which tells Angular to activate the route. This is important because the edit and create features both rely on the same routes, and the guard should not interfere with edit operations.

The other type of result is a `Promise<boolean>`, which I have used instead of `Observable<true>` for variety. The `Promise` uses the modifications to the message service to solicit a response from the user, confirming they accept the (unspecified) terms and conditions. There are two possible responses from the user. If the user clicks the Yes button, then the Promise will resolve and yield `true`, which tells Angular to activate the route, displaying the form that is used to create a new product. The `Promise` will resolve and yield `false` if the user clicks the No button, which tells Angular to ignore the navigation request.

Listing 26-10 registers the `TermsGuard` as a service so that it can be used in the application's routing configuration.

Listing 26-10. Registering the Guard as a Service in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';
import { ModelModule } from "./model/model.module";
import { CoreModule } from "./core/core.module";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { MessageModule } from "./messages/message.module";
import { MessageComponent } from "./messages/message.component";
import { AppComponent } from './app.component';
import { routing } from "./app.routing";
import { TermsGuard } from "./terms.guard"

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, ModelModule, CoreModule, MessageModule, routing],
  providers: [TermsGuard],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

Listing 26-11 applies the guard to the routing configuration. Activation guards are applied to a route using the canActivate property, which is assigned an array of guard services. The canActivate method of all the guards must return true (or return an Observable or Promise that eventually yields true) before Angular will activate the route.

Listing 26-11. Applying the Guard to a Route in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";
import { TermsGuard } from "./terms.guard";

const childRoutes: Routes = [
    {   path: "",
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];

const routes: Routes = [
    {
        path: "form/:mode/:id", component: FormComponent,
        resolve: { model: ModelResolver }
    },
```

```
{
    path: "form/:mode", component: FormComponent,
    resolve: { model: ModelResolver },
    canActivate: [TermsGuard]
},
{ path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
{ path: "table", component: TableComponent, children: childRoutes },
{ path: "table/:category", component: TableComponent, children: childRoutes },
{ path: "", redirectTo: "/table", pathMatch: "full" },
{ path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The effect of creating and applying the activation guard is that the user is prompted when clicking the Create New Product button, as shown in Figure 26-6. If they respond by clicking the Yes button, then the navigation request will be completed, and Angular will activate the route that selects the form component, which will allow a new product to be created. If the user clicks the No button, then the navigation request will be canceled. In both cases, the routing system emits an event that is received by the component that displays the messages to the user, which clears its display and ensures that the user doesn't see stale messages.

Figure 26-6. *Guarding route activation*

Consolidating Child Route Guards

If you have a set of child routes, you can guard against their activation using a child route guard, which is a class that defines a method called canActivateChild. The guard is applied to the parent route in the application's configuration, and the canActivateChild method is called whenever any of the child routes are about to be activated. The method receives the same ActivatedRouteSnapshot and RouterStateSnapshot objects as the other guards and can return the set of result types described in Table 26-4.

This guard in this example is more readily dealt with by changing the configuration before implementing the canActivateChild method, as shown in Listing 26-12.

Listing 26-12. Guarding Child Routes in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";
import { TermsGuard } from "./terms.guard";

const childRoutes: Routes = [
    {   path: "",
        canActivateChild: [TermsGuard],
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];

const routes: Routes = [
    {
        path: "form/:mode/:id", component: FormComponent,
        resolve: { model: ModelResolver }
    },
    {
        path: "form/:mode", component: FormComponent,
        resolve: { model: ModelResolver },
        canActivate: [TermsGuard]
    },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

Child route guards are applied to a route using the canActivateChild property, which is set to an array of service types implementing the canActivateChild method. This method will be called before Angular activates any of the route's children. Listing 26-13 adds the canActivateChild method to the guard class from the previous section.

Listing 26-13. Implementing Child Route Guards in the terms.guard.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";
import {
    ActivatedRouteSnapshot, RouterStateSnapshot,
    Router
} from "@angular/router";
import { MessageService } from "./messages/message.service";
import { Message } from "./messages/message.model";
```

```
@Injectable()
export class TermsGuard {

    constructor(private messages: MessageService,
                private router: Router) { }

    canActivate(route: ActivatedRouteSnapshot, state: RouterStateSnapshot):
        Promise<boolean> | boolean {

        if (route.params["mode"] == "create") {

            return new Promise<boolean>((resolve) => {
                let responses: [string, () => void][]
                    = [["Yes", () => resolve(true)], ["No",  () => resolve(false)]];
                this.messages.reportMessage(
                    new Message("Do you accept the terms & conditions?",
                        false, responses));
            });
        } else {
            return true;
        }
    }

    canActivateChild(route: ActivatedRouteSnapshot, state: RouterStateSnapshot):
        Promise<boolean> | boolean {

        if (route.url.length > 0
            && route.url[route.url.length - 1].path == "categories") {

            return new Promise<boolean>((resolve, reject) => {
                let responses: [string, (arg: string) => void][] = [
                    ["Yes", () => resolve(true)],
                    ["No ", () => resolve(false)]
                ];

                this.messages.reportMessage(
                    new Message("Do you want to see the categories component?",
                        false, responses));
            });
        } else {
            return true;
        }
    }
}
```

The guard only protects the categories child route and will return true immediately for any other route. The guard prompts the user using the message service but does something different if the user clicks the No button. In addition to rejecting the active route, the guard navigates to a different URL using the Router service, which is received as a constructor argument. This is a common pattern for authentication when the user is redirected to a component that will solicit security credentials if a restricted operation is attempted. The example is simpler in this case, and the guard navigates to a sibling route that shows a different component. (You can see an example of using route guards for navigation in the SportsStore application.)

To see the effect of the guard, click the Count Categories button, as shown in Figure 26-7. Responding to the prompt by clicking the Yes button will show the `CategoryCountComponent`, which displays the number of categories in the table. Clicking No will reject the active route and navigate to a route that displays the `ProductCountComponent` instead.

■ **Note** Guards are applied only when the active route changes. So, for example, if you click the Count Categories button when the `/table` URL is active, then you will see the prompt, and clicking Yes will change the active route. But nothing will happen if you click the Count Categories button again because Angular doesn't trigger a route change when the target route and the active route are the same.

Figure 26-7. *Guarding child routes*

Preventing Route Deactivation

When you start working with routes, you will tend to focus on the way that routes are activated to respond to navigation and present new content to the user. But equally important is route *deactivation*, which occurs when the application navigates away from a route.

The most common use for deactivation guards is to prevent the user from navigating when there are unsaved edits to data. In this section, I will create a guard that warns the user when they are about to abandon unsaved changes when editing a product. In preparation for this, Listing 26-14 changes the `FormComponent` class to simplify the work of the guard.

Listing 26-14. Preparing for the Guard in the form.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { FormControl, NgForm, Validators, FormGroup, FormArray }
    from "@angular/forms";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model"
import { Message } from "../messages/message.model"
import { MessageService } from "../messages/message.service";
```

```
import { MODES, SharedState, StateUpdate } from "./sharedState.service";
import { FilteredFormArray } from "./filteredFormArray";
import { LimitValidator } from "../validation/limit";
import { UniqueValidator } from "../validation/unique";
import { ProhibitedValidator } from "../validation/prohibited";
import { ActivatedRoute, Router } from "@angular/router";

@Component({
    selector: "paForm",
    templateUrl: "form.component.html",
    styleUrls: ["form.component.css"]
})
export class FormComponent {
    product: Product = new Product();
    editing: boolean = false;

    keywordGroup = new FilteredFormArray([
        this.createKeywordFormControl(),
    ], {
        validators: UniqueValidator.unique()
    })

    // ...form structure and methods omitted for brevity...

    // resetForm() {
    //     this.keywordGroup.clear();
    //     this.keywordGroup.push(this.createKeywordFormControl());
    //     this.editing = true;
    //     this.product = new Product();
    //     this.productForm.reset();
    // }

    unsavedChanges(): boolean {
        return this.productForm.dirty;
    }

    createKeywordFormControl(): FormControl {
        return new FormControl("", { validators:
            Validators.pattern("^[A-Za-z ]+$") });
    }

    addKeywordControl() {
        this.keywordGroup.push(this.createKeywordFormControl());
    }

    removeKeywordControl(index: number) {
        this.keywordGroup.removeAt(index);
    }
}
```

The unsavedChanges method will be used to indicate whether the user has made changes since editing began, which is determined by checking the state of the top-level FormGroup.

A corresponding change is required in the template so that the Cancel button doesn't invoke the form's reset event handler, as shown in Listing 26-15.

Listing 26-15. Disabling Form Reset in the form.component.html File in the src/app/core Folder

```html
<div *ngIf="editing" class="p-2">
    <button class="btn btn-secondary m-1"
        [routerLink]="['/form', 'edit',
            model.getPreviousProductid(product.id) | async]">
        Previous
    </button>
    <button class="btn btn-secondary"
        [routerLink]="['/form', 'edit',
            model.getNextProductId(product.id) | async]">
        Next
    </button>
</div>
<form [formGroup]="productForm" #form="ngForm" (ngSubmit)="submitForm()">

    <!-- ...elements omitted for brevity... -->

    <div class="mt-2">
        <button type="submit" class="btn btn-primary"
                [class.btn-warning]="editing"
                [disabled]="form.invalid">
            {{editing ? "Save" : "Create"}}
        </button>
        <button type="button" class="btn btn-secondary m-1" routerLink="/">
            Cancel
        </button>
    </div>
</form>
```

To create the guard, I added a file called unsaved.guard.ts in the src/app/core folder and defined the class shown in Listing 26-16.

Listing 26-16. The Contents of the unsaved.guard.ts File in the src/app/core Folder

```typescript
import { Injectable } from "@angular/core";
import {
    ActivatedRouteSnapshot, RouterStateSnapshot,
    Router
} from "@angular/router";
import { Observable, Subject } from "rxjs";
import { MessageService } from "../messages/message.service";
import { Message } from "../messages/message.model";
import { FormComponent } from "./form.component";
```

```
@Injectable()
export class UnsavedGuard {

    constructor(private messages: MessageService,
                private router: Router) { }

    canDeactivate(component: FormComponent, route: ActivatedRouteSnapshot,
        state: RouterStateSnapshot): Observable<boolean> | boolean {

        if (component.editing && component.unsavedChanges()) {
            let subject = new Subject<boolean>();

            let responses: [string, (r: string) => void][] = [
                ["Yes", () => {
                    subject.next(true);
                    subject.complete();
                }],
                ["No", () => {
                    this.router.navigateByUrl(this.router.url);
                    subject.next(false);
                    subject.complete();
                }]
            ];
            this.messages.reportMessage(new Message("Discard Changes?",
                true, responses));
            return subject;
        }
        return true;
    }
}
```

Deactivation guards define a class called `canDeactivate` that receives three arguments: the component that is about to be deactivated and the `ActivatedRouteSnapshot` and `RouteStateSnapshot` objects. This guard checks to see whether there are unsaved edits in the component and prompts the user if there are. For variety, this guard uses an `Observable<true>`, implemented as a `Subject<true>` instead of a `Promise<true>`, to tell Angular whether it should activate the route, based on the response selected by the user.

■ **Tip**   Notice that I call the `complete` method on the `Subject` after calling the `next` method. Angular will wait indefinitely for the `complete` method to be called, effectively freezing the application.

The next step is to register the guard as a service in the module that contains it, as shown in Listing 26-17.

Listing 26-17.   Registering the Guard as a Service in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
```

```
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
//import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";
import { RouterModule } from "@angular/router";
import { ProductCountComponent } from "./productCount.component";
import { CategoryCountComponent } from "./categoryCount.component";
import { NotFoundComponent } from "./notFound.component";
import { UnsavedGuard } from "./unsaved.guard";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule,
        RouterModule],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective, ProductCountComponent,
        CategoryCountComponent, NotFoundComponent],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [UnsavedGuard]
})
export class CoreModule { }
```

Finally, Listing 26-18 applies the guard to the application's routing configuration. Deactivation guards are applied to routes using the canDeactivate property, which is set to an array of guard services.

Listing 26-18. Applying the Guard in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";
import { TermsGuard } from "./terms.guard";
import { UnsavedGuard } from "./core/unsaved.guard";

const childRoutes: Routes = [
    {   path: "",
        canActivateChild: [TermsGuard],
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];
```

```
const routes: Routes = [
    {
        path: "form/:mode/:id", component: FormComponent,
        resolve: { model: ModelResolver },
        canDeactivate: [UnsavedGuard]
    },
    {
        path: "form/:mode", component: FormComponent,
        resolve: { model: ModelResolver },
        canActivate: [TermsGuard]
    },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

To see the effect of the guard, click one of the Edit buttons in the table; edit the data in one of the text fields; then click the Cancel, Next, or Previous button. The guard will prompt you before allowing Angular to activate the route you selected, as shown in Figure 26-8.

Figure 26-8. *Guarding route deactivation*

Loading Feature Modules Dynamically

Angular supports loading feature modules only when they are required, known as *dynamic loading* or *lazy loading*. This can be useful for functionality that is unlikely to be required by all users. In the sections that follow, I create a simple feature module and demonstrate how to configure the application so that Angular will load the module only when the application navigates to a specific URL.

■ **Note** Loading modules dynamically is a trade-off. The application will be smaller and faster to download for most users, improving their overall experience. But users who require the dynamically loaded features will have to wait while Angular gets the module and its dependencies. The effect can be jarring because the user has no idea that some features have been loaded and others have not. When you create dynamically loaded modules, you are balancing improving the experience for some users against making it worse for others. Consider how your users fall into these groups and take care not to degrade the experience of your most valuable and important customers.

Creating a Simple Feature Module

Dynamically loaded modules must contain only functionality that not all users require. I can't use the existing modules because they provide the core functionality for the application, which means that I need a new module for this part of the chapter. I started by creating a folder called ondemand in the src/app folder. To give the new module a component, I added a file called ondemand.component.ts in the example/app/ondemand folder and added the code shown in Listing 26-19.

■ **Caution** It is important not to create dependencies between other parts of the application and the classes in the dynamically loaded module so that the JavaScript module loader doesn't try to load the module before it is required.

Listing 26-19. The Contents of the ondemand.component.ts File in the src/app/ondemand Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "ondemand",
    templateUrl: "ondemand.component.html"
})
export class OndemandComponent { }
```

To provide the component with a template, I added a file called ondemand.component.html and added the markup shown in Listing 26-20.

Listing 26-20. The ondemand.component.html File in the src/app/ondemand Folder

```
<div class="bg-primary text-white p-2">This is the ondemand component</div>
<button class="btn btn-primary m-2" routerLink="/" >Back</button>
```

The template contains a message that will make it obvious when the component is selected and that contains a `button` element that will navigate back to the application's root URL when clicked.

To define the module, I added a file called `ondemand.module.ts` and added the code shown in Listing 26-21.

Listing 26-21. The Contents of the ondemand.module.ts File in the src/app/ondemand Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { OndemandComponent } from "./ondemand.component";

@NgModule({
    imports: [CommonModule],
    declarations: [OndemandComponent],
    exports: [OndemandComponent]
})
export class OndemandModule { }
```

The module imports the `CommonModule` functionality, which is used instead of the browser-specific `BrowserModule` to access the built-in directives in feature modules that are loaded on-demand.

Loading the Module Dynamically

There are two steps to set up dynamically loading a module. The first is to set up a routing configuration inside the feature module to provide the rules that will allow Angular to select a component when the module is loaded. Listing 26-22 adds a single route to the feature module.

Listing 26-22. Defining Routes in the ondemand.module.ts File in the src/app/ondemand Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { OndemandComponent } from "./ondemand.component";
import { RouterModule } from "@angular/router";

let routing = RouterModule.forChild([
    { path: "", component: OndemandComponent }
]);

@NgModule({
    imports: [CommonModule, routing],
    declarations: [OndemandComponent],
    exports: [OndemandComponent]
})
export class OndemandModule { }
```

Routes in dynamically loaded modules are defined using the same properties as in the main part of the application and can use all the same features, including child components, guards, and redirections. The route defined in the listing matches the empty path and selects the `OndemandComponent` for display.

One important difference is the method used to generate the module that contains the routing information, as follows:

```
...
let routing = RouterModule.forChild([
    { path: "", component: OndemandComponent }
]);
...
```

When I created the application-wide routing configuration, I used the `RouterModule.forRoot` method. This is the method that is used to set up the routes in the root module of the application. When creating dynamically loaded modules, the `RouterModule.forChild` method must be used; this method creates a routing configuration that is merged into the overall routing system when the module is loaded.

Creating a Route to Dynamically Load a Module

The second step to set up a dynamically loaded module is to create a route in the main part of the application that provides Angular with the module's location, as shown in Listing 26-23.

Listing 26-23. Creating an On-Demand Route in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";
import { TermsGuard } from "./terms.guard";
import { UnsavedGuard } from "./core/unsaved.guard";

const childRoutes: Routes = [
    {   path: "",
        canActivateChild: [TermsGuard],
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];

const routes: Routes = [
    {
        path: "ondemand",
        loadChildren: () => import("./ondemand/ondemand.module")
                                    .then(m => m.OndemandModule)
    },
    {
        path: "form/:mode/:id", component: FormComponent,
        resolve: { model: ModelResolver },
        canDeactivate: [UnsavedGuard]
    },
```

```
    {
        path: "form/:mode", component: FormComponent,
        resolve: { model: ModelResolver },
        canActivate: [TermsGuard]
    },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The `loadChildren` property is used to provide Angular with details of how the module should be loaded. The property is assigned a function that invokes `import`, passing in the path to the module. The result is a `Promise` whose `then` method is used to select the module after it has been imported. The function in the listing tells Angular to load the `OndemandModule` class from the `ondemand/ondemand.module` file.

Using a Dynamically Loaded Module

All that remains is to add support for navigating to the URL that will activate the route for the on-demand module, as shown in Listing 26-24, which adds a button to the template for the table component.

Listing 26-24. Adding Navigation in the table.component.html File in the src/app/core Folder

```
<div class="container-fluid">
    <!-- ...elements omitted for brevity... -->
</div>
<div class="p-2 text-center">
    <button class="btn btn-primary m-1" routerLink="/form/create">
        Create New Product
    </button>
    <button class="btn btn-danger m-1" (click)="deleteProduct(-1)">
        Generate HTTP Error
    </button>
    <button class="btn btn-danger m-1" routerLink="/does/not/exist">
        Generate Routing Error
    </button>
    <button class="btn btn-danger" routerLink="/ondemand">
        Load Module
    </button>
</div>
```

No special measures are required to target a route that loads a module, and the Load Module button in the listing uses the standard `routerLink` attribute to navigate to the URL specified by the route added in Listing 26-23.

