About the Author

Holger Schwichtenberg is a .NET MVP with more than 20 years of experience as a developer and trainer. He is currently a technical lead with the German company IT-Visions, where he consults and trains at companies throughout Europe. He also serves as a software architect for 5Minds IT-Solutions. Holger is a huge fan of Entity Framework (EF) and Entity Framework Core and regularly speaks about both. He has used EF in projects of all sizes, most recently on a big data project containing billions of records. He is a prolific writer, having published more than 65 books and 1,000 technical articles in well-known IT professional and developer journals, including MSDN. He has presented at events such as TechEd Europe, Microsoft IT Forum, Advanced Developer Conference, Microsoft Launch, MSDN Technical Summit, and others. Holger has a PhD in business informatics.

Introduction

I have always been a big fan of object-relational mapping (ORM); in fact, I developed my own OR mapper for my software development projects in the early days of .NET. I switched to the ADO.NET Entity Framework when Microsoft introduced it in .NET 3.5 Service Pack 1. Nowadays, I prefer its successor, Entity Framework Core. Interestingly, some of my projects are still running the classic Entity Framework. As Microsoft continues to do incremental releases of Entity Framework Core, many of the challenges and gripes developers had with earlier versions have gone away, so my plan is to switch the management of all my projects to Entity Framework Core.

The book you hold in your hands came from an idea I had to cover all the important database access scenarios. I hadn't found much collective information in one place and felt that a compendium could be of great value to others. In this book, you will be introduced to database access concepts, get hands-on experience installing Entity Framework Core, and learn about reverse engineering and forward engineering for existing or legacy databases. I'll delve into topics such as schema migrations, data reading, and data modification with LINQ, Dynamic LINQ, APIs, SQL, stored procedures and table-valued functions, object relationships, and asynchronous programming. I'll also talk about third-party products such as LINQPad, Entity Developer, Entity Framework Profiler, Entity Framework Plus, and AutoMapper.

I'll discuss how to apply Entity Framework Core through case studies using Universal Windows Platform (UWP) apps, Xamarin, and ASP.NET Core. Of course, no book would be complete without sharing a healthy dose of hard-earned tips and tricks from my experience with Entity Framework and Entity Framework Core over the years.

Expectations of the Reader

This book is intended for software developers who have experience with .NET and C# as well as some relational database experience and who now want to use Entity Framework Core to create data access code in .NET, .NET Core, UWP apps, and Xamarin. Previous knowledge in predecessor technologies such as ADO.NET and the classic ADO.NET Entity Framework is useful but not necessary to understand this book.

Programming Language Used in This Book

I chose to use C# in this book because it is by far the most commonly used programming language in .NET. While I still occasionally develop .NET applications in Visual Basic .NET, it doesn't make sense to print all the listings in both languages.

If you are interested, a language converter between C# and Visual Basic .NET is freely available on several web sites, including <http://converter.telerik.com> and <https://www.mindfusion.eu/convert-cs-vb.html>.

The Use of Case Studies and Fictitious Enterprises

Most of the sample code in this book revolves around the fictitious airline World Wide Wings, abbreviated as WWWings or just WWW (see Figure 1).

Figure 1. Logo of the fictional airline World Wide Wings

Note You'll see other case studies used in some chapters, such as the task management app MiracleList.

The World Wide Wings use case deals with the following entities:

- *Flights* between two places where the places were deliberately not modeled as separate entities but as strings (this simplifies the understanding of many examples).
- *Passengers* flying on a flight.
- *Employees* of the airline, who have supervisors who are also employees.
- *Pilots* as a specialization of employees. A flight has only one pilot. There are no copilots at World Wide Wings.

- *Persons* as a collection of common characteristics for all people in this example. A person is not available on their own, but only in one of three specializations: passenger, employee, and pilot. In the object-oriented sense, therefore, Person is an abstract base class that cannot own instances but is used only for inheritance.

The World Wide Wings use case has two data models, explained here:

- The slightly simpler model version 1 (see Figures 2 and 3) is the result of classic relational database design with normalization. The object model is created by reverse engineering.

Figure 2. World Wide Wings data model in the simpler version 1

INTRODUCTION

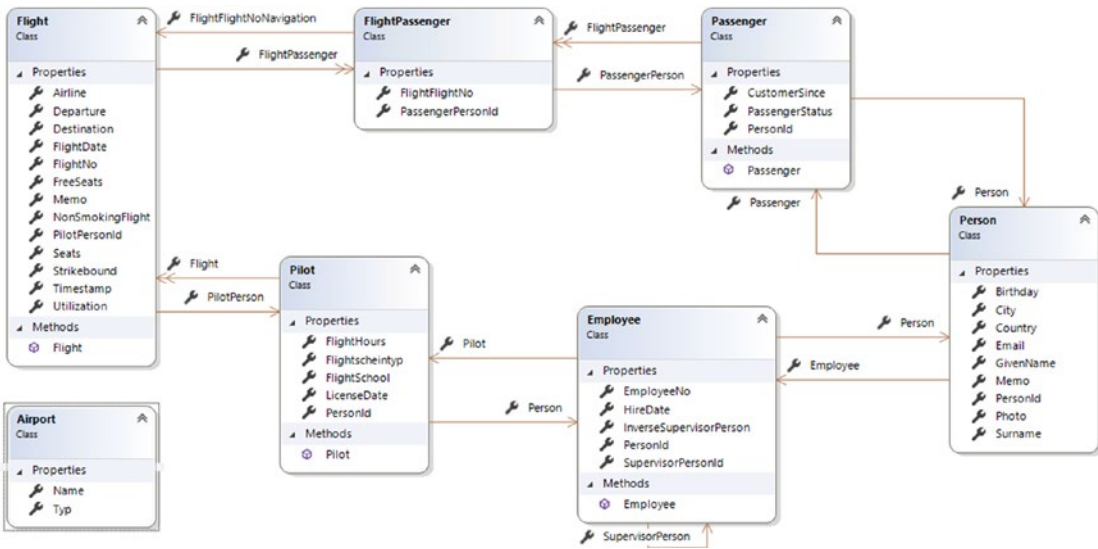

Figure 3. Object model of the World Wide Wings data model in the simpler version 1

- Model version 2 (see Figures 4 and 5) is the result of forward engineering with Entity Framework Core from an object model. In addition, there are other entities (Airline, Persondetail, AircraftType, and AircraftTypeDetail) in this model to show further modeling aspects. In this case, there is an optional copilot for each flight.

In model version 1 there is a separate table for people (called Person), staff, pilots, employee, and passengers. This separation corresponds to the classes in the object model.

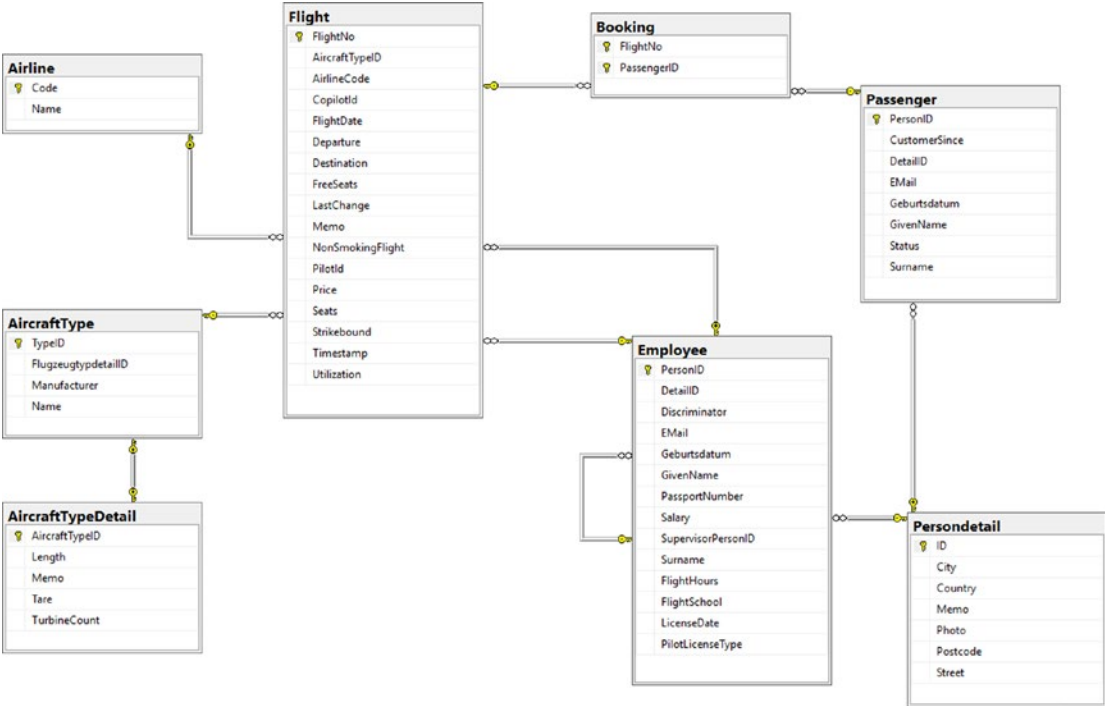

Figure 4. World Wide Wings data model in the more complex version 2

INTRODUCTION

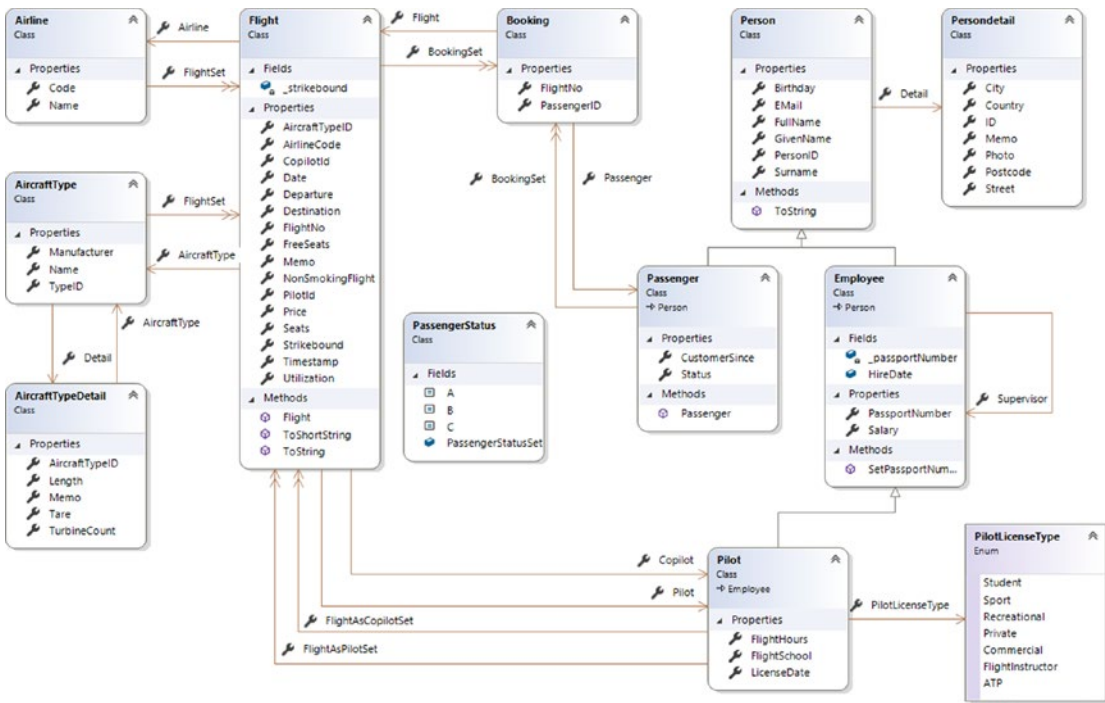

Figure 5. Object model for the World Wide Wings data model in the more complex version 2

Note The object models that were created in this book for the data models do not represent an ideal object model because Entity Framework Core does not support some mapping capabilities, such as N:M mapping, yet.

The object model for the data schema of World Wide Wings version 6.1 (Figure 3) was automatically generated by the Entity Framework Core from the database (through reverse engineering); I deliberately did not change it, even if some of the generated names are ugly.

In model version 2, there are only the Passenger and Employee tables for these four entities. Entity Framework Core is currently somewhat limited and does not support table per type mapping (a separate table for each class). Therefore, the table Passenger also includes all the characteristics of Person. In addition to the Person properties, the

Employee table includes the properties of the Employee and Pilot entities. In the table, a Discriminator column distinguishes between records that are an employee and those that are a pilot. Entity Framework Core mixes the concepts of table by concrete type (TPC) and table by hierarchy (TPH). The developer has no definite influence on the inheritance mapping in Entity Framework Core 1.x/2.0. The classic Entity Framework offers more options here.

The following are the extra dependencies in model version 2:

- A Flight belongs to Airline (there will be only World Wide Wings and its subsidiary Never Come Back Airline in this book).
- There a Copilot entity here, but it is optional.
- A Flight can optionally have an AircraftType object assigned. AircraftType must have an AircraftTypeDetail object.
- Each Person and therefore each Pilot and Passenger must own a Persondetail object.

In this book, both data models are used, partly in modified form, to show certain scenarios (for example, database schema migrations).