Click the Load Module button, and you will see an HTTP request in the browser's F12 developer tools window for the new module. When the button is clicked, Angular uses the routing configuration to load the module, inspect its routing configuration, and select the component that will be displayed to the user, as shown in Figure 26-9.

Figure 26-9. *Loading a module dynamically*

Guarding Dynamic Modules

You can guard against dynamically loading modules to ensure that they are loaded only when the application is in a specific state or when the user has explicitly agreed to wait while Angular does the loading (this latter option is typically used only for administration functions, where the user can be expected to have some understanding of how the application is structured).

The guard for the module must be defined in the main part of the application, so I added a file called load.guard.ts in the src/app folder and defined the class shown in Listing 26-25.

Listing 26-25. The Contents of the load.guard.ts File in the src/app Folder

```
import { Injectable } from "@angular/core";
import { Route, Router } from "@angular/router";
import { MessageService } from "./messages/message.service";
import { Message } from "./messages/message.model";

@Injectable()
export class LoadGuard {
    private loaded: boolean = false;

    constructor(private messages: MessageService,
                private router: Router) { }

    canLoad(route: Route): Promise<boolean> | boolean {

        return this.loaded || new Promise<boolean>((resolve, reject) => {
            let responses: [string, (r: string) => void] [] = [
                ["Yes", () => {
```

```
                    this.loaded = true;
                    resolve(true);
                }],
                ["No", () => {
                    this.router.navigateByUrl(this.router.url);
                    resolve(false);
                }]
            ];

            this.messages.reportMessage(
                new Message("Do you want to load the module?",
                    false, responses));
        });
    }
}
```

Dynamic loading guards are classes that implement a method called `canLoad`, which is invoked when Angular needs to activate the route to which it is applied, and is provided with a `Route` object that describes the route.

The guard is required only when the URL that loads the module is first activated, so it defines a `loaded` property that is set to `true` when the module has been loaded so that subsequent requests are immediately approved. Otherwise, this guard follows the same pattern as earlier examples and returns a `Promise` that will be resolved when the user clicks one of the buttons displayed by the message service. Listing 26-26 registers the guard as a service in the root module.

Listing 26-26. Registering the Guard as a Service in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';
import { ModelModule } from "./model/model.module";
import { CoreModule } from "./core/core.module";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { MessageModule } from "./messages/message.module";
import { MessageComponent } from "./messages/message.component";
import { AppComponent } from './app.component';
import { routing } from "./app.routing";
import { TermsGuard } from "./terms.guard"
import { LoadGuard } from "./load.guard";

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, ModelModule, CoreModule, MessageModule, routing],
  providers: [TermsGuard, LoadGuard],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

Applying a Dynamic Loading Guard

Guards for dynamic loading are applied to routes using the canLoad property, which accepts an array of guard types. Listing 26-27 applies the LoadGuard class, which was defined in Listing 26-25, to the route that dynamically loads the module.

Listing 26-27. Guarding the Route in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { ProductCountComponent } from "./core/productCount.component";
import { CategoryCountComponent } from "./core/categoryCount.component";
import { ModelResolver } from "./model/model.resolver";
import { TermsGuard } from "./terms.guard";
import { UnsavedGuard } from "./core/unsaved.guard";
import { LoadGuard } from "./load.guard";

const childRoutes: Routes = [
    {   path: "",
        canActivateChild: [TermsGuard],
        children: [{ path: "products", component: ProductCountComponent },
                   { path: "categories", component: CategoryCountComponent },
                   { path: "", component: ProductCountComponent }],
        resolve: { model: ModelResolver }
    }
];

const routes: Routes = [
    {
        path: "ondemand",
        loadChildren: () => import("./ondemand/ondemand.module")
                                .then(m => m.OndemandModule),
        canLoad: [LoadGuard]
    },
    {
        path: "form/:mode/:id", component: FormComponent,
        resolve: { model: ModelResolver },
        canDeactivate: [UnsavedGuard]
    },
    {
        path: "form/:mode", component: FormComponent,
        resolve: { model: ModelResolver },
        canActivate: [TermsGuard]
    },
    { path: "does", redirectTo: "/form/create", pathMatch: "prefix" },
    { path: "table", component: TableComponent, children: childRoutes },
    { path: "table/:category", component: TableComponent, children: childRoutes },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }]

export const routing = RouterModule.forRoot(routes);
```

The result is that the user is prompted to determine whether they want to load the module the first time that Angular tries to activate the route, as shown in Figure 26-10.

Figure 26-10. *Guarding dynamic loading*

Targeting Named Outlets

A template can contain more than one router-outlet element, which allows a single URL to select multiple components to be displayed to the user.

To demonstrate this feature, I need to add two new components to the ondemand module. I started by creating a file called first.component.ts in the src/app/ondemand folder and using it to define the component shown in Listing 26-28.

Listing 26-28. The Contents of the first.component.ts File in the src/app/ondemand Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "first",
    template: `<div class="bg-primary text-white p-2">First Component</div>`
})
export class FirstComponent { }
```

This component uses an inline template to display a message whose purpose is simply to make it clear which component has been selected by the routing system. Next, I created a file called second.component.ts in the src/app/ondemand folder and created the component shown in Listing 26-29.

Listing 26-29. The Contents of the second.component.ts File in the src/app/ondemand Folder

```
import { Component } from "@angular/core";

@Component({
    selector: "second",
    template: `<div class="bg-info text-white p-2">Second Component</div>`
})
export class SecondComponent { }
```

This component is almost identical to the one in Listing 26-28, differing only in the message that it displays through its inline template.

Creating Additional Outlet Elements

When you are using multiple outlet elements in the same template, Angular needs some way to tell them apart. This is done using the name attribute, which allows an outlet to be uniquely identified, as shown in Listing 26-30.

Listing 26-30. Adding Outlets in the ondemand.component.html File in the src/app/ondemand Folder

```
<div class="bg-primary text-white p-2">This is the ondemand component</div>
<div class="container-fluid">
    <div class="row">
        <div class="col-12 p-2">
            <router-outlet></router-outlet>
        </div>
    </div>
    <div class="row">
        <div class="col-6 p-2">
            <router-outlet name="left"></router-outlet>
        </div>
        <div class="col-6 p-2">
            <router-outlet name="right"></router-outlet>
        </div>
    </div>
</div>
<button class="btn btn-primary m-2" routerLink="/">Back</button>
```
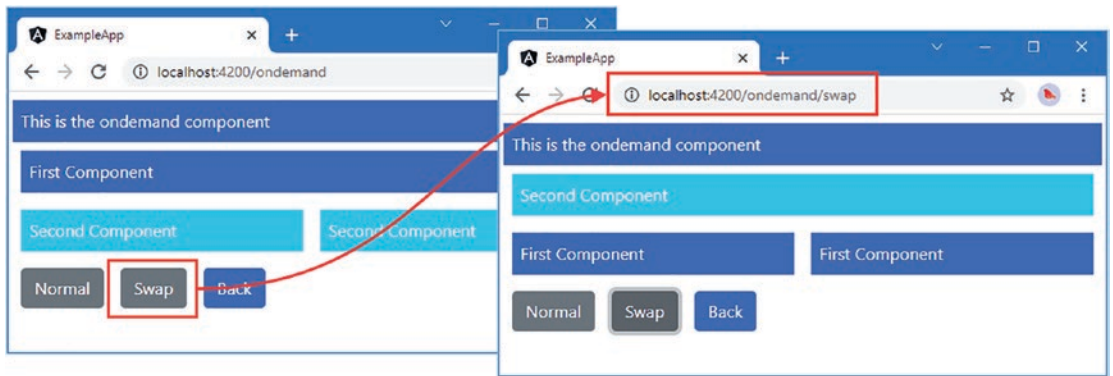

The new elements create three new outlets. There can be at most one router-outlet element without a name element, which is known as the *primary outlet*. This is because omitting the name attribute has the same effect as applying it with a value of primary. All the routing examples so far in this book have relied on the primary outlet to display components to the user.

All other router-outlet elements must have a name element with a unique name. The names I have used in the listing are left and right because the classes applied to the div elements that contain the outlets use CSS to position these two outlets side by side.

The next step is to create a route that includes details of which component should be displayed in each outlet element, as shown in Listing 26-31. If Angular can't find a route that matches a specific outlet, then no content will be shown in that element.

Listing 26-31. Targeting Outlets in the ondemand.module.ts File in the src/app/ondemand Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { OndemandComponent } from "./ondemand.component";
import { RouterModule } from "@angular/router";
import { FirstComponent } from "./first.component";
import { SecondComponent } from "./second.component";

let routing = RouterModule.forChild([
    {
        path: "",
        component: OndemandComponent,
        children: [
            { path: "",
              children: [
                  { outlet: "primary", path: "", component: FirstComponent, },
                  { outlet: "left", path: "", component: SecondComponent, },
                  { outlet: "right", path: "", component: SecondComponent, },
              ]},
        ]
    },
]);

@NgModule({
    imports: [CommonModule, routing],
    declarations: [OndemandComponent, FirstComponent, SecondComponent],
    exports: [OndemandComponent]
})
export class OndemandModule { }
```

The outlet property is used to specify the outlet element that the route applies to. The routing configuration in the listing matches the empty path for all three outlets and selects the newly created components for them: the primary outlet will display FirstComponent, and the left and right outlets will display SecondComponent, as shown in Figure 26-11. To see the effect yourself, click the Load Module button and click the Yes button when prompted. (If you don't see the expected content, reload the browser and try again.)

■ **Tip** If you omit the outlet property, then Angular assumes that the route targets the primary outlet. I tend to include the outlet property on all routes to emphasize which routes match an outlet element.

Figure 26-11. *Using multiple router outlets*

When Angular activates the route, it looks for matches for each outlet. All three of the new outlets have routes that match the empty path, which allows Angular to present the components shown in the figure.

Navigating When Using Multiple Outlets

Changing the components that are displayed by each outlet means creating a new set of routes and then navigating to the URL that contains them. Listing 26-32 sets up a route that will match the path /ondemand/ swap and that will switch the components displayed by the three outlets.

Listing 26-32. Setting Routes for Outlets in the ondemand.module.ts File in the src/app/ondemand Folder

```
import { NgModule } from "@angular/core";
import { CommonModule } from "@angular/common";
import { OndemandComponent } from "./ondemand.component";
import { RouterModule } from "@angular/router";
import { FirstComponent } from "./first.component";
import { SecondComponent } from "./second.component";
let routing = RouterModule.forChild([
    {
        path: "",
        component: OndemandComponent,
        children: [
            {
                path: "",
                children: [
                    { outlet: "primary", path: "", component: FirstComponent, },
                    { outlet: "left", path: "", component: SecondComponent, },
                    { outlet: "right", path: "", component: SecondComponent, },
                ]
            },
```

783

```
            {
                path: "swap",
                children: [
                    { outlet: "primary", path: "", component: SecondComponent, },
                    { outlet: "left", path: "", component: FirstComponent, },
                    { outlet: "right", path: "", component: FirstComponent, },
                ]
            },
        ]
    },
]);
@NgModule({
    imports: [CommonModule, routing],
    declarations: [OndemandComponent, FirstComponent, SecondComponent],
    exports: [OndemandComponent]
})
export class OndemandModule { }
```

Listing 26-33 adds button elements to the component's template that will navigate to the two sets of routes in Listing 26-32, alternating the set of components displayed to the user.

Listing 26-33. Navigating to Outlets in the ondemand.component.html File in the src/app/ondemand Folder

```html
<div class="bg-primary text-white p-2">This is the ondemand component</div>
<div class="container-fluid">
    <div class="row">
        <div class="col-12 p-2">
            <router-outlet></router-outlet>
        </div>
    </div>
    <div class="row">
        <div class="col-6 p-2">
            <router-outlet name="left"></router-outlet>
        </div>
        <div class="col-6 p-2">
            <router-outlet name="right"></router-outlet>
        </div>
    </div>
</div>
<button class="btn btn-secondary m-2" routerLink="/ondemand">Normal</button>
<button class="btn btn-secondary m-2" routerLink="/ondemand/swap">Swap</button>
<button class="btn btn-primary m-2" routerLink="/">Back</button>
```

The result is that clicking the Swap and Normal buttons will navigate to routes whose children tell Angular which components should be displayed by each of the outlet elements, as illustrated by Figure 26-12.

Figure 26-12. *Using navigation to target multiple outlet elements*

Summary

In this chapter, I finished describing the Angular URL routing features and explaining how to guard routes to control when a route is activated, how to load modules only when they are needed, and how to use multiple outlet elements to display components to the user. In the next chapter, I show you how to apply animations to Angular applications.

CHAPTER 27

■ ■ ■

Using Animations

In this chapter, I describe the Angular animation system, which uses data bindings to animate HTML elements to reflect changes in the state of the application. In broad terms, animations have two roles in an Angular application: to emphasize changes in content and to smooth them out.

Emphasizing changes is important when the content changes in a way that may not be obvious to the user. In the example application, using the Previous and Next buttons when editing a product changes the data fields but doesn't create any other visual change, which results in a transition that the user may not notice. Animations can be used to draw the eye to this kind of change, helping the user notice the results of an action.

Smoothing out changes can make an application more pleasant to use. When the user clicks the Edit button to start editing a product, the content displayed by the example application switches in a way that can be jarring. Using animations to slow down the transition can help provide a sense of context for the content change and make it less abrupt. In this chapter, I explain how the animation system works and how it can be used to draw the user's eye or take the edge off of sudden transitions. Table 27-1 puts Angular animations in context.

Table 27-1. *Putting Angular Animations in Context*

Question	Answer
What are they?	The animation system can change the appearance of HTML elements to reflect changes in the application state.
Why are they useful?	Used judiciously, animations can make applications more pleasant to use.
How are they used?	Animations are defined using functions defined in a platform-specific module, registered using the `animations` property in the `@Component` decorator and applied using a data binding.
Are there any pitfalls or limitations?	The main limitation is that Angular animations are fully supported by few browsers and, as a consequence, cannot be relied on to work properly on all the browsers that Angular supports for its other features.
Are there any alternatives?	The only alternative is not to animate the application.

Table 27-2 summarizes the chapter.

Table 27-2. *Chapter Summary*

Problem	Solution	Listing
Drawing the user's attention to a transition in the state of an element	Apply an animation	1–9
Animating the change from one element state to another	Use an element transition	9–14
Performing animations in parallel	Use animation groups	15
Using the same styles in multiple animations	Use common styles	16
Animating the position or size of elements	Use element transformations	17
Using animations to apply CSS framework styles	Use the DOM and CSS APIs	18–21

Preparing the Example Project

In this chapter, I continue using the exampleApp project that was first created in Chapter 20 and has been the focus of every chapter since. The changes in the following sections prepare the example application for the features described in this chapter.

■ **Tip**   You can download the example project for this chapter—and for all the other chapters in this book— from `https://github.com/Apress/pro-angular-5ed`. See Chapter 1 for how to get help if you have problems running the examples.

Disabling the HTTP Delay

The first preparatory step for this chapter is to disable the delay added to asynchronous HTTP requests, as shown in Listing 27-1.

Listing 27-1.   Disabling the Delay in the rest.datasource.ts File in the src/app/model Folder

```
import { Injectable, Inject, InjectionToken } from "@angular/core";
import { HttpClient, HttpHeaders } from "@angular/common/http";
import { catchError, delay, Observable } from "rxjs";
import { Product } from "./product.model";

export const REST_URL = new InjectionToken("rest_url");

@Injectable()
export class RestDataSource {
    constructor(private http: HttpClient,
        @Inject(REST_URL) private url: string) { }

    getData(): Observable<Product[]> {
        return this.sendRequest<Product[]>("GET", this.url);//.pipe(delay(5000));
    }
```

```
    saveProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("POST", this.url, product);
    }

    updateProduct(product: Product): Observable<Product> {
        return this.sendRequest<Product>("PUT",
            `${this.url}/${product.id}`, product);
    }

    deleteProduct(id: number): Observable<Product> {
        return this.sendRequest<Product>("DELETE", `${this.url}/${id}`);
    }

    private sendRequest<T>(verb: string, url: string, body?: Product)
        : Observable<T> {

        let myHeaders = new HttpHeaders();
        myHeaders = myHeaders.set("Access-Key", "<secret>");
        myHeaders = myHeaders.set("Application-Names", ["exampleApp", "proAngular"]);

        return this.http.request<T>(verb, url, {
            body: body,
            headers: myHeaders
        }).pipe(catchError((error: Response) => {
            throw(`Network Error: ${error.statusText} (${error.status})`)
        }));
    }
}
```

Simplifying the Table Template and Routing Configuration

Many of the examples in this chapter are applied to the elements in the table of products. The final preparation for this chapter is to simplify the template for the table component so that I can focus on a smaller amount of content in the listings.

Listing 27-2 shows the simplified template, which removes the buttons that generated HTTP and routing errors and the button and outlet element that counted the categories or products. The listing also removes the buttons that allow the table to be filtered by category.

Listing 27-2. Simplifying the Template in the table.component.html File in the src/app/core Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
    <tr>
        <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
        <th>Details</th><th></th>
    </tr>
    </thead>
    <tbody>
    <tr *ngFor="let item of getProducts()">
        <td>{{item.id}}</td>
        <td>{{item.name}}</td>
```

```
        <td>{{item.category}}</td>
        <td>{{item.price | currency:"USD" }}</td>
        <td>
            <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
            </ng-container>
            <ng-template #empty>(None)</ng-template>
        </td>
        <td class="text-center">
            <button class="btn btn-danger btn-sm m-1"
                    (click)="deleteProduct(item.id)">
                Delete
            </button>
            <button class="btn btn-warning btn-sm"
                    [routerLink]="['/form', 'edit', item.id]">
                Edit
            </button>
        </td>
    </tr>
    </tbody>
</table>

<div class="p-2 text-center">
    <button class="btn btn-primary m-1" routerLink="/form/create">
        Create New Product
    </button>
</div>
```

Listing 27-3 updates the URL routing configuration for the application so that the routes don't target the outlet element that has been removed from the table component's template.