Application Types in This Book

In this book, the examples are for the most time shown via a text-based console in console applications because this allows me to focus on database access. When using graphical user interfaces such as WPF, Windows Forms, ASP.NET Web Forms, or ASP.NET MVC, the representation is decoupled by data binding, which means I would always need to show a second listing so you could understand that the data access was actually delivered. I simulate user inputs in the console examples by writing variables at the beginning of the program code.

I have provided training and consultancy on data access for many years and have learned that console editions are didactically the best tool for teaching because otherwise the listings are large and thus inferior.

Of course, console output is not common practice in 99 percent of software development, but graphical user interfaces are covered in other books, and data binding typically has no impact on the form of data access. Where data access is relevant, this book will also show data binding examples.

Helper Functions for Console Output

I will show the screen output on the console using the standard method `Console.WriteLine()` in several places; in addition, I use auxiliary routines that generate colored screen output. Listing 1 shows these auxiliary routines in the class CUI from `ITV_DemoUtil.dll` for a better understanding.

Access to Code Examples, Updates, and Figures on GitHub

You can download all the examples for this book as Visual Studio projects via the book's product page, located at www.apress.com/9781484235515. This page will also point you to additional complementary content on Entity Framework Core updates, discussion, and errata.

Microsoft continues to release incremental updates to Entity Framework Core and readily admits the following: "These are things we think we need before we can say EF Core is the recommended version of EF for everyone" (<https://github.com/aspnet/EntityFrameworkCore/wiki/roadmap>). To help make sense of the changes coming in 2.1, you can find this book's Appendix C, which outlines new features, on the book's GitHub repository.

You can also find information on the book page I maintain at www.efcore.net.

Please note that not every single line of program code in this book is included in the downloadable projects. This book also discusses alternative solutions for individual cases that do not necessarily fit into a total solution.

Thank you for reading my book, and I welcome any comments and feedback at EFCoreBookFeedback@dotnet-doctor.net.

CHAPTER 1

Introducing Entity Framework Core

In this chapter, you will learn about Entity Framework Core and how it is an OR mapper for .NET (.NET Framework, .NET Core, Mono, and Xamarin). Entity Framework Core is a completely new implementation of the ADO.NET Entity Framework.

Together with .NET Core version 1.0 and ASP.NET Core version 1.0, Entity Framework Core version 1.0 was released on June 27, 2016. Version 2.0 was released on August 14, 2017. Version 2.1 is in progress.

What Is an Object-Relational Mapper?

In the database world, relational databases are prevalent. The programming world is all about objects. There are significant semantic and syntactic differences between the two worlds, called *impedance mismatch*; see https://en.wikipedia.org/wiki/Object-relational_impedance_mismatch.

Working with objects as instances of classes in memory is at the core of object-oriented programming (OOP). Most applications also include the requirement to permanently store data in objects, especially in databases. Basically, there are object-oriented databases (OODBs) that are directly able to store objects, but OODBs have only a small distribution so far. Relational databases are more predominant, but they map the data structures differently than object models.

To make the handling of relational databases more natural in object-oriented systems, the software industry has been relying on object-relational mappers for years. These tools translate concepts from the object-oriented world, such as classes, attributes, or relationships between classes, to corresponding constructs of the relational world, such as tables, columns, and foreign keys (see Figure 1-1). Developers can thus remain

in the object-oriented world and instruct the OR mapper to load or store certain objects that are in the form of records in tables of the relational database. Less interesting tasks and error-prone ones, such as manually creating INSERT, UPDATE, and DELETE statements, are also handled by the OR mapper, further reducing the load on the developer.

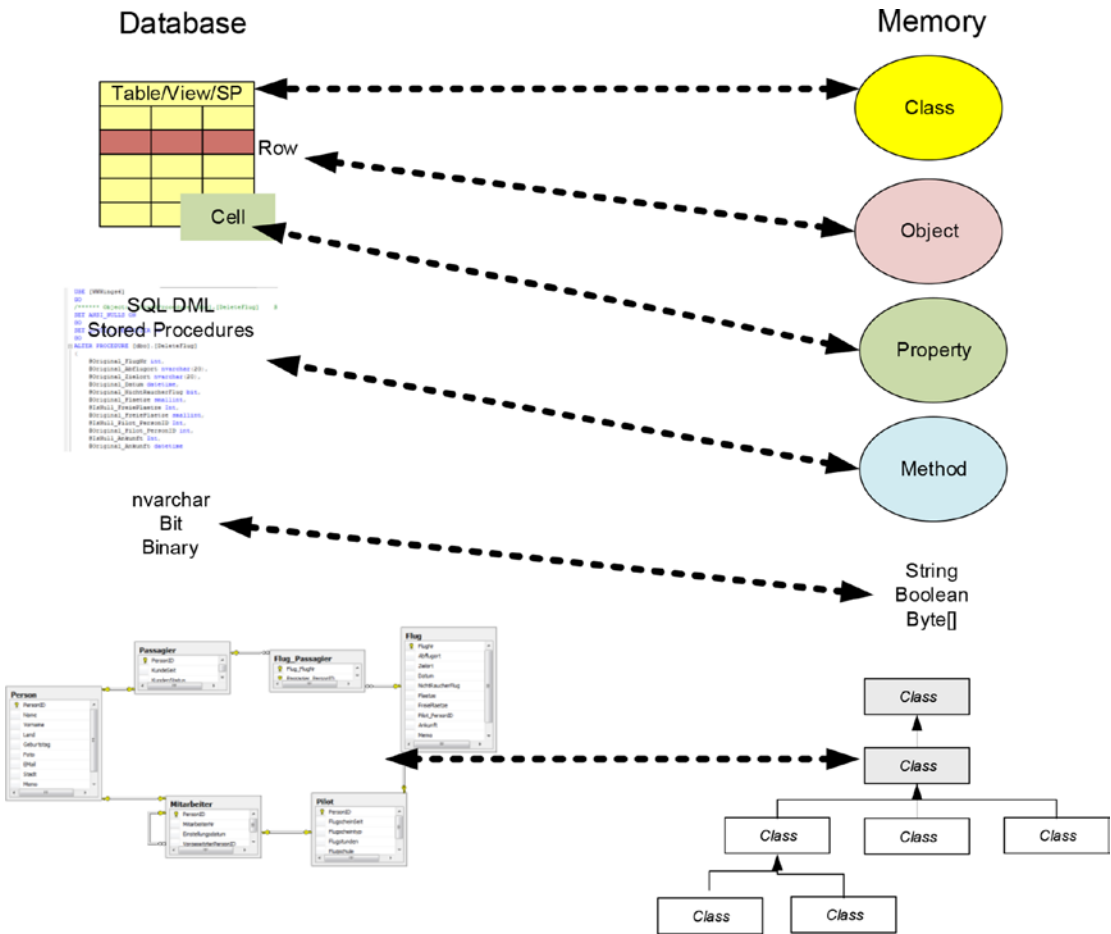

Figure 1-1. The OR mapper translates constructs of the OOP world to the relational world

Two particularly striking differences between the object model and the relation model are N:M relations and inheritance. While in an object model you can map an N:M relationship between objects through a reciprocal set of objects, you need an intermediate table in the relational database. Relational databases do not support inheritance. There are different ways of replicating, but you'll learn more about that later in the book.

OR Mappers in the .NET World

When a .NET developer reads in data from a database with a `DataReader` or `DataSet`, the developer is not doing object-relational mapping at this point. Although `DataReader` and `DataSet` are .NET objects, they only manage table structures. `DataReader` and `DataSet` are untyped, nonspecific containers from the point of view of an object model. Only when the developer defines specific classes for the structures stored in the tables and copies the contents from `DataSet` or `DataReader` into these specific data structures is the developer performing OR mapping. Such “manual” object-relational mapping is time-consuming, tedious, and monotonous programming work for read access (especially for very wide tables). If you then want to save changes in the objects again, the work becomes an intellectual challenge because you have to be able to recognize which objects have been changed. Otherwise, you constantly have to save all the data anew, which is an absurdity in multiuser environments.

While OR mappers have long been established in the Java world, Microsoft failed to bring a suitable product to market for a long time. The first version of .NET did not include an OR mapper but limited itself to direct data access and mapping between XML documents and the relational model. In .NET 3.5, there was an OR mapper named LINQ to SQL, but it was limited to Microsoft SQL Server and had many other restrictions.

Many .NET developers have therefore set about simplifying this work with auxiliary libraries and tools. In addition to the publicly known OR mappers for .NET, you will find many in-house solutions being built.

The following are third-party OR mappers for .NET (some of them open source):

- NHibernate
- Telerik Data Access (aka Open Access)
- Genome
- LLBLGen Pro
- Wilson
- SubSonic
- OBJ.NET
- DataObjects.NET
- Dapper

- PetaPoco
- Massive
- DevExpress XPO

With LINQ to SQL, ADO.NET Entity Framework, and Entity Framework, Microsoft itself now has three ORM products. The software company has meanwhile announced that further development efforts will concentrate solely on Entity Framework Core.

Figure 1-2. Entity Framework Core version history (<https://www.nuget.org/packages/Microsoft.EntityFrameworkCore>)

Major and minor versions (1.0, 1.1, and so on) indicate feature releases from Microsoft, and revision releases (1.0.1, 1.0.2, and so on) indicate bug fix releases. This book mentions the minimum version when discussing a function that requires a particular version.

Note The Entity Framework Core tools for Entity Framework Core 1.x were released on March 6, 2017, within the framework of Entity Framework Core 1.1.1 and Visual Studio 2017. Previously, there were only “preview” versions of the tools. Since Entity Framework Core 2.0, the tools are always delivered with the new product releases.

Supported Operating Systems

Like the other products in the Core product family, Entity Framework Core (formerly Entity Framework 7.0) is platform independent. The Core version of the established object-relational mapper runs not only on the “full” .NET Framework but also on .NET Core and Mono, including Xamarin. This allows you to use Entity Framework Core on Windows, Windows Phone/Mobile, Linux, macOS, iOS, and Android.

Supported .NET Versions

Entity Framework Core 1.x runs on .NET Core 1.x, .NET Framework 4.5.1, Mono 4.6, Xamarin.iOS 10, Xamarin Android 7.0 or higher, and the Universal Windows Platform (UWP).

Entity Framework Core 2.0 is based on .NET Standard 2.0 and therefore requires one of the following .NET implementations (see Figure 1-3):

- .NET Core 2.0 (or higher)
- .NET Framework 4.6.1 (or higher)
- Mono 5.4 (or higher)
- Xamarin.iOS 10.14 (or higher)
- Xamarin.Mac 3.8 (or higher)
- Xamarin.Android 7.5 (or higher)
- UWP 10.0.16299 (or higher)

.NET Standard	1.0	1.1	1.2	1.3	1.4	1.5	1.6	2.0
.NET Core	1.0	1.0	1.0	1.0	1.0	1.0	1.0	2.0
.NET Framework (with .NET Core 1.x SDK)	4.5	4.5	4.5.1	4.6	4.6.1	4.6.2		
.NET Framework (with .NET Core 2.0 SDK)	4.5	4.5	4.5.1	4.6	4.6.1	4.6.1	4.6.1	4.6.1
Mono	4.6	4.6	4.6	4.6	4.6	4.6	4.6	5.4
Xamarin.iOS	10.0	10.0	10.0	10.0	10.0	10.0	10.0	10.14
Xamarin.Mac	3.0	3.0	3.0	3.0	3.0	3.0	3.0	3.8
Xamarin.Android	7.0	7.0	7.0	7.0	7.0	7.0	7.0	8.0
Universal Windows Platform	10.0	10.0	10.0	10.0	10.0	10.0.16299	10.0.16299	10.0.16299
Windows	8.0	8.0	8.1					
Windows Phone	8.1	8.1	8.1					
Windows Phone Silverlight	8.0							

Figure 1-3. Implementations of .NET Standard (<https://docs.microsoft.com/en-us/dotnet/standard/library>)

Note Microsoft justifies the restriction to .NET Standard in Entity Framework Core 2.0 at <https://github.com/aspnet/Announcements/issues/246>. Among other things, it can significantly reduce the size of the NuGet packages.

Supported Visual Studio Versions

For the use of Entity Framework Core 2.0/2.1 you need Visual Studio 2017 Update 3 or higher, even if you are programming with the classic .NET Framework, because Visual Studio only with this update recognizes .NET Standard 2.0 and understands that .NET Framework 4.6.1 and later are implementations of .NET Standard 2.0.

Supported Databases

Table 1-1 shows the database management systems supported by Entity Framework Core, including ones by Microsoft (SQL Server, SQL Compact, and SQLite) and third-party vendors (PostgreSQL, DB2, Oracle, MySQL, and others).