Listing 27-3. Updating the Routing Configuration in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { UnsavedGuard } from "./core/unsaved.guard";

const routes: Routes = [
    {
        path: "form/:mode/:id", component: FormComponent,
        canDeactivate: [UnsavedGuard]
    },
    { path: "form/:mode", component: FormComponent },
    { path: "table", component: TableComponent },
    { path: "table/:category", component: TableComponent },
    { path: "", redirectTo: "/table", pathMatch: "full" },
    { path: "**", component: NotFoundComponent }
]

export const routing = RouterModule.forRoot(routes);
```

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the server that provides the RESTful web server:

```
npm run json
```

Open a separate command prompt, navigate to the exampleApp folder, and run the following command to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 27-1.

Figure 27-1. *Running the example application*

Getting Started with Angular Animation

As with most Angular features, the best place to start is with an example, which will let me introduce how animation works and how it fits into the rest of the Angular functionality. In the sections that follow, I create a basic animation that will affect the rows in the table of products. Once you have seen how the basic features work, I will dive into the details of each of the different configuration options and explain how they work in depth.

But to get started, I am going to add a `select` element to the application that allows the user to select a category. When a category is selected, the table rows for products in that category will be shown in one of two styles, as described in Table 27-3.

Table 27-3. *The Styles for the Animation Example*

Description	Styles
The product is in the selected category.	The table row will have a green background and larger text.
The product is not in the selected category.	The table row will have a red background and smaller text.

Enabling the Animation Module

The animation features are contained in their own module that must be imported in the application's root module, as shown in Listing 27-4.

Listing 27-4. Importing the Animation Module in the app.module.ts File in the src/app Folder

```
import { NgModule } from '@angular/core';
import { BrowserModule } from '@angular/platform-browser';
import { ModelModule } from "./model/model.module";
import { CoreModule } from "./core/core.module";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { MessageModule } from "./messages/message.module";
import { MessageComponent } from "./messages/message.component";
import { AppComponent } from './app.component';
import { routing } from "./app.routing";
import { TermsGuard } from "./terms.guard"
import { LoadGuard } from "./load.guard";
import { BrowserAnimationsModule } from "@angular/platform-browser/animations";

@NgModule({
  declarations: [AppComponent],
  imports: [BrowserModule, ModelModule, CoreModule, MessageModule, routing,
    BrowserAnimationsModule],
  providers: [TermsGuard, LoadGuard],
  bootstrap: [AppComponent]
})
export class AppModule { }
```

Creating the Animation

To get started with the animation, I created a file called `table.animations.ts` in the `src/app/core` folder and added the code shown in Listing 27-5.

Listing 27-5. The Contents of the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    transition("selected => notselected", animate("200ms")),
    transition("notselected => selected", animate("400ms"))
]);
```

The syntax used to define animations can be dense and relies on a set of functions defined in the @ angular/animations module. In the following sections, I start at the top and work my way down through the details to explain each of the animation building blocks used in the listing.

■ **Tip** Don't worry if all the building blocks described in the following sections don't make immediate sense. This is an area of functionality that starts to make more sense only when you see how all the parts fit together.

Defining Style Groups

The heart of the animation system is the style group, which is a set of CSS style properties and values that will be applied to an HTML element. Style groups are defined using the style function, which accepts a JavaScript object literal that provides a map between property names and values, like this:

```
...
style({
    backgroundColor: "lightgreen",
    fontSize: "20px"
})
...
```

This style group tells Angular to set the background color to lightgreen and to set the font size to 20 pixels.

CSS PROPERTY NAME CONVENTIONS

There are two ways to specify CSS properties when using the style function. You can use the JavaScript property naming convention, such that the property to set the background color of an element is specified as backgroundColor (all one word, no hyphens, and subsequent words capitalized). This is the convention I used in Listing 27-5:

```
...
style({
    backgroundColor: "lightgreen",
    fontSize: "20px"
})),
...
```

Alternatively, you can use the CSS convention, where the same property is expressed as `background-color` (all lowercase with hyphens between words). If you use the CSS format, then you must enclose the property names in quotes to stop JavaScript from trying to interpret the hyphens as arithmetic operators, like this:

```
...
state("green", style({
    "background-color": "lightgreen",
    "font-size": "20px"
})),
...
```

It doesn't matter which name convention you use, just as long as you are consistent. At the time of writing, Angular does not correctly apply styles if you mix and match property name conventions. To get consistent results, pick a naming convention and use it for all the style properties you set throughout your application.

Defining Element States

Angular needs to know when it needs to apply a set of styles to an element. This is done by defining an element state, which provides a name by which the set of styles can be referred. Element states are created using the `state` function, which accepts the name and the style set that should be associated with it. This is one of the two element states that are defined in Listing 27-5:

```
...
state("selected", style({
    backgroundColor: "lightgreen",
    fontSize: "20px"
})),
...
```

There are two states in the listing, called `selected` and `notselected`, which will correspond to whether the product described by a table row is in the category selected by the user.

Defining State Transitions

When an HTML element is in one of the states created using the `state` function, Angular will apply the CSS properties in the state's style group. The `transition` function is used to tell Angular how the new CSS properties should be applied. There are two transitions in Listing 27-5.

```
...
transition("selected => notselected", animate("200ms")),
transition("notselected => selected", animate("400ms"))
...
```

794

The first argument passed to the transition function tells Angular which states this instruction applies to. The argument is a string that specifies two states and an arrow that expresses the relationship between them. Two kinds of arrow are available, as described in Table 27-4.

Table 27-4. *The Animation Transition Arrow Types*

Arrow	Example	Description
=>	selected => notselected	This arrow specifies a one-way transition between two states, such as when the element moves from the selected state to the notselected state.
<=>	selected <=> notselected	This array specifies a two-way transition between two states, such as when the element moves from the selected state to the notselected state and from the notselected state to the selected state.

The transitions defined in Listing 27-5 use one-way arrows to tell Angular how it should respond when an element moves from the selected state to the notselected state and from the notselected state to the selected state.

The second argument to the transition function tells Angular what action it should take when the state change occurs. The animate function tells Angular to gradually transition between the properties defined in the CSS style set defined by two element states. The arguments passed to the animate function in Listing 27-5 specify the period of time that this gradual transition should take, either 200 milliseconds or 400 milliseconds.

GUIDANCE FOR APPLYING ANIMATIONS

Developers often get carried away when applying animations, resulting in applications that users find frustrating. Animations should be applied sparingly, they should be simple, and they should be quick. Use animations to help the user make sense of your application and not as a vehicle to demonstrate your artistic skills. Users, especially for corporate line-of-business applications, have to perform the same task repeatedly, and excessive and long animations just get in the way.

I suffer from this tendency, and, unchecked, my applications behave like Las Vegas slot machines. I have two rules that I follow to keep the problem under control. The first is that I perform the major tasks or workflows in the application 20 times in a row. In the case of the example application, that might mean creating 20 products and then editing 20 products. I remove or shorten any animation that I find myself having to wait to complete before I can move on to the next step in the process.

The second rule is that I don't disable animations during development. It can be tempting to comment out an animation when I am working on a feature because I will be performing a series of quick tests as I write the code. But any animation that gets in my way will also get in the user's way, so I leave the animations in place and adjust them—generally reducing their duration—until they become less obtrusive and annoying.

You don't have to follow my rules, of course, but it is important to make sure that the animations are helpful to the user and not a barrier to working quickly or a distracting annoyance.

Defining the Trigger

The final piece of plumbing is the animation trigger, which packages up the element states and transitions and assigns a name that can be used to apply the animation in a component. Triggers are created using the `trigger` function, like this:

```
...
export const HighlightTrigger = trigger("rowHighlight", [...])
...
```

The first argument is the name by which the trigger will be known, which is `rowHighlight` in this example, and the second argument is the array of states and transitions that will be available when the trigger is applied.

Applying the Animation

Once you have defined an animation, you can apply it to one or more components by using the `animations` property of the `@Component` decorator. Listing 27-6 applies the animation defined in Listing 27-5 to the table component and adds some additional features that are needed to support the animation.

Listing 27-6. Applying an Animation in the table.component.ts File in the src/app/core Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";
import { HighlightTrigger } from "./table.animations";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html",
    animations: [HighlightTrigger]
})
export class TableComponent {
    category: string | null = null;

    constructor(public model: Model, activeRoute: ActivatedRoute) {
        activeRoute.params.subscribe(params => {
            this.category = params["category"] || null;
        })
    }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts()
            .filter(p => this.category == null || p.category == this.category);
    }
```

```
    get categories(): (string) [] {
        return (this.model.getProducts()
            .map(p => p.category)
            .filter((c, index, array) => c != undefined
                && array.indexOf(c) == index)) as string[];
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    highlightCategory: string = "";

    getRowState(category: string | undefined): string {
        return this.highlightCategory == "" ? "" :
            this.highlightCategory == category ? "selected" : "notselected";
    }
}
```

The `animations` property is set to an array of triggers. You can define animations inline, but they can quickly become complex and make the entire component hard to read, which is why I used a separate file and exported a constant value from it, which I then assign to the `animations` property.

The other changes are to provide a mapping between the category selected by the user and the animation state that will be assigned to elements. The value of the `highlightCategory` property will be set using a `select` element and is used in the `getRowState` method to tell Angular which of the animation states defined in Listing 27-7 should be assigned based on a product category. If a product is in the selected category, then the method returns `selected`; otherwise, it returns `notselected`. If the user has not selected a category, then the empty string is returned.

The final step is to apply the animation to the component's template, telling Angular which elements are going to be animated, as shown in Listing 27-7. This listing also adds a `select` element that sets the value of the component's `highlightCategory` property using the `ngModel` binding.

Listing 27-7. Applying an Animation in the table.component.html File in the src/app/core Folder

```html
<div class="form-group bg-info text-white p-2">
    <label>Category</label>
    <select [(ngModel)]="highlightCategory" class="form-control">
        <option value="">None</option>
        <option *ngFor="let category of categories">
            {{category}}
        </option>
    </select>
</div>

<table class="table table-sm table-bordered table-striped">
    <thead>
    <tr>
        <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
        <th>Details</th><th></th>
    </tr>
    </thead>
```

```
    <tbody>
        <tr *ngFor="let item of getProducts()"
            [@rowHighlight]="getRowState(item.category)">
        <td>{{item.id}}</td>
        <td>{{item.name}}</td>
        <td>{{item.category}}</td>
        <td>{{item.price | currency:"USD" }}</td>
        <td>
            <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
            </ng-container>
            <ng-template #empty>(None)</ng-template>
        </td>
        <td class="text-center">
            <button class="btn btn-danger btn-sm m-1"
                    (click)="deleteProduct(item.id)">
                Delete
            </button>
            <button class="btn btn-warning btn-sm"
                    [routerLink]="['/form', 'edit', item.id]">
                Edit
            </button>
        </td>
    </tr>
    </tbody>
</table>

<div class="p-2 text-center">
    <button class="btn btn-primary m-1" routerLink="/form/create">
        Create New Product
    </button>
</div>
```

Animations are applied to templates using special data bindings, which associate an animation trigger with an HTML element. The binding's target tells Angular which animation trigger to apply, and the binding's expression tells Angular how to work out which state an element should be assigned to, like this:

```
...
<tr *ngFor="let item of getProducts()" [@rowHighlight]="getRowState(item.category)">
...
```

The target of the binding is the name of the animation trigger, prefixed with the @ character, which denotes an animation binding. This binding tells Angular that it should apply the rowHighlight trigger to the tr element. The expression tells Angular that it should invoke the component's getRowState method to work out which state the element should be assigned to, using the item.category value as an argument. Figure 27-2 illustrates the anatomy of an animation data binding for quick reference.

Figure 27-2. *The anatomy of an animation data binding*

Testing the Animation Effect

The changes in the previous section add a select element above the product table. To see the effect of the animation, restart the Angular development tools, request http://localhost:4200, and then select Soccer from the list at the top of the window. Angular will use the trigger to figure out which of the animation states each element should be applied to. Table rows for products in the Soccer category will be assigned to the selected state, while the other rows will be assigned to the notselected state, creating the effect shown in Figure 27-3.

Figure 27-3. *Selecting a product category*

The new styles are applied suddenly. To see a smoother transition, select the Chess category from the list, and you will see a gradual animation as the Chess rows are assigned to the selected state and the other rows are assigned to the notselected state. This happens because the animation trigger contains transitions between these states that tell Angular to animate the change in CSS styles, as illustrated in Figure 27-4. There is no transition for the earlier change, so Angular defaults to applying the new styles immediately.

■ **Tip**   It is impossible to capture the effect of animations in a series of screenshots, and the best I can do is present some of the intermediate states. This is a feature that requires firsthand experimentation to understand. I encourage you to download the project for this chapter from GitHub and create your own animations.

Figure 27-4. *A gradual transition between animation states*

To understand the Angular animation system, you need to understand the relationship between the different building blocks used to define and apply an animation, which can be described like this:

1.   Evaluating the data binding expression tells Angular which animation state the host element is assigned to.

2.   The data binding target tells Angular which animation target defines CSS styles for the element's state.

3. The state tells Angular which CSS styles should be applied to the element.

4. The transition tells Angular how it should apply CSS styles when evaluating the data binding expression results in a change to the element's state.

Keep these four points in mind as you read through the rest of the chapter, and you will find the animation system easier to understand.

Understanding the Built-in Animation States

Animation states are used to define the end result of an animation, grouping together the styles that should be applied to an element with a name that can be selected by an animation trigger. There are two built-in states that Angular provides that make it easier to manage the appearance of elements, as described in Table 27-5.

Table 27-5. *The Built-in Animation States*

State	Description
*	This is a fallback state that will be applied if the element isn't in any of the other states defined by the animation trigger.
void	Elements are in the void state when they are not part of the template. When the expression for an ngIf directive evaluates as false, for example, the host element is in the void state. This state is used to animate the addition and removal of elements, as described in the next section.

An asterisk (the * character) is used to denote a special state that Angular should apply to elements that are not in any of the other states defined by an animation trigger. Listing 27-8 adds the fallback state to the animations in the example application.

Listing 27-8. Using the Fallback State in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("*", style({
        border: "solid black 2px"
    })),
    transition("selected => notselected", animate("200ms")),
    transition("notselected => selected", animate("400ms"))
]);
```

In the example application, elements are assigned only to the `selected` or `notselected` state once the user has picked a value with the `select` element. The fallback state defines a style group that will be applied to elements until they are entered into one of the other states, as shown in Figure 27-5.

Figure 27-5. *Using the fallback state*

Understanding Element Transitions

The transitions are the real power of the animation system; they tell Angular how it should manage the change from one state to another. In the sections that follow, I describe different ways in which transitions can be created and used.

Creating Transitions for the Built-in States

The built-in states described in Table 27-5 can be used in transitions. The fallback state can be used to simplify the animation configuration by representing any state, as shown in Listing 27-9.

Listing 27-9. Using the Fallback State in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("*", style({
        border: "solid black 2px"
    })),
```

```
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms"))
]);
```

The transitions in the listing tell Angular how to deal with the change from any state into the `notselected` and `selected` states.

Animating Element Addition and Removal

The `void` state is used to define transitions for when an element is added to or removed from the template, as shown in Listing 27-10.

Listing 27-10. Using the Void State in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("void", style({
        opacity: 0
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms")),
    transition("void => *", animate("500ms"))
]);
```

This listing includes a definition for the `void` state that sets the `opacity` property to zero, which makes the element transparent and, as a consequence, invisible. There is also a transition that tells Angular to animate the change from the `void` state to any other state. The effect is that the rows in the table fade into view as the browser gradually increases the opacity value until the fill opacity is reached, as shown in Figure 27-6.

Figure 27-6. *Animating element addition*

Controlling Transition Animations

All the examples so far in this chapter have used the animate function in its simplest form, which is to specify how long a transition between two states should take, like this:

```
...
transition("void => *", animate("500ms"))
...
```

The string argument passed to the animate method can be used to exercise finer-grained control over the way that transitions are animated by providing an initial delay and specifying how intermediate values for the style properties are calculated.

EXPRESSING ANIMATION DURATIONS

Durations for animations are expressed using CSS time values, which are string values containing one or more numbers followed by either s for seconds or ms for milliseconds. This value, for example, specifies a duration of 500 milliseconds:

```
...
transition("void => *", animate("500ms"))
...
```

Durations are expressed flexibly, and the same value could be expressed as a fraction of a second, like this:

```
...
transition("void => *", animate("0.5s"))
...
```

My advice is to stick to one set of units throughout a project to avoid confusion, although it doesn't matter which one you use.

Specifying a Timing Function

The timing function is responsible for calculating the intermediate values for CSS properties during the transition. The timing functions, which are defined as part of the Web Animations specification, are described in Table 27-6.

Table 27-6. *The Animation Timing Functions*

Name	Description
linear	This function changes the value in equal amounts. This is the default.
ease-in	This function starts with small changes that increase over time, resulting in an animation that starts slowly and speeds up.
ease-out	This function starts with large changes that decrease over time, resulting in an animation that starts quickly and then slows down.
ease-in-out	This function starts with large changes that become smaller until the midway point, after which they become larger again. The result is an animation that starts quickly, slows down in the middle, and then speeds up again at the end.
cubic-bezier	This function is used to create intermediate values using a Bezier curve. See http://w3c.github.io/web-animations/#time-transformations for details.

Listing 27-11 applies a timing function to one of the transitions in the example application. The timing function is specified after the duration in the argument to the animate function.

Listing 27-11. Applying a Timing Function in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("void", style({
        opacity: 0
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms ease-in")),
    transition("void => *", animate("500ms"))
]);
```

Specifying an Initial Delay

An initial delay can be provided to the `animate` method, which can be used to stagger animations when there are multiple transitions being performed simultaneously. The delay is specified as the second value in the argument passed to the `animate` function, as shown in Listing 27-12.

Listing 27-12. Adding an Initial Delay in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("void", style({
        opacity: 0
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms 200ms ease-in")),
    transition("void => *", animate("500ms"))
]);
```

The 200-millisecond delay in this example corresponds to the duration of the animation used when an element transitions to the `notselected` state. The effect is that changing the selected category will show elements returning to the `notselected` state before the `selected` elements are changed.

Using Additional Styles During Transition

The `animate` function can accept a style group as its second argument, as shown in Listing 27-13. These styles are applied to the host element gradually, over the duration of the animation.