Table 1-1. Available Database Drivers for Entity Framework Core

Database	Company/Price	URL
Microsoft SQL Server	Microsoft/free	www.nuget.org/packages/Microsoft.EntityFrameworkCore.SqlServer
Microsoft SQL Server Compact 3.5	Microsoft/free	www.nuget.org/packages/Microsoft.EntityFrameworkCore.SqlServerCompact35
Microsoft SQL Server Compact 4.0	Microsoft/free	www.nuget.org/packages/Microsoft.EntityFrameworkCore.SqlServerCompact40

In Memory	Microsoft/free	www.nuget.org/packages/Microsoft.EntityFrameworkCore.InMemory
MySQL	Oracle/free	www.nuget.org/packages/MySQL.Data.EntityFrameworkCore
PostgreSQL	Open source team npgsql.org/free	www.nuget.org/packages/Npgsql.EntityFrameworkCore.PostgreSQL
DB2	IBM/free	www.nuget.org/packages/EntityFramework.IBMDataServer

On mobile devices running Xamarin or Windows 10 UWP apps, Entity Framework Core 1.x can address only local databases (SQLite). With the introduction of .NET Standard 2.0, the Microsoft SQL Server client is now also available on Xamarin and the Windows 10 UWP (from the fall of 2017 Creators Update).

The planned support for NoSQL databases such as Redis and Azure Table storage is not yet included in Entity Framework Core version 1.x/2.x. However, there is an open source development project on GitHub for MongoDB; see <https://github.com/crhairr/EntityFrameworkCore.MongoDb>.

Caution Because of breaking changes in the provider interfaces, Entity Framework Core 1.x providers are not compatible with Entity Framework Core 2.0. So, you need new providers for version 2.0!

Features of Entity Framework Core

Figure 1-4 visualizes that Entity Framework Core (right areas) contains some new features compared to the previous Entity Framework (left area). Some features are included in Entity Framework 6.x, but not in Entity Framework Core 1.x/2.0. Microsoft will be upgrading some of these features in the upcoming versions of Entity Framework Core, but will no longer add new features.

Note If you download the figures from the book's web site, you'll be able to distinguish the products in the figure based on color.

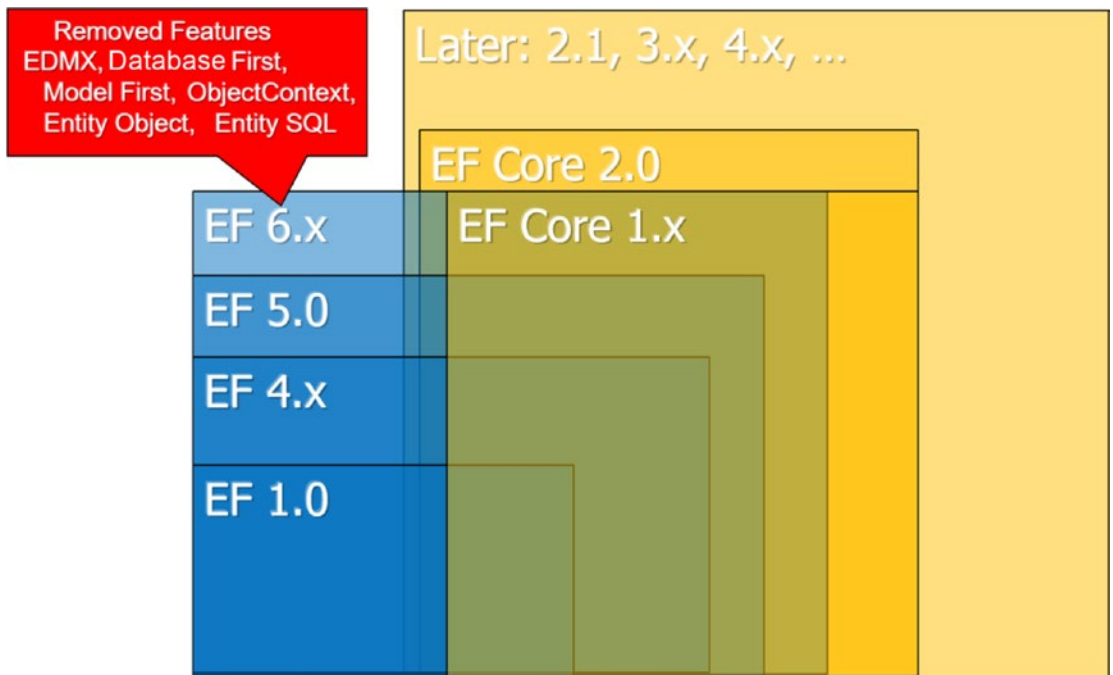

Figure 1-4. Functional scope of the classic Entity Framework compared to Entity Framework Core. On the left, a balloon shows some features that have been permanently eliminated.

Functions That Have Been Eliminated

The following features from the classic Entity Framework have been removed in Entity Framework Core:

- The process models Database First and Model First have been eliminated. In Entity Framework Core, there is only code-based modeling (formerly Code First), with which you can generate both program code from databases (reverse engineering) and databases from program code (forward engineering).
- The Entity Data Model (EDM) and the XML representation (EDMX) have been eliminated. So far, an EDM has also been generated internally in RAM in the Code First model. This overhead has also been eliminated.

- The base class `ObjectContext` for the Entity Framework context has been dropped. There is only the base class `DbContext`. `DbContext` is now no longer a wrapper around `ObjectContext` in Entity Framework Core but a completely new, stand-alone implementation.
- The `EntityObject` base class for entity classes has been eliminated. Entity classes are now always plain old CLR objects (POCOs).
- The query language Entity SQL (ESQL) has been omitted. There is support for LINQ, SQL, stored procedures (SPs), and table-valued functions (TVFs).
- Automatic schema migrations are no longer offered. Schema migrations, including the creation of a database schema, must now always be executed manually at development time. At runtime, a migration can still occur the first time the database is accessed.
- There used to be some scenarios of more complex mapping between tables and types. This includes multiple entity sets per type (MEST, which maps different tables to the same entity), and a combination of the table by hierarchy (TPH), table by type (TPT), and table by concrete type (TPC) strategies in an inheritance hierarchy. All these features have been removed.

Missing Critical Features

In the Entity Framework Core road map (<https://github.com/aspnet/EntityFramework/wiki/Roadmap>), Microsoft developer Rowan Miller documents what features are missing in Entity Framework Core that will be upgraded soon. This is not backed by a specific timetable, but Microsoft calls some of these features “critical.”

- Entity Framework Core supports access only to tables, not to views in the database. You can use a view only if you create the view and the program code manually and treat the view like a table.
- Previously, stored procedures could be used only to query data (SELECT) but not to insert (INSERT), update (UPDATE), and delete (DELETE).

- Some LINQ commands are currently executed in RAM, not in the database. This also includes the `group by` operator, which means that all data sets from the database are read into RAM and grouped there, which leads to catastrophic performance for all tables (except very small ones).
- There is neither automatic lazy loading nor explicit reloading in the Entity Framework Core API. Currently, developers can only load linked data sets directly (eager loading) or reload them with separate commands.
- Direct SQL and stored procedures can be used only if they return entity types. Other types are not supported yet.
- The reverse engineering of existing databases can be started only from the command line or from the NuGet console in Visual Studio. The GUI-based wizard is gone.
- There is also no Update Model from Database command for existing databases; in other words, after reverse engineering a database, the developer must manually add database schema changes in the object model or regenerate the entire object model. This function was also not available in Code First but only in Database First.
- There are no complex types, in other words, classes that do not represent their own entity but are part of another entity.

Preview Some of these features will be added in version 2.1; see Appendix C.

High-Priority Features

In a second list, Microsoft calls other features that it does not consider critical “high priority”:

- So far, there is no graphic visualization of an object model, as was previously possible with EDMX.
- Some of the previously existing type conversions, such as between XML and strings, do not yet exist.

- The geography and geometry data types of Microsoft SQL Server are not yet supported.
- Entity Framework Core does not support N:M mappings. So far, the developer has to replicate this with two 1:N mappings and an intermediate entity analogous to the intermediate table in the database.
- Table per type is not yet supported as an inheritance strategy. Entity Framework Core uses TPH if there is a `DBSet<T>` for the base class; otherwise, it uses TPC. You cannot explicitly configure TPC.
- It is not possible to populate the database with data as part of the migration (the `seed()` function).
- The Entity Framework 6.0 command interceptors, which allow an Entity Framework software developer to manipulate commands sent to the database before and after execution in the database, do not yet exist.

Some of the items on this high-priority list from Microsoft are also new features that Entity Framework 6.x itself does not (yet) master.

- Definition of conditions for data records to be loaded in eager loading (eager loading rules)
- Support for e-tags
- Support for nonrelational data stores (NoSQL) such as Azure Table storage and Redis

This prioritization is from Microsoft's perspective. Based on my practical experience, I would prioritize some points differently; for example, I would upgrade the N:M mapping to critical. A replication of N:M by two 1:N relationships in the object model is possible but makes the program code more complex. Migrating from existing Entity Framework solutions to the Entity Framework Core becomes difficult.

This also applies to the lack of support for table per type inheritance. Again, existing program code has to be extensively changed. And even for new applications with a new database schema and forward engineering, there is a problem: if the inheritance is first realized with TPH or TPC, you have to laboriously rearrange the data in the database schema if you later want to bet on TPH.

Also missing in Microsoft's lists are features such as validating entities, which can save unnecessary round-trips to the database when it's already clear in RAM that the entity does not meet the required conditions.

Preview Some of these features will be added in version 2.1; see Appendix C.

New Features in Entity Framework Core

Entity Framework Core can boast the following advantages over its predecessor:

- Entity Framework Core runs not only on Windows, Linux, and macOS but also on mobile devices running Windows 10, iOS, and Android. On mobile devices, of course only access to local databases (such as SQLite) is provided.
- Entity Framework Core provides faster execution speeds, especially when reading data (almost the same performance as manually copying data from a `DataReader` object to a typed .NET object).
- Projections with `Select()` can now be mapped directly to entity classes. The detour via anonymous .NET objects is no longer necessary.
- Batching allows the Entity Framework Core to merge INSERT, DELETE, and UPDATE operations into one database management system round-trip rather than sending each command one at a time.
- Default values for columns in the database are now supported in both reverse engineering and forward engineering.
- In addition to the classic auto-increment values, newer methods such as sequences are now also allowed for key generation.
- The term *shadow properties* in Entity Framework Core refers to the now possible access to columns of the database table for which there are no attributes in the class.

When to Use Entity Framework Core

Given this long list of missing features, the question arises as to whether and when Entity Framework Core in version 1.x/2.0 can be used.

The main application area is on platforms where Entity Framework does not run so far: Windows Phone/Mobile, Android, iOS, Linux, and macOS.

- UWP apps and Xamarin apps can use only Entity Framework Core. The classic Entity Framework is not possible here.
- If you want to develop a new ASP.NET Core web application or web API and you do not want to base it on the full .NET Framework but on .NET Core, there is no way around to do this with Entity Framework Core because the classic Entity Framework 6.x does not work on .NET Core. However, in ASP.NET Core it is also possible to use the .NET Framework 4.6.x/4.7.x as a basis so that you use Entity Framework 6.x too.
- Another scenario in which the use of Entity Framework Core on a web server can be recommended is an offline scenario, where there should be a local copy of the server database on the mobile device. In this case, you can use the same data access code on both the client and the server. The client uses Entity Framework Core to access SQLite, and the web server uses the same Entity Framework Core code to access a Microsoft SQL Server.

For projects on other platforms, note the following:

- Migrating existing code from Entity Framework 6.x to Entity Framework Core is expensive. It's important to consider whether the improved features and performance of Entity Framework Core justify the effort.
- However, in new projects, developers can already use Entity Framework Core as a high-performance future technology and, if necessary, use the existing Entity Framework there as an intermediate solution for existing gaps.

CHAPTER 2

Installing Entity Framework Core

Entity Framework Core has no `setup.exe`. Entity Framework Core is installed in a project via NuGet packages.

NuGet Packages

Entity Framework Core, in contrast to the classic Entity Framework, consists of several NuGet packages. Table 2-1 shows only the root packages. Their dependencies, to which NuGet then automatically adds the associated packages, are not listed here. If you're using a project template such as the ASP.NET Core Web Application template, you might have some of the dependencies already included.

Table 2-1. *Main Packages Available on nuget.org for Entity Framework Core*

Database Management System	NuGet Package Needed at Runtime	NuGet Package Needed at Development Time for Reverse Engineering or Schema Migrations
Microsoft SQL Server Express, Standard, Enterprise, Developer, LocalDB (from version 2008)	Microsoft. EntityFrameworkCore. SqlServer	Microsoft. EntityFrameworkCore.Tools Microsoft. EntityFrameworkCore. SqlServer (for EF Core 2.0) Microsoft. EntityFrameworkCore. SqlServer.Design (for EF Core 1.x)
Microsoft SQL Server Compact 3.5	EntityFrameworkCore. SqlServerCompact35	Not available
Microsoft SQL Server Compact 4.0	EntityFrameworkCore. SqlServerCompact40	Not available
SQLite	Microsoft. EntityFrameworkCore. Sqlite	Microsoft. EntityFrameworkCore.Tools Microsoft. EntityFrameworkCore. Sqlite (for EF Core 2.0) Microsoft. EntityFrameworkCore. Sqlite.Design (for EF Core 1.x)
In-Memory	Microsoft. EntityFrameworkCore. InMemory	Not available

(continued)

Table 2-1. (continued)

Database Management System	NuGet Package Needed at Runtime	NuGet Package Needed at Development Time for Reverse Engineering or Schema Migrations
PostgreSQL	Npgsql. EntityFrameworkCore. PostgreSQL	Microsoft. EntityFrameworkCore.Tools Npgsql. EntityFrameworkCore. PostgreSQL (for EF Core 2.0) Npgsql. EntityFrameworkCore. PostgreSQL.Design (for EF Core 1.x)
MySQL	MySQL.Data. EntityFrameworkCore	MySQL.Data. EntityFrameworkCore. Design
Oracle (Devart Provider)	Devart.Data.Oracle. EFCore	Microsoft. EntityFrameworkCore.Tools

In Entity Framework Core version 2.0, Microsoft changed the tailoring of the packages (as it did during the alpha and beta versions), as shown in Figure 2-1. Before, there were two packages for each driver, one of them with *design* in the name. The “design” packages were dissolved and integrated into the actual driver assemblies.