Listing 27-13. Defining Transition Styles in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("void", style({
        opacity: 0
    })),
```

```
    transition("* => notselected", animate("200ms")),
    transition("* => selected",
        animate("400ms 200ms ease-in",
            style({
                backgroundColor: "lightblue",
                fontSize: "25px"
            }))
    ),
    transition("void => *", animate("500ms"))
]);
```

The effect of this change is that when an element is transitioning into the selected state, its appearance will be animated so that the background color will be lightblue and its font size will be 25 pixels. At the end of the animation, the styles defined by the selected state will be applied all at once, creating a snap effect.

The sudden change in appearance at the end of the animation can be jarring. An alternative approach is to change the second argument of the transition function to an array of animations. This defines multiple animations that will be applied to the element in sequence, and as long as it doesn't define a style group, the final animation will be used to transition to the styles defined by the state. Listing 27-14 uses this feature to add two animations to the transition, the last of which will apply the styles defined by the selected state.

Listing 27-14. Using Multiple Animations in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate } from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("void", style({
        opacity: 0
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected",
        [animate("400ms 200ms ease-in",
            style({
                backgroundColor: "lightblue",
                fontSize: "25px"
            })),
            animate("250ms", style({
                backgroundColor: "lightcoral",
                fontSize: "30px"
            })),
            animate("200ms")]
    ),
    transition("void => *", animate("500ms"))
]);
```

There are three animations in this transition, and the last one will apply the styles defined by the selected state. Table 27-7 describes the sequence of animations.

Table 27-7. *The Sequence of Animations in the Transition to the selected State*

Duration	Style Properties and Values
400 milliseconds	backgroundColor: lightblue; fontSize: 25px
250 milliseconds	backgroundColor: lightcoral; fontSize: 30px
200 milliseconds	backgroundColor: lightgreen; fontSize: 20px

Pick a category using the select element to see the sequence of animations. Figure 27-7 shows one frame from each animation.

Figure 27-7. *Using multiple animations in a transition*

Performing Parallel Animations

Angular can perform animations at the same time, which means you can have different CSS properties change over different time periods. Parallel animations are passed to the group function, as shown in Listing 27-15.

Listing 27-15. Performing Parallel Animations in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate, group }
    from "@angular/animations";

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style({
        backgroundColor: "lightgreen",
        fontSize: "20px"
    })),
```

```
    state("notselected", style({
        backgroundColor: "lightsalmon",
        fontSize: "12px"
    })),
    state("void", style({
        opacity: 0
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected",
        [animate("400ms 200ms ease-in",
            style({
                backgroundColor: "lightblue",
                fontSize: "25px"
            })),
            group([
                animate("250ms", style({
                    backgroundColor: "lightcoral",
                })),
                animate("450ms", style({
                    fontSize: "30px"
                })),
            ]),
            animate("200ms")]
    ),
    transition("void => *", animate("500ms"))
]);
```

The listing replaces one of the animations in sequence with a pair of parallel animations. The animations for the backgroundColor and fontSize properties will be started at the same time but last for differing durations. When both of the animations in the group have completed, Angular will move on to the final animation, which will target the styles defined in the state.

Understanding Animation Style Groups

The outcome of an Angular animation is that an element is put into a new state and styled using the properties and values in the associated style group. In this section, I explain some different ways in which style groups can be used.

■ **Tip** Not all CSS properties can be animated, and of those that can be animated, some are handled better by the browser than others. As a rule of thumb, the best results are achieved with properties whose values can be easily interpolated, which allows the browser to provide a smooth transition between element states. This means you will usually get good results using properties whose values are colors or numerical values, such as background, text and font colors, opacity, element sizes, and borders. See `https://www.w3.org/TR/css3-transitions/#animatable-properties` for a complete list of properties that can be used with the animation system.

809

Defining Common Styles in Reusable Groups

As you create more complex animations and apply them throughout your application, you will inevitably find that you need to apply some common CSS property values in multiple places. The `style` function can accept an array of objects, all of which are combined to create the overall set of styles in the group. This means you can reduce duplication by defining objects that contain common styles and use them in multiple style groups, as shown in Listing 27-16. (To keep the example simple, I have also removed the sequence of styles defined in the previous section.)

Listing 27-16. Defining Common Styles in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate, group }
    from "@angular/animations";

const commonStyles = {
    border: "black solid 4px",
    color: "white"
};

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style([commonStyles, {
        backgroundColor: "lightgreen",
        fontSize: "20px"
    }])),
    state("notselected", style([commonStyles, {
        backgroundColor: "lightsalmon",
        fontSize: "12px",
        color: "black"
    }])),
    state("void", style({
        opacity: 0
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms 200ms ease-in")),
    transition("void => *", animate("500ms"))
]);
```

The `commonStyles` object defines values for the `border` and `color` properties and is passed to the `style` function in an array along with the regular style objects. Angular processes the style objects in order, which means you can override a style value by redefining it in a later object. As an example, the second style object for the `notselected` state overrides the common value for the `color` property with a custom value. The result is that the styles for both animation states incorporate the common value for the `border` property, and the styles for the `selected` state also use the common value for the `color` property, as shown in Figure 27-8.

Figure 27-8. *Defining common properties*

Using Element Transformations

All the examples so far in this chapter have animated properties that have affected an aspect of an element's appearance, such as background color, font size, or opacity. Animations can also be used to apply CSS element transformation effects, which are used to move, resize, rotate, or skew an element. These effects are applied by defining a transform property in a style group, as shown in Listing 27-17.

Listing 27-17. Using an Element Transformation in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate, group }
    from "@angular/animations";

const commonStyles = {
    border: "black solid 4px",
    color: "white"
};

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style([commonStyles, {
        backgroundColor: "lightgreen",
        fontSize: "20px"
    }])),
    state("notselected", style([commonStyles, {
        backgroundColor: "lightsalmon",
        fontSize: "12px",
        color: "black"
    }])),
    state("void", style({
        transform: "translateX(-50%)"
    })),
```

```
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms 200ms ease-in")),
    transition("void => *",  animate("500ms"))
]);
```

The value of the `transform` property is `translateX(50%)`, which tells Angular to move the element 50 percent of its length along the x-axis. The `transform` property has been applied to the `void` state, which means that it will be used on elements as they are being added to the template. The animation contains a transition from the `void` state to any other state and tells Angular to animate the changes over 500 milliseconds. The result is that new elements will be shifted to the left initially and then slid back into their default position over a period of half a second, as illustrated in Figure 27-9.

Figure 27-9. *Transforming an element*

Table 27-8 describes the set of transformations that can be applied to elements.

■ **Tip** Multiple transformations can be applied in a single `transform` property by separating them with spaces, like this: `transform: "scale(1.1, 1.1) rotate(10deg)"`.

Table 27-8. *The CSS Transformation Functions*

Function	Description
`translateX(offset)`	This function moves the element along the x-axis. The amount of movement can be specified as a percentage or as a length (expressed in pixels or one of the other CSS length units). Positive values translate the element to the right, negative values to the left.
`translateY(offset)`	This function moves the element along the y-axis.
`translate(xOffset, yOffset)`	This function moves the element along both axes.

(continued)

Table 27-8. *(continued)*

Function	Description
scaleX(amount)	This function scales the element along the x-axis. The scaling size is expressed as a fraction of the element's regular size, such that 0.5 reduces the element to 50 percent of the original width and 2.0 will double the width.
scaleY(amount)	This function scales the element along the y-axis.
scale(xAmount, yAmount)	This function scales the element along both axes.
rotate(angle)	This function rotates the element clockwise. The amount of rotation is expressed as an angle, such as 90deg or 3.14rad.
skewX(angle)	This function skews the element along the x-axis by a specified angle, expressed in the same way as for the rotate function.
skewY(angle)	This function skews the element along the y-axis by a specified angle, expressed in the same way as for the rotate function.
skew(xAngle, yAngle)	This function skews the element along both axes.

Applying CSS Framework Styles

If you are using a CSS framework like Bootstrap, you may want to apply classes to elements, rather than having to define groups of properties. There is no built-in support for working directly with CSS classes, but the Document Object Model (DOM) and the CSS Object Model (CSSOM) provide API access to inspect the CSS stylesheets that have been loaded and to see whether they apply to an HTML element. To get the set of styles defined by classes, I created a file called animationUtils.ts to the src/app/core folder and added the code shown in Listing 27-18.

■ **Caution** This technique can require substantial processing in an application that uses a lot of complex stylesheets, and you may need to adjust the code to work with different browsers and different CSS frameworks.

Listing 27-18. The Contents of the animationUtils.ts File in the src/app/core Folder

```
export const stateClassMap : {[key: string]: string[] | string} = {
    selected: ["table-success", "h2"],
    notselected: ["table-info"]
};

export function getStylesFromClasses(names: string | string[],
    elementType: string = "div") : { [key: string]: string | number } {
    return findStylesOrProps(names, elementType, (name) => !name.startsWith("--"))
}

export function setPropertiesFromClasses(state: string,  target: HTMLElement)  {
    let props = findStylesOrProps(stateClassMap[state], "div",
        (name) => name.startsWith("--"));
```

```
    Object.keys(props).forEach(k => {
        target.style.setProperty(k, props[k]);
    })
}

function findStylesOrProps(names: string | string[], elementType: string,
        selector: (name: string) => boolean) : { [key: string]: string  } {

    let elem = document.createElement(elementType);
    (typeof names == "string" ? [names] : names)
        .forEach(c => elem.classList.add(c));

    let result : { [key: string]: string } = {};

    for (let i = 0; i < document.styleSheets.length; i++) {
        let sheet = document.styleSheets[i] as CSSStyleSheet;
        let rules = sheet.cssRules || sheet.cssRules;
        for (let j = 0; j < rules.length; j++) {
            if (rules[j] instanceof CSSStyleRule) {
                let styleRule = rules[j] as CSSStyleRule;
                if (elem.matches(styleRule.selectorText)) {
                    for (let k = 0; k < styleRule.style.length; k++) {
                        let name = styleRule.style[k];
                        if (selector(name)) {
                            result[name] = styleRule.style.getPropertyValue(name);
                        }
                    }
                }
            }
        }
    }
    return result;
}
```

The getStylesFromClass method accepts a single class name or an array of class names and the element type to which they should be applied, which defaults to a div element. An element is created and assigned to the classes and then inspected to see which of the CSS rules defined in the CSS stylesheets apply to it. One complication of applying the Bootstrap styles in an animation is they rely on custom CSS properties, which are not supported for animation. To work around this issue, the getStylesFromClasses method skips styles whose name begins with --, and the setPropertiesFromClasses is used to set these properties on the element to be animated. This is an inefficient and error-prone approach, but it is the best that I have been able to find. I hope future releases of Angular will address this problem directly.

The style properties for each matching style are added to an object that can be used to create Angular animation style groups, as shown in Listing 27-19.

Listing 27-19. Using Bootstrap Classes in the table.animations.ts File in the src/app/core Folder

```
import { trigger, style, state, transition, animate, group }
    from "@angular/animations";
import { getStylesFromClasses, stateClassMap } from "./animationUtils";
```

```
// const commonStyles = {
//      border: "black solid 4px",
//      color: "white"
// };

export const HighlightTrigger = trigger("rowHighlight", [
    state("selected", style(getStylesFromClasses(stateClassMap["selected"]))),
    state("notselected", style(getStylesFromClasses(stateClassMap["notselected"]))),
    state("void", style({
        transform: "translateX(-50%)"
    })),
    transition("* => notselected", animate("200ms")),
    transition("* => selected", animate("400ms 200ms ease-in")),
    transition("void => *",  animate("500ms"))
]);
```

The selected state and unselected states use the styles defined in Listing 27-18. To ensure that the custom properties are set correctly, Listing 27-20 updates the table component.

Listing 27-20. Setting Custom Properties in the table.component.ts File in the src/app/core Folder

```
import { Component, ElementRef } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";
import { HighlightTrigger } from "./table.animations";
import { setPropertiesFromClasses, stateClassMap } from "./animationUtils";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html",
    animations: [HighlightTrigger]
})
export class TableComponent {
    category: string | null = null;

    constructor(public model: Model, activeRoute: ActivatedRoute) {
        activeRoute.params.subscribe(params => {
            this.category = params["category"] || null;
        })
    }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts()
            .filter(p => this.category == null || p.category == this.category);
    }
```

```
    get categories(): (string) [] {
        return (this.model.getProducts()
            .map(p => p.category)
            .filter((c, index, array) => c != undefined
                && array.indexOf(c) == index)) as string[];
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    highlightCategory: string = "";

    getRowState(category: string | undefined, elem: HTMLTableRowElement): string {
        let state = this.highlightCategory == "" ? "" :
            this.highlightCategory == category ? "selected" : "notselected"
        if (state != "") {
            setPropertiesFromClasses(state, elem);
        }
        return state;
    }
}
```

The getRowState method has been modified to receive the element that is being modified. Listing 27-21 updates the template to provide the additional argument using a template variable.

Listing 27-21. Adding a Template Variable in the table.component.html File in the src/app/core Folder

```
...
<tbody>
    <tr *ngFor="let item of getProducts()" #elem
        [@rowHighlight]="getRowState(item.category, elem)">
    <td>{{item.id}}</td>
    <td>{{item.name}}</td>
...
```

The effect is that the Bootstrap styles are applied to the rows in the table, based on the selected category, as shown in Figure 27-10.

Figure 27-10. *Using CSS framework styles in Angular animations*

Summary

I described the Angular animation system in this chapter and explained how it uses data bindings to animate changes in the application's state. In the next chapter, I describe the features that Angular provides to support unit testing.

CHAPTER 28

■ ■ ■

Working with Component Libraries

Component libraries are packages that contain Angular components and directives, such as buttons, tables, and layouts. Throughout this book, I have been creating custom components and directives to demonstrate Angular features, but component libraries use these same features to provide building blocks that you can use to simplify the development process.

One of the recurring themes in this book is that nothing in Angular is magic, and this extends to component libraries, which are written using the same features that you used in earlier chapters. Component libraries are useful because they mean you don't have to write code and templates for basic tasks, such as creating a button, for example, and can focus on dealing with what happens when the user clicks the button.

In this chapter, I use the Angular Material component library to add components to the project and explain how to use CSS to give a custom component an appearance that is consistent with the library components. Table 28-1 puts the use of component libraries in context.

■ **Note** This chapter is not a detailed description of Angular Material or any other component library. There are several good component libraries available for Angular and each has its own set of features and its own API.

Table 28-1. *Putting Component Libraries in Context*

Question	Answer
What are they?	Component libraries are packages containing commonly required user interface features for Angular applications.
Why are they useful?	Component libraries can speed up project development and ensure a consistent appearance in the finished application.
How are they used?	Features are presented as Angular components or directives, which are applied in the same way as custom components and directives.
Are there any pitfalls or limitations?	Component libraries can require data to be presented in a specific way or for the application to be structured using a specific pattern. These restrictions may not suit all projects.
Are there any alternatives?	Component libraries are entirely optional and are not required for Angular development.

Table 28-2 summarizes the chapter.

Table 28-2. *Chapter Summary*

Problem	Solution	Listing
Applying the features provided by a component library	Use the components or directives provided contained in the library package	4–11
Using the advanced features provided by a component library	Adopt the structure or API that the component library provides for integration	12–15
Styling custom components to match the theme used by the component library	Use the CSS styles provided by the component library, which are typically provided for use with Sass	16–24

Preparing for This Chapter

In this chapter, I continue using the exampleApp project that was first created in Chapter 20 and has been the focus of every chapter since. To prepare for this chapter, Listing 28-1 removes the animations added in Chapter 27 and simplifies the table component to remove features that are no longer required.

■ **Tip** You can download the example project for this chapter—and for all the other chapters in this book—from https://github.com/Apress/pro-angular-5ed. See Chapter 1 for how to get help if you have problems running the examples.

Listing 28-1. Simplifying the Component in the table.component.ts File in the src/app/core Folder

```
import { Component, ElementRef } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";
// import { HighlightTrigger } from "./table.animations";
// import { setPropertiesFromClasses, stateClassMap } from "./animationUtils";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html",
    // animations: [HighlightTrigger]
})
export class TableComponent {
    category: string | null = null;

    constructor(public model: Model, activeRoute: ActivatedRoute) {
        activeRoute.params.subscribe(params => {
            this.category = params["category"] || null;
        })
    }
```

```
    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts()
            // .filter(p => this.category == null || p.category == this.category);
    }

    // get categories(): (string) [] {
    //     return (this.model.getProducts()
    //         .map(p => p.category)
    //         .filter((c, index, array) => c != undefined
    //             && array.indexOf(c) == index)) as string[];
    // }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    // highlightCategory: string = "";

    // getRowState(category: string | undefined, elem: HTMLTableRowElement): string {

    //     let state = this.highlightCategory == "" ? "" :
    //         this.highlightCategory == category ? "selected" : "notselected"
    //     if (state != "") {
    //         setPropertiesFromClasses(state, elem);
    //     }
    //     return state
    // }
}
```

Listing 28-2 makes the corresponding changes to the template.

Listing 28-2. Simplifying the Template in the table.component.html File in the src/app/core Folder

```
<!-- <div class="form-group bg-info text-white p-2">
    <label>Category</label>
    <select [(ngModel)]="highlightCategory" class="form-control">
        <option value="">None</option>
        <option *ngFor="let category of categories">
            {{category}}
        </option>
    </select>
</div> -->

<table class="table table-sm table-bordered table-striped">
    <thead>
    <tr>
```

```
        <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
        <th>Details</th><th></th>
    </tr>
    </thead>
    <tbody>
        <tr *ngFor="let item of getProducts()">
        <td>{{item.id}}</td>
        <td>{{item.name}}</td>
        <td>{{item.category}}</td>
        <td>{{item.price | currency:"USD" }}</td>
        <td>
            <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
            </ng-container>
            <ng-template #empty>(None)</ng-template>
        </td>
        <td class="text-center">
            <button class="btn btn-danger btn-sm m-1"
                    (click)="deleteProduct(item.id)">
                Delete
            </button>
            <button class="btn btn-warning btn-sm"
                    [routerLink]="['/form', 'edit', item.id]">
                Edit
            </button>
        </td>
    </tr>
    </tbody>
</table>

<div class="p-2 text-center">
    <button class="btn btn-primary m-1" routerLink="/form/create">
        Create New Product
    </button>
</div>
```

Installing the Component Library

Open a new command prompt, navigate to the exampleApp folder, and run the following command to
download and install the Angular Material package:

```
ng add @angular/material@13.0.2
```

The Angular Material package uses the schematics API to configure the project. The installation process presents several queries, the first of which is to confirm the package installation:

```
Using package manager: npm
Package information loaded.
The package @angular/material@13.0.2 will be installed and executed.
Would you like to proceed? (Y/n)
```

Press Y to confirm the installation. Select the default option for the remaining questions to complete the installation.

CHOOSING A COMPONENT LIBRARY

I have used Angular Material because it is the most popular Angular component library. There are several other packages available. Teradata Covalent (https://teradata.github.io/covalent) is an open-source library that follows the same Material Design standard as Angular Material, but with the addition of good charting components. Some packages present the features of the Bootstrap CSS package using Angular features, such as ng-bootstrap (https://ng-bootstrap.github.io) and ngx-bootstrap (https://valor-software.com/ngx-bootstrap), and each provides a different approach to developing components. There are also commercial packages, such as Kendo UI (https://www.telerik.com/kendo-angular-ui), which can be useful for development teams that require support.

If you don't know where to start, then try Angular Material. The documentation (https://material.angular.io) is good, and the package contains the components required by most projects.

Adjusting the HTML File

Installing the Angular Material package requires a change to the index.html file to resolve a conflict with the Bootstrap CSS styles that causes a scrollbar to be displayed even when the content fits within the browser window, caused by styles added to the styles.css file. Listing 28-3 changes the class to which the body element is assigned to resolve the issue.

Listing 28-3. Changing an Element Class in the index.html File in the src Folder

```
<!doctype html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <title>ExampleApp</title>
    <base href="/">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <link rel="icon" type="image/x-icon" href="favicon.ico">
    <link rel="preconnect" href="https://fonts.gstatic.com">
    <link href=
  "https://fonts.googleapis.com/css2?family=Roboto:wght@300;400;500&display=swap"
        rel="stylesheet">
    <link href="https://fonts.googleapis.com/icon?family=Material+Icons"
        rel="stylesheet">
</head>
```

```
<body class="p-1">
    <app-root></app-root>
</body>
</html>
```

Running the Project

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the server that provides the RESTful web server:

```
npm run json
```

Open a separate command prompt, navigate to the exampleApp folder, and run the following command to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 28-1.

Figure 28-1. *Running the example application*

Using the Library Components

The simplest approach to using a component library is, as you might expect, to use the components it provides. In this section, I demonstrate how to integrate two features from the Angular Material library into the example project.

Using the Angular Button Directive

The Angular Material support for buttons is provided as a directive applied to button or anchor elements, as shown in Listing 28-4.

Listing 28-4. Using the Angular Material Button in the table.component.html File in the src/app/ core Folder

```
<table class="table table-sm table-bordered table-striped">
    <thead>
    <tr>
        <th>ID</th><th>Name</th><th>Category</th><th>Price</th>
        <th>Details</th><th></th>
    </tr>
    </thead>
    <tbody>
        <tr *ngFor="let item of getProducts()">
        <td>{{item.id}}</td>
        <td>{{item.name}}</td>
        <td>{{item.category}}</td>
        <td>{{item.price | currency:"USD" }}</td>
        <td>
            <ng-container *ngIf="item.details else empty">
                {{ item.details?.supplier }}, {{ item.details?.keywords}}
            </ng-container>
            <ng-template #empty>(None)</ng-template>
        </td>
        <td class="text-center">
            <button mat-flat-button color="accent" (click)="deleteProduct(item.id)">
                Delete
            </button>
            <button mat-flat-button color="warn"
                    [routerLink]="['/form', 'edit', item.id]">
                Edit
            </button>
        </td>
    </tr>
    </tbody>
</table>

<div class="p-2 text-center">
    <button mat-flat-button color="primary" routerLink="/form/create">
        Create New Product
    </button>
</div>
```

Angular Material provides several different styles of button, which are applied using the attributes described in Table 28-3.

Table 28-3. *The Angular Material Button Attributes*

Name	Description
mat-button	This attribute creates a simple borderless button, whose text is styled using an Angular Material theme color.
mat-stroked-button	This attribute adds a rectangular border to the mat-button style.
mat-raised-button	This attribute creates a button that appears to be raised from the page, displayed with a small amount of shadow. The button background is styled using an Angular Material theme color.
mat-flat-button	This attribute creates a button without the raised shadow and whose background is styled using an Angular Material theme color.
mat-icon-button	This attribute creates a button with a transparent background, intended to display an icon, which is styled using an Angular Material theme color.
mat-fab	This attribute creates a circular button with a shadow, whose background is styled using an Angular Material theme color.
mat-mini-fab	This button creates a small circular button with a shadow and a background styled using an Angular Material theme color.

Angular Material uses a color theme that is selected when the package is installed and which defines three color names, as described in Table 28-4.

Table 28-4. *The Angular Material Color Names*

Name	Description
primary	This name refers to the color used most often throughout the application.
accent	This name refers to the color used to highlight key parts of the user interface.
warn	This name refers to the color used for warnings and errors or to denote operations that require caution.

In Listing 28-4, I applied the mat-flat-button attribute, which will create a button whose appearance most closely matches the buttons I created using the Bootstrap styles. The theme color is specified using the color attribute, like this:

```
...
<button mat-flat-button color="accent" (click)="deleteProduct(item.id)">
...
```

The Angular Material button is applied to a regular HTML button element, which means that the click event is used to respond to user interaction.

Adding the Margin Style

Angular Material doesn't include utility styles for adding margins or padding to elements. Listing 28-5 defines a new global style that adds space around flat buttons.

■ **Caution** You may be tempted to mix and match styles from different packages, such as applying the Bootstrap `m-1` style to button elements to which the `mat-flat-button` attribute has been added. Care must be taken because package styles are rarely written with this kind of combination in mind and there can be odd interactions.

Listing 28-5. Adding Styles in the styles.css File in the src Folder

```
html, body { height: 100%; }
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }
```

`button.mat-flat-button { margin: 2px; }`

Angular Material adds elements to classes that correspond to the attribute names described in Table 28-3, which means that I can use class selectors to locate button elements and apply a margin.

Importing the Component Module

Angular Material uses separate modules for each feature, which means that an application includes only the features it requires and doesn't add unused code to the download required by the client.

In a complex project, there can be a large number of dependencies on a component library, and they can be spread throughout the project's modules. To make it easier to manage the dependencies, it is a good idea to use a separate module. Add a file named material.module.ts in the src/app folder with the content shown in Listing 28-6.

Listing 28-6. The Contents of the material.module.ts File in the src/app Folder

```
import { NgModule } from "@angular/core";
import { MatButtonModule } from "@angular/material/button";

const features = [MatButtonModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

The `MaterialFeatures` module imports and exports the `MatButtonModule` module from the Angular Material package. Listing 28-7 adds a dependency on the new module, which will be the only change to the core module to enable Angular Material features.

Listing 28-7. Importing a Module in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
//import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";
import { RouterModule } from "@angular/router";
import { ProductCountComponent } from "./productCount.component";
import { CategoryCountComponent } from "./categoryCount.component";
import { NotFoundComponent } from "./notFound.component";
import { UnsavedGuard } from "./unsaved.guard";
import { MaterialFeatures } from "../material.module"

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule,
        RouterModule, MaterialFeatures],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective, ProductCountComponent,
        CategoryCountComponent, NotFoundComponent],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [UnsavedGuard]
})
export class CoreModule { }
```

Save the changes, and the Angular Material button will be displayed when the application is reloaded, as shown in Figure 28-2.

Figure 28-2. *Using a component library*

The Angular Material button feature is simple, but it shows the basic pattern to follow when using a component from a package: apply the component, add some tuning CSS styles, and import the feature module.

■ **Note** Styles provided by the Bootstrap CSS package are still being used in the example, with classes such as `p-2` and `text-center`, which are used to center content and add padding. Most projects will use a single package, but Bootstrap and Angular Material will coexist.

Using the Angular Material Table

Buttons are relatively simple, and the main benefit of using the Angular Material button is consistency. Other components are more complex and provide more features, such as tables. Listing 28-8 removes the Bootstrap CSS styles from the table that displays product details and introduces the Angular Material table feature.

Listing 28-8. Changing the Table in the table.component.html File in the src/app/core Folder

```html
<table mat-table [dataSource]="getProducts()">

    <mat-text-column name="id"></mat-text-column>
    <mat-text-column name="name"></mat-text-column>
    <mat-text-column name="category"></mat-text-column>

    <ng-container matColumnDef="price">
      <th mat-header-cell *matHeaderCellDef>Price</th>
      <td mat-cell *matCellDef="let item"> {{item.price | currency:"USD"}} </td>
    </ng-container>

    <ng-container matColumnDef="details">
      <th mat-header-cell *matHeaderCellDef>Details</th>
      <td mat-cell *matCellDef="let item">
          <ng-container *ngIf="item.details else empty">
              {{ item.details?.supplier }}, {{ item.details?.keywords}}
          </ng-container>
          <ng-template #empty>(None)</ng-template>
      </td>
    </ng-container>

    <ng-container matColumnDef="buttons">
      <th mat-header-cell *matHeaderCellDef></th>
      <td mat-cell *matCellDef="let item">
          <button mat-flat-button color="accent"
                  (click)="deleteProduct(item.id)">
              Delete
          </button>
          <button mat-flat-button color="warn"
                  [routerLink]="['/form', 'edit', item.id]">
              Edit
          </button>
      </td>
    </ng-container>

    <tr mat-header-row *matHeaderRowDef="colsAndRows"></tr>
    <tr mat-row *matRowDef="let row; columns: colsAndRows"></tr>
</table>

<div class="p-2 text-center">
    <button mat-flat-button color="primary" routerLink="/form/create" >
        Create New Product
    </button>
</div>
```

Angular Material tables are created by applying the `mat-table` attribute to a table element and creating
a `dataSource` data binding that selects an array of values to display.

Angular Material focuses on defining columns to describe the contents of a table. A `mat-text-column`
element is used for simple columns, where the column header is the name of the data property and the
value is displayed without modification, like this:

```
...
<mat-text-column name="id"></mat-text-column>
...
```

The `name` attribute selects the property to be displayed and sets the name by which the column is identified. For more complex columns, the `matColumnDef` attribute is applied to an `ng-container` element that contains `th` and `td` elements that are included in the table head and body, respectively:

```
...
<ng-container matColumnDef="price">
    <th mat-header-cell *matHeaderCellDef>Price</th>
    <td mat-cell *matCellDef="let item"> {{item.price | currency:"USD"}} </td>
</ng-container>
...
```

The `th` element is given the `mat-header-cell` attribute, and the concise syntax is used to apply the `matHeaderCellDef` directive. The `td` element is given the `mat-cell` attribute, and the `matCellDef` directive is used to create an expression that selects the data used to create the contents of a table cell. There is an implicit value that provides the current data value, and, for the `price` column, this is formatted as a currency value using a pipe. This approach allows data values to be formatted or composed from multiple data source properties.

If you jump directly to using a component library without taking the time to understand how Angular works, the steps required to set up complex features can be impenetrable. But the knowledge you gained in earlier chapters helps reveal how the Angular Material table works, using features such as the concise directive syntax and implicit values to map the data in the data source to the content in the column descriptions.

The next step is to define the templates for the header and body rows, like this:

```
...
<tr mat-header-row *matHeaderRowDef="colsAndRows"></tr>
<tr mat-row *matRowDef="let row; columns: colsAndRows"></tr>
...
```

Columns are not shown unless they are configured with a row template. Columns are selected using an array containing the names assigned to the column's template, and Listing 28-9 adds a property to the component class to select all of the columns defined in Listing 28-8.

Listing 28-9. Selecting Columns in the table.component.ts File in the src/app/core Folder

```
import { Component, ElementRef } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html",
})
export class TableComponent {
    category: string | null = null;
```

```
    constructor(public model: Model, activeRoute: ActivatedRoute) {
        activeRoute.params.subscribe(params => {
            this.category = params["category"] || null;
        })
    }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): Product[] {
        return this.model.getProducts()
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    colsAndRows: string[] = ['id', 'name', 'category', 'price', 'details', 'buttons'];
}
```

The next step is to define CSS styles that will supplement those used by Angular Material and style the table, as shown in Listing 28-10.

Listing 28-10. Defining Styles in the styles.css File in the src Folder

```
html, body { height: 100%; }
body { margin: 0; font-family: Roboto, "Helvetica Neue", sans-serif; }

button.mat-flat-button { margin: 2px; }

table.mat-table {  width: 100%; }
th.mat-header-cell { font-size: large; font-weight: bold;}
td.mat-column-price { font-style: italic;}
```

The `table` element is added to the `mat-table` class, which allows me to set the width of the table. As the Angular Material generates the content for the table, it adds the elements it creates to classes that make it easy to adjust the appearance. The `mat-cell` and `mat-header-cell` classes are used to denote cells in the header and body. Elements are also added to classes that indicate which column a cell belongs to so that cells for the `price` column, for example, are added to the `mat-column-price` class. I use these classes to change the font settings for all `th` elements in the header and to italicize the values in the `price` column.

To finish up applying the Angular Material table, Listing 28-11 imports the module that contains the table features.

Listing 28-11. Importing the Component Module in the material.module.ts File in the src/app Folder

```
import { NgModule } from "@angular/core";
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";

const features = [MatButtonModule, MatTableModule];
```

```
@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

When the application reloads, the Angular Material features are used to generate the table content, as shown in Figure 28-3.

Figure 28-3. *Using the Angular Material table*

Using the Built-in Table Features

The basic table features don't offer much beyond the code with which I started the chapter. But one of the reasons for using a component library is to take advantage of features that are provided by the library authors, which you would otherwise have to write yourself.

The Angular Material table has some useful capabilities, including integrated support for paginating and sorting data. In Listing 28-12, I have declared dependencies on the Angular Material modules that provide these features.

Listing 28-12. Adding Dependencies in the material.module.ts File in the src/app Folder

```
import { NgModule } from "@angular/core";
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";
import { MatPaginatorModule } from "@angular/material/paginator"
import { MatSortModule } from "@angular/material/sort"

const features = [MatButtonModule, MatTableModule, MatPaginatorModule, MatSortModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

Next, I need to expand the use of the observable in the repository, as shown in Listing 28-13. The Angular Material table will work with an array of data values, as the previous section showed, but its other features require a different approach, which is most easily achieved using the observable added to the repository.

Listing 28-13. Updating the Repository in the repository.model.ts File in the src/app/model Folder

```
import { Injectable } from "@angular/core";
import { Product } from "./product.model";
import { StaticDataSource } from "./static.datasource";
import { Observable, ReplaySubject } from "rxjs";
import { RestDataSource } from "./rest.datasource";

@Injectable()
export class Model {
    private products: Product[];
    private locator = (p: Product, id?: number) => p.id == id;
    private replaySubject: ReplaySubject<Product[]>;

    constructor(private dataSource: RestDataSource) {
        this.products = new Array<Product>();
        this.replaySubject = new ReplaySubject<Product[]>(1);
        this.dataSource.getData().subscribe(data => {
            this.products = data
            this.replaySubject.next(data);
            //this.replaySubject.complete();
        });
    }

    getProducts(): Product[] {
        return this.products;
    }

    getProduct(id: number): Product | undefined {
        return this.products.find(p => this.locator(p, id));
    }
```

```
getProductObservable(id: number): Observable<Product | undefined> {
    let subject = new ReplaySubject<Product | undefined>(1);
    this.replaySubject.subscribe(products => {
        subject.next(products.find(p => this.locator(p, id)));
        subject.complete();
    });
    return subject;
}

getProductsObservable(): Observable<Product[]> {
    return this.replaySubject;
}

getNextProductId(id?: number): Observable<number> {
    let subject = new ReplaySubject<number>(1);
    this.replaySubject.subscribe(products => {
        let nextId = 0;
        let index = products.findIndex(p => this.locator(p, id));
        if (index > -1) {
            nextId = products[products.length > index + 1
                ? index + 1 : 0].id ?? 0;
        } else {
            nextId = id || 0;
        }
        subject.next(nextId);
        subject.complete();
    });
    return subject;
}

getPreviousProductid(id?: number): Observable<number> {
    let subject = new ReplaySubject<number>(1);
    this.replaySubject.subscribe(products => {
        let nextId = 0;
        let index = products.findIndex(p => this.locator(p, id));
        if (index > -1) {
            nextId = products[index > 0
                ? index - 1 : products.length - 1].id ?? 0;
        } else {
            nextId = id || 0;
        }
        subject.next(nextId);
        subject.complete();
    });
    return subject;
}

saveProduct(product: Product) {
    if (product.id == 0 || product.id == null) {
        this.dataSource.saveProduct(product)
            .subscribe(p => this.products.push(p));
```

```
        } else {
            this.dataSource.updateProduct(product).subscribe(p => {
                let index = this.products
                    .findIndex(item => this.locator(item, p.id));
                this.products.splice(index, 1, p);
            });
        }
        this.replaySubject.next(this.products);
    }

    deleteProduct(id: number) {
        this.dataSource.deleteProduct(id).subscribe(() => {
            let index = this.products.findIndex(p => this.locator(p, id));
            if (index > -1) {
                this.products.splice(index, 1);
                this.replaySubject.next(this.products);
            }
        });
    }
}
```

These changes ensure that a new array of Product objects is sent via the observable when there is a change. Listing 28-14 changes the template that displays the table to add support for sorting data by the price column and for paginating data.

Listing 28-14. Enhancing the Table in the table.component.html File in the src/app/core Folder

```html
<table mat-table [dataSource]="getProducts()" matSort>

    <mat-text-column name="id"></mat-text-column>
    <mat-text-column name="name"></mat-text-column>
    <mat-text-column name="category"></mat-text-column>

    <ng-container matColumnDef="price">
      <th mat-header-cell *matHeaderCellDef mat-sort-header>Price</th>
      <td mat-cell *matCellDef="let item"> {{item.price | currency:"USD"}} </td>
    </ng-container>

    <ng-container matColumnDef="details">
      <th mat-header-cell *matHeaderCellDef>Details</th>
      <td mat-cell *matCellDef="let item">
          <ng-container *ngIf="item.details else empty">
              {{ item.details?.supplier }}, {{ item.details?.keywords}}
          </ng-container>
          <ng-template #empty>(None)</ng-template>
      </td>
    </ng-container>

    <ng-container matColumnDef="buttons">
      <th mat-header-cell *matHeaderCellDef></th>
      <td mat-cell *matCellDef="let item">
          <button mat-flat-button color="accent"
```

```
                (click)="deleteProduct(item.id)">
            Delete
        </button>
        <button mat-flat-button color="warn"
                [routerLink]="['/form', 'edit', item.id]">
            Edit
        </button>
    </ng-container>