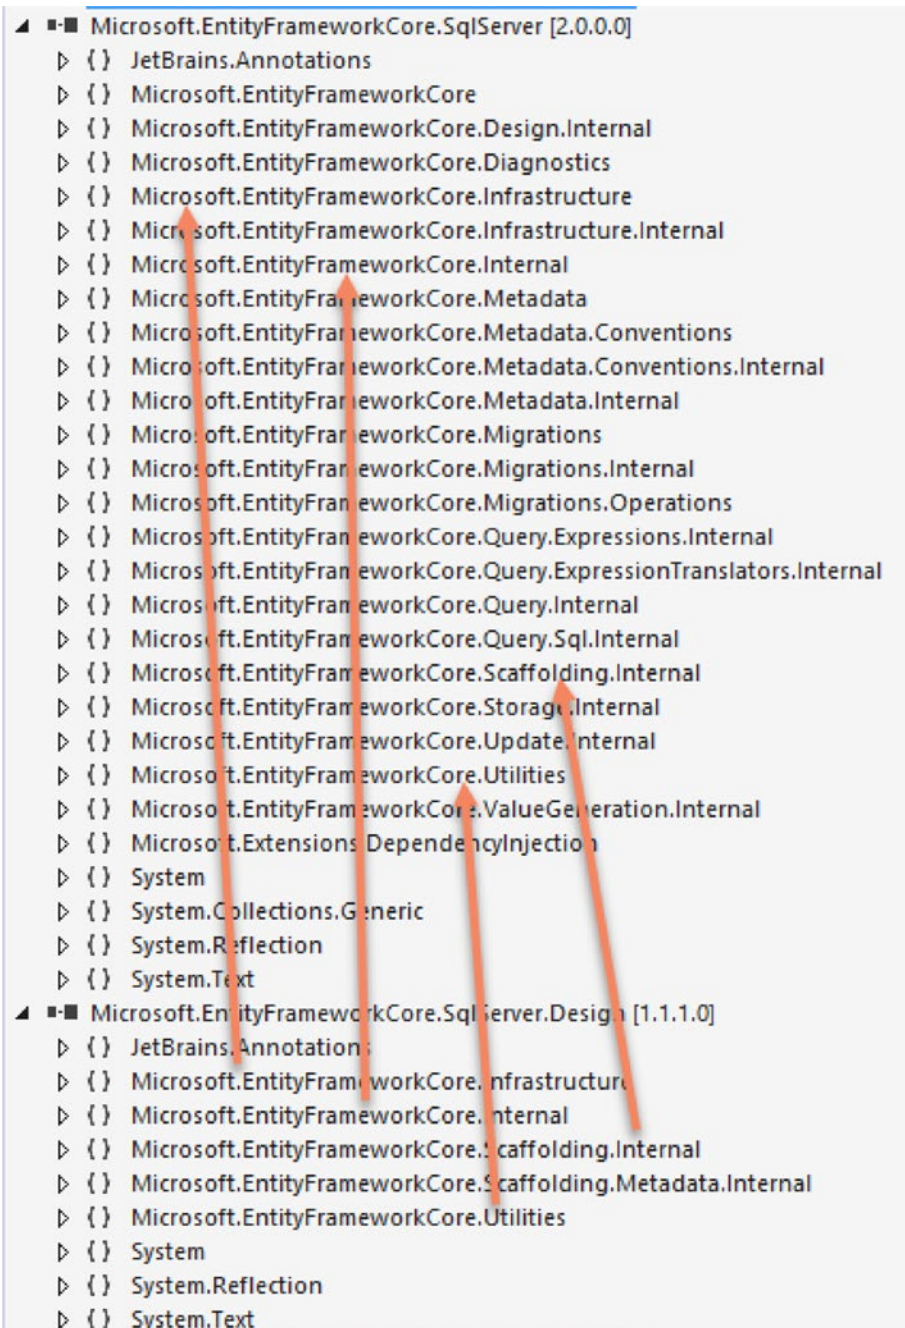

Figure 2-1. In Entity Framework Core 2.0, Microsoft has integrated the classes of *Microsoft.EntityFrameworkCore.SqlServer.Design.dll* into *Microsoft.EntityFrameworkCore.SqlServer.dll*.

Installing the Packages

You can install the packages with the NuGet Package Manager (Figure 2-2 and 2-3 and 2-4) or the PowerShell cmdlet `Install-Package` in Visual Studio (Figure 2-5 and 2-6).

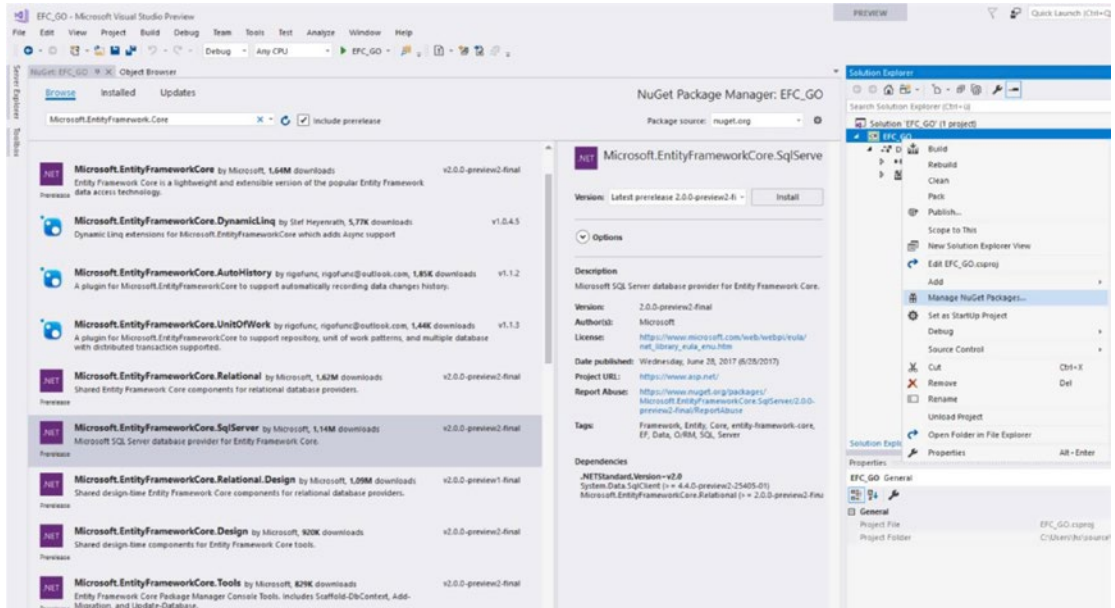

Figure 2-2. Installing the driver for Microsoft SQL Server with the NuGet Package Manager GUI