    <tr mat-header-row *matHeaderRowDef="colsAndRows"></tr>
    <tr mat-row *matRowDef="let row; columns: colsAndRows"></tr>
</table>

<mat-paginator [pageSize]="5" [pageSizeOptions]="[3, 5, 10]">
</mat-paginator>

<div class="p-2 text-center">
  <button mat-flat-button color="primary" routerLink="/form/create" >
      Create New Product
  </button>
</div>
```

The matSort attribute is applied to the table element, and the mat-sort-header attribute is added to headers that will allow the user to sort data. The mast-paginator component displays pagination controls for the table data.

The final step is to create a data source that supports sorting and pagination and that is populated with data through the observable exposed by the repository, as shown in Listing 28-15.

Listing 28-15. Creating a Data Source in the table.component.ts File in the src/app/core Folder

```
import { Component, ElementRef, ViewChild } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { ActivatedRoute } from "@angular/router";
import { MatTableDataSource } from "@angular/material/table";
import { MatPaginator } from "@angular/material/paginator";
import { MatSort } from "@angular/material/sort";

@Component({
    selector: "paTable",
    templateUrl: "table.component.html",
})
export class TableComponent {
    category: string | null = null;
    dataSource: MatTableDataSource<Product>;

    constructor(public model: Model, activeRoute: ActivatedRoute) {
        activeRoute.params.subscribe(params => {
            this.category = params["category"] || null;
        })
        this.dataSource = new MatTableDataSource<Product>();
        this.model.getProductsObservable().subscribe(newData => {
```

```
            this.dataSource.data = newData;
        })
    }

    getProduct(key: number): Product | undefined {
        return this.model.getProduct(key);
    }

    getProducts(): MatTableDataSource<Product> {
        return this.dataSource;
    }

    deleteProduct(key?: number) {
        if (key != undefined) {
            this.model.deleteProduct(key);
        }
    }

    colsAndRows: string[] = ['id', 'name', 'category', 'price', 'details', 'buttons'];

    @ViewChild(MatPaginator) paginator!: MatPaginator;
    @ViewChild(MatSort) sort!: MatSort;

    ngAfterViewInit() {
        this.dataSource.paginator = this.paginator;
        this.dataSource.sort = this.sort;
    }
}
```

The MatTableDataSource<Product> object represents a data source for Product objects, and its data property is used to update the data the table displays. The paginator and sort properties are used to associate the MatPaginator component and MatSort directive with the data source, which I do in the ngAfterViewInit method, to ensure that the child content is queried and assigned to the ViewChild properties. The result is that the data in the table is paginated and can be sorted by clicking the header for the Price column, as shown in Figure 28-4.

Figure 28-4. *Using built-in table features*

Writing your own pagination and sorting code isn't difficult—I demonstrated a simple paginator in the SportsStore application, for example—but using a component library means that you can rely on out-of-the-box features that are already tested. The trade-off is that you generally have to fit into a predefined model of how data will be expressed to get the most benefit, such as using the MatTableDataSource<T> class with Angular Material.

Matching the Component Library Theme

You can get a long way using just the features provided by a good component library, but some projects require more specialized features, which leads to custom Angular directives or components.

Most component libraries provide access to the underlying themes they use to style content, often expressed using *Sass*, which is a superset of CSS that makes it easier to create complex sets of styles without endless duplication of CSS properties. Sass files have the .scss extension and are compiled when the project is built to generate standard CSS stylesheets that the browser can understand. (Confusingly, Sass also supports a closely related syntax in files with the .sass file extension. The history of CSS and attempts to improve it are long and complex and can be ignored.)

I am not going to describe Sass in detail in this book—see https://sass-lang.com for full details—but I will explain the features that are required to style custom components with the Angular Material theme.

Creating the Custom Component

I am going to create a custom button component, which will let me show the use of themes without getting bogged down in the component itself. Add a file named customButton.component.ts to the src/app/core folder, with the content shown in Listing 28-16.

Listing 28-16. The Contents of the customButton.component.ts File in the src/app/core Folder

```
import { Component, ElementRef, Input, ViewChild } from "@angular/core";

@Component({
    selector: "customButton",
    templateUrl: "customButton.component.html"
})
export class CustomButton {

    @Input("themeColor")
    themeColor: string = "primary"

    @ViewChild("buttonTarget")
    button?: ElementRef

    ngAfterViewInit() {
        this.button?.nativeElement.classList.add(`custom-button-${this.themeColor}`);
    }
}
```

The component queries its template to locate a button element and assigns it to a class based on the value received through an input property.

To define the template for the component, add a file named customButton.component.html to the src/app/core folder with the content shown in Listing 28-17.

Listing 28-17. The Contents of the customButton.component.html File in the src/app/core Folder

```
<button #buttonTarget>
    <ng-content></ng-content>
</button>
```

Listing 28-18 adds the custom button component to the core module.

Listing 28-18. Adding the Component to the Module in the core.module.ts File in the src/app/core Folder

```
import { NgModule } from "@angular/core";
import { BrowserModule } from "@angular/platform-browser";
import { FormsModule, ReactiveFormsModule } from "@angular/forms";
import { ModelModule } from "../model/model.module";
import { TableComponent } from "./table.component";
import { FormComponent } from "./form.component";
//import { SharedState } from "./sharedState.service";
import { ValidationHelper } from "./validation_helper";
import { ValidationErrorsDirective } from "./validationErrors.directive";
import { HiLowValidatorDirective } from "../validation/hilow";
import { RouterModule } from "@angular/router";
import { ProductCountComponent } from "./productCount.component";
import { CategoryCountComponent } from "./categoryCount.component";
import { NotFoundComponent } from "./notFound.component";
import { UnsavedGuard } from "./unsaved.guard";
import { MaterialFeatures } from "../material.module"
import { CustomButton } from "./customButton.component";

@NgModule({
    imports: [BrowserModule, FormsModule, ModelModule, ReactiveFormsModule,
        RouterModule, MaterialFeatures],
    declarations: [TableComponent, FormComponent, ValidationHelper,
        ValidationErrorsDirective, HiLowValidatorDirective, ProductCountComponent,
        CategoryCountComponent, NotFoundComponent, CustomButton],
    exports: [ModelModule, TableComponent, FormComponent],
    providers: [UnsavedGuard]
})
export class CoreModule { }
```

The final preparatory step is to use the new component, as shown in Listing 28-19.

Listing 28-19. Applying the Custom Component in the table.component.html File in the src/app/core Folder

```
<table mat-table [dataSource]="getProducts()" matSort>

    <!-- ...elements omitted for brevity... -->

</table>

<mat-paginator [pageSize]="5" [pageSizeOptions]="[3, 5, 10]">
</mat-paginator>
```

```
<div class="p-2 text-center">
  <button mat-flat-button color="primary" routerLink="/form/create" >
      Create New Product
  </button>

  <customButton themeColor="primary" routerLink="/form/create">
      Create New Product
  </customButton>

</div>
```

Save the changes, and you will see the new (unstyled) button shown alongside the standard Angular Material button, as shown in Figure 28-5.

Figure 28-5. *Applying a custom component*

Using the Angular Material Theme

The Angular build tools have integrated support for working with SCSS files, which is the file format used by SASS. Add a file named customButton.component.scss to the src/app/core folder with the content shown in Listing 28-20.

<div style="border: 2px solid black; text-align: center; padding: 8px;">

FIGURING OUT THEME DETAILS

</div>

An investment of time is required to figure out how to apply the Angular Material themes to custom components, so do not rush into this process expecting it to be quick and easy.

To figure out how to create the styles I needed for the button component, I relied on the Angular Material theme documentation (https://material.angular.io/guide/theming-your-components) and the Material Design theme description (https://material.io/design/material-theming/overview.html), both of which contain useful guidance. But I spent most of the time reading through the SCSS files in the Angular Material package (https://github.com/angular/components) to figure out the purpose of different functions and to understand how the styles for the built-in components are generated. It was also helpful to use the browser F12 developer tools to see how HTML elements are styled.

But don't be put off. Once you have worked your way through the process for one component, you will have learned enough to make subsequent components much simpler.

Listing 28-20. The Contents of the customButton.component.scss File in the src/app/core Folder

```scss
@use "@angular/material" as material;

$primary: material.define-palette(material.$indigo-palette);
$accent: material.define-palette(material.$pink-palette, A200, A100, A400);
$warn: material.define-palette(material.$red-palette);

$typography: material.define-typography-config();

button[class*="custom-button-"] {
    padding: 7px 12px;
    border: none;
    border-radius: 4px;
    margin: 2px;
}

button.custom-button {
    @each $name, $palette in (primary: $primary, accent: $accent, warn: $warn) {
        &-#{$name} {
            background-color: material.get-color-from-palette($palette, default);
            color: material.get-color-from-palette($palette, default-contrast);
            font: {
                family: material.font-family($typography, button);
                size: material.font-size($typography, button);
                weight: material.font-weight($typography, button);
            }
        }
    }
}

$bg: material.$light-theme-background-palette;
$fg: material.$light-theme-foreground-palette;
```

```
:host[disabled] button[class*="custom-button-"],
        button[class*="custom-button-"]:disabled  {
    background-color: material.get-color-from-palette($bg, disabled-button);
    color: material.get-color-from-palette($fg, disabled-button);
}
```

Sass has a concise syntax, which can make it difficult to understand what is happening in the listing until you have at least a little experience. The first statement is an @use expression:

```
...
@use "@angular/material" as material;
...
```

Sass support function and variables, which can be used to generate CSS styles, and the @use expression provides access to the Sass features that Angular Material provides. The next group of statements create the primary, accent, and warn palettes from the Angular Material theme:

```
...
$primary: material.define-palette(material.$indigo-palette);
$accent: material.define-palette(material.$pink-palette, A200, A100, A400);
$warn: material.define-palette(material.$red-palette);
...
```

Angular Material defines a set of base palettes, which contain a range of hues for a single color. The term material.$indigo-palette, for example, refers to the set of indigo hues. (The material prefix was specified in the @use expression and allows me to access Angular Material Sass features, and the $ sign indicates a variable so that material.$indigo-palette refers to a variable named indigo-palette defined by the Angular Material package.) The define-palette function is used to select specific hues and give them convenient names, such as default and text, which help ensure consistency when applying styles. The indigo and pink palettes correspond to the default theme, which was chosen when the Angular Material package was installed. If you select a different theme for a project, then you will need to use the palettes that correspond to the colors of that theme.

The next step is to get the font configuration that Angular Material applies to its components:

```
...
$typography: material.define-typography-config();
...
```

The define-typography-config function returns a map where the keys are the names of styles that can be applied to text. A complete list of these styles can be found at https://material.angular.io/guide/typography, but the style name I want for this example is button, which provides the font settings for buttons.

Not all of the styles applied to buttons are specific to a palette, and I have used a selector that will match all of the palette-specific classes to apply these styles:

```
...
button[class*="custom-button-"] {
    padding: 7px 12px;
    border: none;
    border-radius: 4px;
    margin: 2px;
}
...
```

The next expression is the most complex and is responsible for generating the styles that are specific to a palette:

```
...
button.custom-button {
    @each $name, $palette in (primary: $primary, accent: $accent, warn: $warn) {
        &-#{$name} {
            background-color: material.get-color-from-palette($palette, default);
            color: material.get-color-from-palette($palette, default-contrast);
            font: {
                family: material.font-family($typography, button);
                size: material.font-size($typography, button);
                weight: material.font-weight($typography, button);
            }
        }
    }
}
...
```

The effect of this expression is to generate a style for each of the primary, accent, and warn palettes, which contains background-color, color, and font properties that are specific to each palette. The get-color-from-palette function is used to get a color from a palette, either by hue or by using one of the names created by the define-palette function. The name default refers to the default color, and the default-contrast name refers to a color that can be used for text:

```
...
background-color: material.get-color-from-palette($palette, default);
color: material.get-color-from-palette($palette, default-contrast);
...
```

The values for the font properties are obtained using the font-family, font-size, and font-weight functions, which read values from the typography configuration settings.

Two more palettes are required to deal with disabled buttons:

```
...
$bg: material.$light-theme-background-palette;
$fg: material.$light-theme-foreground-palette;
...
```

The themes that Angular Material provides are categorized as either *light* or *dark*, and there are additional palettes of foreground and background colors that are shared by these light and dark themes, such as the colors for disabled buttons. The default indigo/pink theme is light, so I have assigned the light theme palettes to variables named fg and bg. These palettes are used to create a style that is applied to disabled buttons:

```
...
:host[disabled] button[class*="custom-button-"],
        button[class*="custom-button-"]:disabled  {
    background-color: material.get-color-from-palette($bg, disabled-button);
    color: material.get-color-from-palette($fg, disabled-button);
}
...
```

The foreground and background palettes contain colors named `disabled-button`, which are used to set the `background-color` and `color` properties when a button is disabled. The selector matches button elements that are disabled or whose host element is disabled. The `:host` selector is required by the Angular view encapsulation feature and allows the component to be disabled by applying the disabled attribute to the `customButton` element.

SCSS files are applied to the component in just the same way as regular CSS files, as shown in Listing 28-21.

Listing 28-21. Applying Styles in the customButton.component.ts File in the src/app/core Folder

```
import { Component, ElementRef, Input, ViewChild } from "@angular/core";

@Component({
    selector: "customButton",
    templateUrl: "customButton.component.html",
    styleUrls: ["customButton.component.scss"]
})
export class CustomButton {

    @Input("themeColor")
    themeColor: string = "primary"

    @ViewChild("buttonTarget")
    button?: ElementRef

    ngAfterViewInit() {
        this.button?.nativeElement.classList.add(`custom-button-${this.themeColor}`);
    }
}
```

During the build process, the SCSS files are processed to generate CSS files that can be sent to the browser. Figure 28-6 shows the built-in Angular Material button alongside the styles custom component.

Figure 28-6. *Applying a theme to a custom component*

Applying the Ripple Effect

To finish off this chapter, I am going to add an animation effect to my custom button. Angular Material includes a ripple effect that is used to highlight user interaction, such as when a button is clicked. It is difficult to show this on a printed page, but Figure 28-7 gives an idea of how the color of a built-in Angular Material button is progressively changed when it is clicked.

Figure 28-7. *The Angular Material button ripple effect*

When the user clicks a button, a circle of lighter color spreads out from the pointer. The best way to see this effect is to hold the mouse button down because the animation will be terminated when the mouse is released.

Angular Material makes the ripple feature available as a directive that can be applied to any component. Listing 28-22 imports the ripple module from the Angular Material package.

Listing 28-22. Adding a Dependency in the material.module.ts File in the src/app Folder

```
import { NgModule } from "@angular/core";
import { MatButtonModule } from "@angular/material/button";
import { MatTableModule } from "@angular/material/table";
import { MatPaginatorModule } from "@angular/material/paginator"
import { MatSortModule } from "@angular/material/sort"
import { MatRippleModule } from "@angular/material/core";

const features = [MatButtonModule, MatTableModule, MatPaginatorModule, MatSortModule,
    MatRippleModule];

@NgModule({
    imports: [features],
    exports: [features]
})
export class MaterialFeatures {}
```

Listing 28-23 applies the ripple directive to the `button` element in the custom component's template.

Listing 28-23. Applying a Ripple in the customButton.component.html File in the src/core/app Folder

```
<button #buttonTarget matRipple>
    <ng-content></ng-content>
</button>
```

Ripples work by adding a `div` element inside the button, to which the animation is applied. The color used for the ripple is derived from the palette used for the button, as shown in Listing 28-24.

Listing 28-24. Defining a Style in the customButton.component.scss File in the src/app/core Folder

```
@use "@angular/material" as material;

$primary: material.define-palette(material.$indigo-palette);
$accent: material.define-palette(material.$pink-palette, A200, A100, A400);
$warn: material.define-palette(material.$red-palette);

$typography: material.define-typography-config();

button[class*="custom-button-"] {
    padding: 7px 12px;
    border: none;
    border-radius: 4px;
    margin: 2px;
}

button.custom-button {
    @each $name, $palette in (primary: $primary, accent: $accent, warn: $warn) {
        &-#{$name} {
            background-color: material.get-color-from-palette($palette, default);
            color: material.get-color-from-palette($palette, default-contrast);
            font: {
```

```
                family: material.font-family($typography, button);
                size: material.font-size($typography, button);
                weight: material.font-weight($typography, button);
            }
        }

        &-#{$name} ::ng-deep .mat-ripple-element {
            background-color: material.get-color-from-palette($palette,
                default-contrast, 0.1);
        }
    }
}

$bg: material.$light-theme-background-palette;
$fg: material.$light-theme-foreground-palette;

:host[disabled] button[class*="custom-button-"],
        button[class*="custom-button-"]:disabled  {
    background-color: material.get-color-from-palette($bg, disabled-button);
    color: material.get-color-from-palette($fg, disabled-button);
}
```

The `::ng-deep` pseudoclass is used to prevent Angular from modifying the name of the `mat-ripple-element` class selector for view encapsulation. (The `/deep/` and `>>>` selectors are not supported by Sass.) The `get-color-from-palette` function is used to get a color from the chosen palette with an opacity value, which was chosen to match the one used by the built-in Angular Material button feature. The result is that the custom button displays a ripple when clicked, as shown in Figure 28-8.

Figure 28-8. *Applying a ripple effect to a custom component*

Summary

In this chapter, I demonstrated how a component library such as Angular Material can be introduced into a project to supplement or replace custom components. I also explained how the theme provided by Angular Material can be applied to custom components to ensure consistency across the application. In the next chapter, I explain how to perform unit testing in an Angular project.

CHAPTER 29

■ ■ ■

Angular Unit Testing

In this chapter, I describe the tools that Angular provides for unit testing components and directives. Some Angular building blocks, such as pipes and services, can be readily tested in isolation using the basic testing tools that I set up at the start of the chapter. Components (and, to a lesser extent, directives) have complex interactions with their host elements and with their template content and require special features. Table 29-1 puts Angular unit testing in context.

DECIDING WHETHER TO UNIT TEST

Unit testing is a contentious topic. This chapter assumes you do want to do unit testing and shows you how to set up the tools and apply them to Angular components and directives. It isn't an introduction to unit testing, and I make no effort to persuade skeptical readers that unit testing is worthwhile. If you would like an introduction to unit testing, then there is a good article here: https://en.wikipedia.org/wiki/Unit_testing.

I like unit testing, and I use it in my own projects—but not all of them and not as consistently as you might expect. I tend to focus on writing unit tests for features and functions that I know will be hard to write and that are likely to be the source of bugs in deployment. In these situations, unit testing helps structure my thoughts about how to best implement what I need. I find that just thinking about what I need to test helps produce ideas about potential problems, and that's before I start dealing with actual bugs and defects.

That said, unit testing is a tool and not a religion, and only you know how much testing you require. If you don't find unit testing useful or if you have a different methodology that suits you better, then don't feel you need to unit test just because it is fashionable. (However, if you don't have a better methodology and you are not testing at all, then you are probably letting users find your bugs, which is rarely ideal.)

Table 29-1. *Putting Angular Unit Testing Context*

Question	Answer
What is it?	Angular components and directives require special support for testing so that their interactions with other parts of the application infrastructure can be isolated and inspected.
Why is it useful?	Isolated unit tests can assess the basic logic provided by the class that implements a component or directive but do not capture the interactions with host elements, services, templates, and other important Angular features.
How is it used?	Angular provides a test bed that allows a realistic application environment to be created and then used to perform unit tests.
Are there any pitfalls or limitations?	Like much of Angular, the unit testing tools are complex. It can take some time and effort to get to the point where unit tests are easily written and run and you are sure that you have isolated the correct part of the application for testing.
Are there any alternatives?	As noted, you don't have to unit test your projects. But if you do want to unit testing, then you will need to use the Angular features described in this chapter.

Table 29-2 summarizes the chapter.

Table 29-2. *Chapter Summary*

Problem	Solution	Listing
Performing a basic test on a component	Initialize a test module and create an instance of the component. If the component has an external template, an additional compilation step must be performed.	1–9, 11–13
Testing a component's data bindings	Use the DebugElement class to query the component's template.	10
Testing a component's response to events	Trigger the events using the debug element.	14–16
Testing a component's output properties	Subscribe to the EventEmitter created by the component.	17, 18
Testing a component's input properties	Create a test component whose template applies the component under test.	19, 20
Testing a directive	Create a test component whose template applies the directive under test.	21, 22

Preparing the Example Project

I continue to use the exampleApp project from earlier chapters. I need a simple target to focus on for unit testing, so Listing 29-1 changes the routing configuration so that the ondemand feature module is loaded by default.

Listing 29-1. Changing the Routing Configuration in the app.routing.ts File in the src/app Folder

```
import { Routes, RouterModule } from "@angular/router";
import { TableComponent } from "./core/table.component";
import { FormComponent } from "./core/form.component";
import { NotFoundComponent } from "./core/notFound.component";
import { UnsavedGuard } from "./core/unsaved.guard";

const routes: Routes = [
    {
        path: "ondemand",
        loadChildren: () => import("./ondemand/ondemand.module")
                                .then(m => m.OndemandModule)
    },
    { path: "", redirectTo: "/ondemand", pathMatch: "full" }
]

export const routing = RouterModule.forRoot(routes);
```

This module contains some simple components that I will use to demonstrate different unit testing features. To keep the content shown by the application simple, Listing 29-2 tidies up the template displayed by the top-level component in the feature module.

Listing 29-2. Simplifying the ondemand.component.html File in the src/app/ondemand Folder

```
<div class="container-fluid">
    <div class="row">
        <div class="col-12 p-2">
            <router-outlet></router-outlet>
        </div>
    </div>
    <div class="row">
        <div class="col-6 p-2">
            <router-outlet name="left"></router-outlet>
        </div>
        <div class="col-6 p-2">
            <router-outlet name="right"></router-outlet>
        </div>
    </div>
</div>
<button class="btn btn-secondary m-2" routerLink="/ondemand">Normal</button>
<button class="btn btn-secondary m-2" routerLink="/ondemand/swap">Swap</button>
```

Open a new command prompt, navigate to the exampleApp folder, and run the following command to start the server that provides the RESTful web server:

```
npm run json
```

The RESTful web service isn't used directly in this chapter, but running it prevents errors. Open a separate command prompt, navigate to the exampleApp folder, and run the following command to start the Angular development tools:

```
ng serve
```

Open a new browser window and navigate to http://localhost:4200 to see the content shown in Figure 29-1.

Figure 29-1. *Running the example application*

Running a Simple Unit Test

When a new project is created using the ng new command, all the packages and tools required for unit testing are installed, based on the Jasmine test framework. To create a simple unit test to confirm that everything is working, I created the src/app/tests folder and added to it a file named app.component. spec.ts with the contents shown in Listing 29-3. The naming convention for unit tests makes it obvious which file the tests apply to.

Listing 29-3. The Contents of the app.component.spec.ts File in the src/app/tests Folder

```
describe("Jasmine Test Environment", () => {
    it("is working", () => expect(true).toBe(true));
});
```

I explain the basics of working with the Jasmine API shortly, and you can ignore the syntax for the moment. Using a new command prompt, navigate to the exampleApp folder, and run the following command:

```
ng test
```

This command starts the Karma test runner, which opens a new browser tab with the content shown in Figure 29-2.

Figure 29-2. *Starting the Karma test runner*

The browser window is used to run the tests, but the important information is written out to the command prompt used to start the test tools, where you will see a message like this:

```
Chrome 98.0.4758.82 (Windows 10): Executed 1 of 1 SUCCESS (0.106 secs / 0.001 secs)
```

This shows that the single unit test in the project has been located and executed successfully. Whenever you make a change that updates one of the JavaScript files in the project, the unit tests will be located and executed, and any problems will be written to the command prompt. To show what an error looks like, Listing 29-4 changes the unit test so that it will fail.

Listing 29-4. Making a Unit Test Fail in the app.component.spec.ts File in the src/app/tests Folder

```
describe("Jasmine Test Environment", () => {
    it("is working", () => expect(true).toBe(false));
});
```

This test will fail and will result in the following output, which indicates the test that has failed and what went wrong:

```
Chrome 98.0.4758.82 (Windows 10) Jasmine Test Environment is working FAILED
    Error: Expected true to be false.
        at <Jasmine>
        at UserContext.<anonymous> (src/app/tests/app.component.spec.ts:2:41)
        at ZoneDelegate.invoke (node_modules/zone.js/fesm2015/zone.js:372:1)
        at ProxyZoneSpec.onInvoke (node_modules/zone.js/fesm2015/zone-testing.js:287:1)
Chrome 98.0.4758.82 (Windows 10): Executed 1 of 1 (1 FAILED)
TOTAL: 1 FAILED, 0 SUCCESS
```

Working with Jasmine

The API that Jasmine provides chains together JavaScript methods to define unit tests. You can find the full documentation for Jasmine at http://jasmine.github.io, but Table 29-3 describes the most useful functions for Angular testing.

Table 29-3. Useful Jasmine Methods

Name	Description
describe(description, function)	This method is used to group a set of related tests.
beforeEach(function)	This method is used to specify a task that is performed before each unit test.
afterEach(function)	This method is used to specify a test that is performed after each unit test.
it(description, function)	This method is used to perform the test action.
expect(value)	This method is used to identify the result of the test.
toBe(value)	This method specifies the expected value of the test.

You can see how the methods in Table 29-3 were used to create the unit test in Listing 29-4.

```
...
describe("Jasmine Test Environment", () => {
    it("is working", () => expect(true).toBe(false));
});
...
```

You can also see why the test has failed since the expect and toBe methods have been used to check that true and false are equal. Since this cannot be the case, the test fails.

The toBe method isn't the only way to evaluate the result of a unit test. Table 29-4 shows other evaluation methods provided by Angular.

Table 29-4. *Useful Jasmine Evaluation Methods*

Name	Description
toBe(value)	This method asserts that a result is the same as the specified value (but need not be the same object).
toEqual(object)	This method asserts that a result is the same object as the specified value.
toMatch(regexp)	This method asserts that a result matches the specified regular expression.
toBeDefined()	This method asserts that the result has been defined.
toBeUndefined()	This method asserts that the result has not been defined.
toBeNull()	This method asserts that the result is null.
toBeTruthy()	This method asserts that the result is truthy, as described in Chapter 3.
toBeFalsy()	This method asserts that the result is falsy, as described in Chapter 3.
toContain(substring)	This method asserts that the result contains the specified substring.
toBeLessThan(value)	This method asserts that the result is less than the specified value.
toBeGreaterThan(value)	This method asserts that the result is more than the specified value.

Listing 29-5 shows how these evaluation methods can be used in tests, replacing the failing test from the previous section.

Listing 29-5. Replacing the Unit Test in the app.component.spec.ts File in the src/app/tests Folder

```
describe("Jasmine Test Environment", () => {
    it("test numeric value", () => expect(12).toBeGreaterThan(10));
    it("test string value", () => expect("London").toMatch("^Lon"));
});
```

When you save the changes to the file, the tests will be executed, and the results will be shown in the command prompt.

Testing an Angular Component

The building blocks of an Angular application can't be tested in isolation because they depend on the underlying features provided by Angular and by the other parts of the project, including the services, directives, templates, and modules it contains. As a consequence, testing a building block such as a component means using testing utilities that are provided by Angular to re-create enough of the application to let the component function so that tests can be performed against it. In this section, I walk through the process of performing a unit test on the FirstComponent class in the OnDemand feature module. As a reminder, here is the definition of the component:

```
import { Component } from "@angular/core";

@Component({
    selector: "first",
    template: `<div class="bg-primary text-white p-2">First Component</div>`
})
export class FirstComponent { }
```

This component is so simple that it doesn't have functionality of its own to test, but it is enough to demonstrate how the test process is applied.

Working with the TestBed Class

At the heart of Angular unit testing is a class called `TestBed`, which is responsible for simulating the Angular application environment so that tests can be performed. Table 29-5 describes the most useful methods provided by the `TestBed` method, all of which are static.

Table 29-5. *Useful TestBed Methods*

Name	Description
configureTestingModule	This method is used to configure the Angular testing module.
createComponent	This method is used to create an instance of the component.
compileComponents	This method is used to compile components, as described in the "Testing a Component with an External Template" section.

The `configureTestingModule` method is used to configure the Angular module that is used in testing, using the same properties supported by the `@NgModel` decorator. Just like in a real application, a component cannot be used in a unit test unless it has been added to the `declarations` property of the module. This means that the first step in most unit tests is to configure the testing module. To demonstrate, I added a file named `first.component.spec.ts` to the `src/app/tests` folder with the content shown in Listing 29-6.

Listing 29-6. The Contents of the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed } from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";

describe("FirstComponent", () => {

    beforeEach(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent]
        });
    });
});
```

The `TestBed` class is defined in the `@angular/core/testing` module, and the `configureTestingModule` accepts an object whose `declarations` property tells the test module that the `FirstComponent` class is going to be used.

■ **Tip** Notice that the TestBed class is used within the beforeEach function. If you try to use the TestBed outside of this function, you will see an error about using Promises.

The next step is to create a new instance of the component so that it can be used in tests. This is done using the createComponent method, as shown in Listing 29-7.

Listing 29-7. Creating a Component in the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture} from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";

describe("FirstComponent", () => {

    let fixture: ComponentFixture<FirstComponent>;
    let component: FirstComponent;

    beforeEach(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent]
        });
        fixture = TestBed.createComponent(FirstComponent);
        component = fixture.componentInstance;
    });

    it("is defined", () => {
        expect(component).toBeDefined()
    });
});
```

The argument to the createComponent method tells the test bed which component type it should instantiate, which is FirstComponent in this case. The result is a ComponentFixture<FirstComponent> object, which provides features for testing a component, using the methods and properties described in Table 29-6.

Table 29-6. *Useful ComponentFixture Methods and Properties*

Name	Description
componentInstance	This property returns the component object.
debugElement	This property returns the test host element for the component.
nativeElement	This property returns the DOM object representing the host element for the component.
detectChanges()	This method causes the test bed to detect state changes and reflect them in the component's template.
whenStable()	This method returns a Promise that is resolved when the effect of an operation has been fully applied.

In the listing, I use the `componentInstance` property to get the `FirstComponent` object that has been created by the test bed and perform a simple test to ensure that it has been created by using the `expect` method to select the `component` object as the target of the test and the `toBeDefined` method to perform the test. I demonstrate the other methods and properties in the sections that follow.

Configuring the Test Bed for Dependencies

One of the most important features of Angular applications is dependency injection, which allows components and other building blocks to receive services by declaring dependencies on them using constructor parameters. Listing 29-8 adds a dependency on the data model repository service to the `FirstComponent` class.

Listing 29-8. Adding a Service Dependency in the first.component.ts File in the src/app/ondemand Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";

@Component({
    selector: "first",
        template: `<div class="bg-primary p-a-1">
                There are
                    <span class="strong"> {{getProducts().length}} </span>
                products
                </div>`
})
export class FirstComponent {

    constructor(private repository: Model) {}

    category: string = "Soccer";

    getProducts(): Product[] {
        return this.repository.getProducts()
            .filter(p => p.category == this.category);
    }
}
```

The component uses the repository to provide a filtered collection of `Product` objects, which are exposed through a method called `getProducts` and filtered using a `category` property. The inline template has a corresponding data binding that displays the number of products that the `getProducts` method returns.

Being able to unit test the component means providing it with a repository service. The Angular test bed will take care of resolving dependencies as long as they are configured through the test module. Effective unit testing generally requires components to be isolated from the rest of the application, which means that mock or fake objects (also known as *test doubles*) are used as substitutes for real services in unit tests. Listing 29-9 configures the test bed so that a fake repository is used to provide the component with its service.

Listing 29-9. Providing a Service in the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture} from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";
import { Product } from ".//model/product.model";
import { Model } from "../model/repository.model";

describe("FirstComponent", () => {

    let fixture: ComponentFixture<FirstComponent>;
    let component: FirstComponent;

    let mockRepository = {
        getProducts: function () {
            return [
                new Product(1, "test1", "Soccer", 100),
                new Product(2, "test2", "Chess", 100),
                new Product(3, "test3", "Soccer", 100),
            ]
        }
    }

    beforeEach(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent],
            providers: [
                { provide: Model, useValue: mockRepository }
            ]
        });
        fixture = TestBed.createComponent(FirstComponent);
        component = fixture.componentInstance;
    });

    it("filters categories", () => {
        component.category = "Chess"
        expect(component.getProducts().length).toBe(1);
        component.category = "Soccer";
        expect(component.getProducts().length).toBe(2);
        component.category = "Running";
        expect(component.getProducts().length).toBe(0);
    });
});
```

The mockRepository variable is assigned an object that provides a getProducts method that returns fixed data that can be used to test for known outcomes. To provide the component with the service, the providers property for the object passed to the TestBed.configureTestingModule method is configured in the same way as a real Angular module, using the value provider to resolve dependencies on the Model class using the mockRepository variable. The test invokes the component's getProducts method and compares the results with the expected outcome, changing the value of the category property to check different filters.

Testing Data Bindings

The previous example showed how a component's properties and methods can be used in a unit test. This is a good start, but many components will also include small fragments of functionality in the data binding expressions contained in their templates, and these should be tested as well. Listing 29-10 checks that the data binding in the component's template correctly displays the number of products in the mock data model.

Listing 29-10. Unit Testing a Data Binding in the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture} from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";
import { DebugElement } from "@angular/core";
import { By } from "@angular/platform-browser";

describe("FirstComponent", () => {

    let fixture: ComponentFixture<FirstComponent>;
    let component: FirstComponent;
    let debugElement: DebugElement;
    let bindingElement: HTMLSpanElement;

    let mockRepository = {
        getProducts: function () {
            return [
                new Product(1, "test1", "Soccer", 100),
                new Product(2, "test2", "Chess", 100),
                new Product(3, "test3", "Soccer", 100),
            ]
        }
    }

    beforeEach(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent],
            providers: [
                { provide: Model, useValue: mockRepository }
            ]
        });
        fixture = TestBed.createComponent(FirstComponent);
        component = fixture.componentInstance;
        debugElement = fixture.debugElement;
        bindingElement = debugElement.query(By.css("span")).nativeElement;
    });

    it("filters categories", () => {
        component.category = "Chess"
        fixture.detectChanges();
        expect(component.getProducts().length).toBe(1);
        expect(bindingElement.textContent).toContain("1");
```

```
        component.category = "Soccer";
        fixture.detectChanges();
        expect(component.getProducts().length).toBe(2);
        expect(bindingElement.textContent).toContain("2");

        component.category = "Running";
        fixture.detectChanges();
        expect(component.getProducts().length).toBe(0);
        expect(bindingElement.textContent).toContain("0");
    });
});
```

The `ComponentFixture.debugElement` property returns a `DebugElement` object that represents the root element from the component's template, and Table 29-7 lists the most useful methods and properties described by the `DebugElement` class.

■ **Tip**   If you don't see the test output, then restart the ng test command.

Table 29-7. *Useful DebugElement Properties and Methods*

Name	Description
nativeElement	This property returns the object that represents the HTML element in the DOM.
children	This property returns an array of `DebugElement` objects representing the children of this element.
query(selectorFunction)	The `selectorFunction` is passed a `DebugElement` object for each HTML element in the component's template, and this method returns the first `DebugElement` for which the function returns `true`.
queryAll(selectorFunction)	This is similar to the `query` method, except the result is all the `DebugElement` objects for which the function returns `true`.
triggerEventHandler(name, event)	This method triggers an event. See the "Testing Component Events" section for details.

Locating elements is done through the `query` and `queryAll` methods, which accept functions that inspect `DebugElement` objects and return `true` if they should be included in the results. The `By` class, defined in the `@angular/platform-browser` module, makes it easier to locate elements in the component's template through the static methods described in Table 29-8.

Table 29-8. *The By Methods*

Name	Description
By.all()	This method returns a function that matches any element.
By.css(selector)	This method returns a function that uses a CSS selector to match elements.
By.directive(type)	This method returns a function that matches elements to which the specified directive class has been applied, as demonstrated in the "Testing Input Properties" section.

861

In the listing, I use the By.css method to locate the first span element in the template and access the DOM object that represents it through the nativeElement property so that I can check the value of the textContent property in the unit tests.

Notice that after each change to the component's category property, I call the ComponentFixture object's detectChanges method, like this:

```
...
component.category = "Soccer";
fixture.detectChanges();
expect(component.getProducts().length).toBe(2);
expect(bindingElement.textContent).toContain("2");
...
```

This method tells the Angular testing environment to process any changes and evaluate the data binding expressions in the template. Without this method call, the change to the value of the category component would not be reflected in the template, and the test would fail.

Testing a Component with an External Template

Angular components are compiled into factory classes, either within the browser or by the ahead-of-time compiler that I demonstrated in Chapter 8. As part of this process, Angular processes any external templates and includes them as text in the JavaScript code that is generated similar to an inline template. When unit testing a component with an external template, the compilation step must be performed explicitly. In Listing 29-11, I changed the @Component decorator applied to the FirstComponent class so that it specifies an external template.

Listing 29-11. Specifying a Template in the first.component.ts File in the src/app/ondemand Folder

```
import { Component } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";

@Component({
    selector: "first",
    templateUrl: "first.component.html"
})
export class FirstComponent {

    constructor(private repository: Model) {}

    category: string = "Soccer";

    getProducts(): Product[] {
        return this.repository.getProducts()
            .filter(p => p.category == this.category);
    }
}
```

To provide the template, I created a file called first.component.html in the exampleApp/app/ondemand folder and added the elements shown in Listing 29-12.

Listing 29-12. The first.component.html File in the exampleApp/app/ondemand Folder

```html
<div class="bg-primary text-white p-2">
    There are
        <span class="strong"> {{getProducts().length}} </span>
    products
</div>
```

This is the same content that was previously defined inline. Listing 29-13 updates the unit test for the component to deal with the external template by explicitly compiling the component.

Listing 29-13. Compiling a Component in the first.component.spec.ts File in the src/app/tests Folder

```typescript
import { TestBed, ComponentFixture, waitForAsync } from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";
import { Product } from ".//model/product.model";
import { Model } from "../model/repository.model";
import { DebugElement } from "@angular/core";
import { By } from "@angular/platform-browser";

describe("FirstComponent", () => {

    let fixture: ComponentFixture<FirstComponent>;
    let component: FirstComponent;
    let debugElement: DebugElement;
    let bindingElement: HTMLSpanElement;
    let spanElement: HTMLSpanElement;

    let mockRepository = {
        getProducts: function () {
            return [
                new Product(1, "test1", "Soccer", 100),
                new Product(2, "test2", "Chess", 100),
                new Product(3, "test3", "Soccer", 100),
            ]
        }
    }

    beforeEach(waitForAsync(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent],
            providers: [
                { provide: Model, useValue: mockRepository }
            ]
        });
        TestBed.compileComponents().then(() => {
            fixture = TestBed.createComponent(FirstComponent);
            component = fixture.componentInstance;
            debugElement = fixture.debugElement;
            spanElement = debugElement.query(By.css("span")).nativeElement;
        });
    }));
```

863

```
    it("filters categories", () => {
        component.category = "Chess"
        fixture.detectChanges();
        expect(component.getProducts().length).toBe(1);
        expect(bindingElement.textContent).toContain("1");

        component.category = "Soccer";
        fixture.detectChanges();
        expect(component.getProducts().length).toBe(2);
        expect(bindingElement.textContent).toContain("2");

        component.category = "Running";
        fixture.detectChanges();
        expect(component.getProducts().length).toBe(0);
        expect(bindingElement.textContent).toContain("0");
    });
});
```

Components are compiled using the `TestBed.compileComponents` method. The compilation process is asynchronous, and the `compileComponents` method returns a `Promise`, which must be used to complete the test setup when the compilation is complete. To make it easier to work with asynchronous operations in unit tests, the `@angular/core/testing` module contains a function called `waitForAsync`, which is used with the `beforeEach` method.

Testing Component Events

To demonstrate how to test for a component's response to events, I defined a new property in the `FirstComponent` class and added a method to which the `@HostBinding` decorator has been applied, as shown in Listing 29-14.

Listing 29-14. Adding Event Handling in the first.component.ts File in the src/app/ondemand Folder

```
import { Component, HostListener} from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";

@Component({
    selector: "first",
    templateUrl: "first.component.html"
})
export class FirstComponent {

    constructor(private repository: Model) {}

    category: string = "Soccer";
    highlighted: boolean = false;

    getProducts(): Product[] {
        return this.repository.getProducts()
            .filter(p => p.category == this.category);
    }
```

```
    @HostListener("mouseenter", ["$event.type"])
    @HostListener("mouseleave", ["$event.type"])
    setHighlight(type: string) {
        this.highlighted = type == "mouseenter";
    }
}
```

The setHighlight method has been configured so that it will be invoked when the host element's mouseenter and mouseleave events are triggered. Listing 29-15 updates the component's template so that it uses the new property in a data binding.

Listing 29-15. Binding to a Property in the first.component.html File in the src/app/ondemand Folder

```
<div class="bg-primary text-white p-2" [class.bg-success]="highlighted">
    There are
    <span class="strong"> {{getProducts().length}} </span>
    products
</div>
```

Events can be triggered in unit tests through the triggerEventHandler method defined by the DebugElement class, as shown in Listing 29-16.

Listing 29-16. Triggering Events in the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture, waitForAsync } from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";
import { Product } from "..//model/product.model";
import { Model } from "../model/repository.model";
import { DebugElement } from "@angular/core";
import { By } from "@angular/platform-browser";

describe("FirstComponent", () => {

    let fixture: ComponentFixture<FirstComponent>;
    let component: FirstComponent;
    let debugElement: DebugElement;
    // let bindingElement: HTMLSpanElement;
    // let spanElement: HTMLSpanElement;
    let divElement: HTMLDivElement;

    let mockRepository = {
        getProducts: function () {
            return [
                new Product(1, "test1", "Soccer", 100),
                new Product(2, "test2", "Chess", 100),
                new Product(3, "test3", "Soccer", 100),
            ]
        }
    }
```

```
    beforeEach(waitForAsync(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent],
            providers: [
                { provide: Model, useValue: mockRepository }
            ]
        });
        TestBed.compileComponents().then(() => {
            fixture = TestBed.createComponent(FirstComponent);
            component = fixture.componentInstance;
            debugElement = fixture.debugElement;
            //spanElement = debugElement.query(By.css("span")).nativeElement;
            divElement = debugElement.children[0].nativeElement;
        });
    }));

    // it("filters categories", () => {
    //     component.category = "Chess"
    //     fixture.detectChanges();
    //     expect(component.getProducts().length).toBe(1);
    //     expect(bindingElement.textContent).toContain("1");

    //     component.category = "Soccer";
    //     fixture.detectChanges();
    //     expect(component.getProducts().length).toBe(2);
    //     expect(bindingElement.textContent).toContain("2");

    //     component.category = "Running";
    //     fixture.detectChanges();
    //     expect(component.getProducts().length).toBe(0);
    //     expect(bindingElement.textContent).toContain("0");
    // });

    it("handles mouse events", () => {
        expect(component.highlighted).toBeFalsy();
        expect(divElement.classList.contains("bg-success")).toBeFalsy();
        debugElement.triggerEventHandler("mouseenter", new Event("mouseenter"));
        fixture.detectChanges();
        expect(component.highlighted).toBeTruthy();
        expect(divElement.classList.contains("bg-success")).toBeTruthy();
        debugElement.triggerEventHandler("mouseleave", new Event("mouseleave"));
        fixture.detectChanges();
        expect(component.highlighted).toBeFalsy();
        expect(divElement.classList.contains("bg-success")).toBeFalsy();
    });

});
```

The test in this listing checks the initial state of the component and the template and then triggers the mouseenter and mouseleave events, checking the effect that each has.

Testing Output Properties

Testing output properties is a simple process because the EventEmitter objects used to implement them are Observable objects that can be subscribed to in unit tests. Listing 29-17 adds an output property to the component under test.

Listing 29-17. Adding an Output Property in the first.component.ts File in the src/app/ondemand Folder

```
import { Component, HostListener, Output, EventEmitter} from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";

@Component({
    selector: "first",
    templateUrl: "first.component.html"
})
export class FirstComponent {

    constructor(private repository: Model) {}

    category: string = "Soccer";
    highlighted: boolean = false;

    @Output("pa-highlight")
    change = new EventEmitter<boolean>();

    getProducts(): Product[] {
        return this.repository.getProducts()
            .filter(p => p.category == this.category);
    }

    @HostListener("mouseenter", ["$event.type"])
    @HostListener("mouseleave", ["$event.type"])
    setHighlight(type: string) {
        this.highlighted = type == "mouseenter";
        this.change.emit(this.highlighted);
    }
}
```

The component defines an output property called change, which is used to emit an event when the setHighlight method is called. Listing 29-18 shows a unit test that targets the output property.

Listing 29-18. Testing an Output Property in the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture, waitForAsync } from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";
import { Product } from ".//model/product.model";
import { Model } from "../model/repository.model";
import { DebugElement } from "@angular/core";
import { By } from "@angular/platform-browser";
```

```
describe("FirstComponent", () => {

    let fixture: ComponentFixture<FirstComponent>;
    let component: FirstComponent;
    let debugElement: DebugElement;
    let divElement: HTMLDivElement;

    let mockRepository = {
        getProducts: function () {
            return [
                new Product(1, "test1", "Soccer", 100),
                new Product(2, "test2", "Chess", 100),
                new Product(3, "test3", "Soccer", 100),
            ]
        }
    }

    beforeEach(waitForAsync(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent],
            providers: [
                { provide: Model, useValue: mockRepository }
            ]
        });
        TestBed.compileComponents().then(() => {
            fixture = TestBed.createComponent(FirstComponent);
            component = fixture.componentInstance;
            debugElement = fixture.debugElement;
            divElement = debugElement.children[0].nativeElement;
        });
    }));

    // it("handles mouse events", () => {
    //     expect(component.highlighted).toBeFalsy();
    //     expect(divElement.classList.contains("bg-success")).toBeFalsy();
    //     debugElement.triggerEventHandler("mouseenter", new Event("mouseenter"));
    //     fixture.detectChanges();
    //     expect(component.highlighted).toBeTruthy();
    //     expect(divElement.classList.contains("bg-success")).toBeTruthy();
    //     debugElement.triggerEventHandler("mouseleave", new Event("mouseleave"));
    //     fixture.detectChanges();
    //     expect(component.highlighted).toBeFalsy();
    //     expect(divElement.classList.contains("bg-success")).toBeFalsy();
    // });

    it("implements output property", () => {
        let highlighted: boolean = false;
        component.change.subscribe(value => highlighted = value);
        debugElement.triggerEventHandler("mouseenter", new Event("mouseenter"));
        expect(highlighted).toBeTruthy();
```

```
        debugElement.triggerEventHandler("mouseleave", new Event("mouseleave"));
        expect(highlighted).toBeFalsy();
    });
});
```

I could have invoked the component's `setHighlight` method directly in the unit test, but instead I have chosen to trigger the `mouseenter` and `mouseleave` events, which will activate the output property indirectly. Before triggering the events, I use the `subscribe` method to receive the event from the `output` property, which is then used to check for the expected outcomes.

Testing Input Properties

The process for testing input properties requires a little extra work. To get started, I added an input property to the `FirstComponent` class that is used to receive the data model repository, replacing the service that was received by the constructor, as shown in Listing 29-19. I have also removed the host event bindings and the output property to keep the example simple.

Listing 29-19. Adding an Input Property in the first.component.ts File in the src/app/ondemand Folder

```
import { Component, Input } from "@angular/core";
import { Product } from "../model/product.model";
import { Model } from "../model/repository.model";

@Component({
    selector: "first",
    templateUrl: "first.component.html"
})
export class FirstComponent {
    constructor(private repository: Model) {}

    category: string = "Soccer";
    highlighted: boolean = false;

    // @Output("pa-highlight")
    // change = new EventEmitter<boolean>();

    getProducts(): Product[] {
        return this.model == null ? [] : this.model.getProducts()
            .filter(p => p.category == this.category);
    }

    // @HostListener("mouseenter", ["$event.type"])
    // @HostListener("mouseleave", ["$event.type"])
    // setHighlight(type: string) {
    //     this.highlighted = type == "mouseenter";
    //     this.change.emit(this.highlighted);
    // }

    @Input("pa-model")
    model?: Model;
}
```

869

The input property is set using an attribute called pa-model and is used within the getProducts method. Listing 29-20 shows how to write a unit test that targets the input property.

Listing 29-20. Testing an Input Property in the first.component.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture, waitForAsync } from "@angular/core/testing";
import { FirstComponent } from "../ondemand/first.component";
import { Product } from ".//model/product.model";
import { Model } from "../model/repository.model";
import { DebugElement } from "@angular/core";
import { By } from "@angular/platform-browser";
import { Component, ViewChild } from "@angular/core";

@Component({
    template: `<first [pa-model]="model"></first>`
})
class TestComponent {

    constructor(public model: Model) { }

    @ViewChild(FirstComponent)
    firstComponent!: FirstComponent;
}

describe("FirstComponent", () => {

    let fixture: ComponentFixture<TestComponent>;
    let component: FirstComponent;
    let debugElement: DebugElement;
    let divElement: HTMLDivElement;

    let mockRepository = {
        getProducts: function () {
            return [
                new Product(1, "test1", "Soccer", 100),
                new Product(2, "test2", "Chess", 100),
                new Product(3, "test3", "Soccer", 100),
            ]
        }
    }

    beforeEach(waitForAsync(() => {
        TestBed.configureTestingModule({
            declarations: [FirstComponent, TestComponent],
            providers: [
                { provide: Model, useValue: mockRepository }
            ]
        });
        TestBed.compileComponents().then(() => {
            fixture = TestBed.createComponent(TestComponent);
            fixture.detectChanges();
            component = fixture.componentInstance.firstComponent;
```

```
            debugElement = fixture.debugElement.query(By.directive(FirstComponent));
        });
    }));

    // it("implements output property", () => {
    //     let highlighted: boolean = false;
    //     component.change.subscribe(value => highlighted = value);
    //     debugElement.triggerEventHandler("mouseenter", new Event("mouseenter"));
    //     expect(highlighted).toBeTruthy();
    //     debugElement.triggerEventHandler("mouseleave", new Event("mouseleave"));
    //     expect(highlighted).toBeFalsy();
    // });

    it("receives the model through an input property", () => {
        component.category = "Chess";
        fixture.detectChanges();
        let products = mockRepository.getProducts()
            .filter(p => p.category == component.category);
        let componentProducts = component.getProducts();
        for (let i = 0; i < componentProducts.length; i++) {
            expect(componentProducts[i]).toEqual(products[i]);
        }
        expect(debugElement.query(By.css("span")).nativeElement.textContent)
            .toContain(products.length);
    });
});
```

The trick here is to define a component that is only required to set up the test and whose template contains an element that matches the selector of the component you want to target. In this example, I defined a component class called TestComponent with an inline template defined in the @Component decorator that contains a first element with a pa-model attribute, which corresponds to the @Input decorator applied to the FirstComponent class.

The test component class is added to the declarations array for the testing module, and an instance is created using the TestBed.createComponent method. I used the @ViewChild decorator in the TestComponent class so that I can get hold of the FirstComponent instance I require for the test. To get the FirstComponent root element, I used the DebugElement.query method with the By.directive method.

The result is that I can access both the component and its root element for the test, which sets the category property and then validates the results both from the component and via the data binding in its template.

Testing an Angular Directive

The process for testing directives is similar to the one required to test input properties, in that a test component and template are used to create an environment for testing in which the directive can be applied. To have a directive to test, I added a file called attr.directive.ts to the src/app/ondemand folder and added the code shown in Listing 29-21.

■ **Note** I have shown an attribute directive in this example, but the technique in this section can be used to test structural directives equally well.

Listing 29-21. The Contents of the attr.directive.ts File in the src/app/ondemand Folder

```
import {
    Directive, ElementRef, Attribute, Input, SimpleChange
} from "@angular/core";

@Directive({
    selector: "[pa-attr]"
})
export class PaAttrDirective {

    constructor(private element: ElementRef) { }

    @Input("pa-attr")
    bgClass?: string;

    ngOnChanges(changes: { [property: string]: SimpleChange }) {
        let change = changes["bgClass"];
        let classList = this.element.nativeElement.classList;
        if (!change.isFirstChange() && classList.contains(change.previousValue)) {
            classList.remove(change.previousValue);
        }
        if (!classList.contains(change.currentValue)) {
            classList.add(change.currentValue);
        }
    }
}
```

This is an attribute directive based on an example from Chapter 13. To create a unit test that targets the directive, I added a file called `attr.directive.spec.ts` to the `src/app/tests` folder and added the code shown in Listing 29-22.

Listing 29-22. The Contents of the attr.directive.spec.ts File in the src/app/tests Folder

```
import { TestBed, ComponentFixture } from "@angular/core/testing";
import { Component, DebugElement, ViewChild } from "@angular/core";
import { By } from "@angular/platform-browser";
import { PaAttrDirective } from "../ondemand/attr.directive";

@Component({
    template: `<div><span [pa-attr]="className">Test Content</span></div>`
})
class TestComponent {
    className = "initialClass"

    @ViewChild(PaAttrDirective)
    attrDirective!: PaAttrDirective;
}

describe("PaAttrDirective", () => {

    let fixture: ComponentFixture<TestComponent>;
```

```
        let directive: PaAttrDirective;
        let spanElement: HTMLSpanElement;

        beforeEach(() => {
            TestBed.configureTestingModule({
                declarations: [TestComponent, PaAttrDirective],
            });
            fixture = TestBed.createComponent(TestComponent);
            fixture.detectChanges();
            directive = fixture.componentInstance.attrDirective;
            spanElement = fixture.debugElement.query(By.css("span")).nativeElement;
        });

        it("generates the correct number of elements", () => {
            fixture.detectChanges();
            expect(directive.bgClass).toBe("initialClass");
            expect(spanElement.className).toBe("initialClass");

            fixture.componentInstance.className = "nextClass";
            fixture.detectChanges();
            expect(directive.bgClass).toBe("nextClass");
            expect(spanElement.className).toBe("nextClass");
        });
    });
```

The text component has an inline template that applies the directive and a property that is referred to in the data binding. The @ViewChild decorator provides access to the directive object that Angular creates when it processes the template, and the unit test can check that changing the value used by the data binding has an effect on the directive object and the element it has been applied to.

Summary

In this chapter, I demonstrated the different ways in which Angular components and directives can be unit tested. I explained the process of installing the test framework and tools and how to create the testbed through which tests are applied. I demonstrated how to test the different aspects of components and how the same techniques can be applied to directives as well.

That is all I have to teach you about Angular. I started by creating a simple application and then took you on a comprehensive tour of the different building blocks in the framework, showing you how they can be created, configured, and applied to create web applications.

I wish you every success in your Angular projects, and I can only hope that you have enjoyed reading this book as much as I enjoyed writing it.