At the command line (select NuGet Package Manager Console ► PMC), you can install the current stable version and associated dependencies with the following:

```
Install-Package Microsoft.EntityFrameworkCore.SqlServer
```

You can install the current prelease version with the following:

```
Install-Package Microsoft.EntityFrameworkCore.SqlServer -Pre
```

You can install a specific version with the following:

```

Figure 2-6. The `Get-Package` cmdlet shows that some projects have already been upgraded to Entity Framework Core 2.0, others not yet

Updating to a New Version

Existing projects are upgraded to a new version of Entity Framework Core with the NuGet Package Manager, either in its graphical version or at the command line.

The NuGet Package Manager GUI indicates that many NuGet packages are to be updated when a new Entity Framework Core version is available.

Tip Since the NuGet Package Manager sometimes “gets tangled up” with many updates, you should not update all the packages at once, as Figure 2-7 shows. You should update only the actual root package, in other words, the package with the desired Entity Framework Core driver (for example, `Microsoft.EntityFrameworkCore.SqlServer`, as shown in Figure 2-8). This package update also entails updating its dependencies.

CHAPTER 2 INSTALLING ENTITY FRAMEWORK CORE

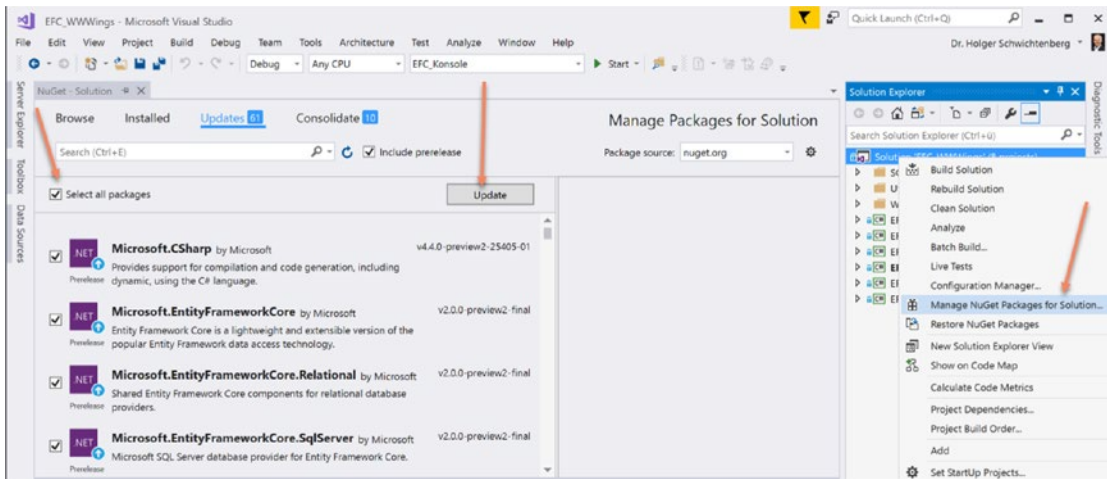

Figure 2-7. Graphical update of all NuGet packages (not recommended!)

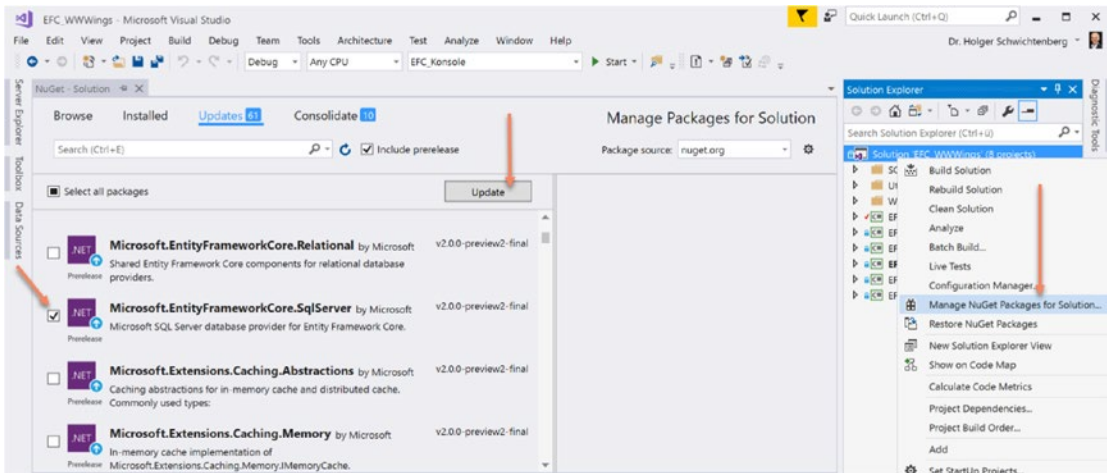

Figure 2-8. It is better to choose only the root packages, in other words, the package with the database driver

This corresponds to the procedure on the command line, on which you do not want to type in all packages but only the root package updates, for example, when upgrading to Entity Framework Core 2.0:

```
Update-Package Microsoft.EntityFrameworkCore.SqlServer version 2.0.0
```

Tip If you get the error message “Could not install package 'Microsoft.EntityFrameworkCore.SqlServer 2.0.0'. You are trying to install this package into a project that targets '.NETFramework,Version=v4.x, but the package does not contain any assembly references or content files that are compatible with that framework,” this may have the following causes:

- You are using a .NET version prior to 4.6.1 that is not compatible with .NET Standard 2.0 and therefore cannot use Entity Framework Core 2.0.
- However, if the version number in the error message is 4.6.1 or higher (see Figure 2-9), this is because you are using a too-old version of Visual Studio. Entity Framework Core 2.0 can be used only as of Visual Studio 2015 Update 3 with .NET Core installed. (Even if you use the classic .NET Framework, .NET Core must be installed on the development system!)

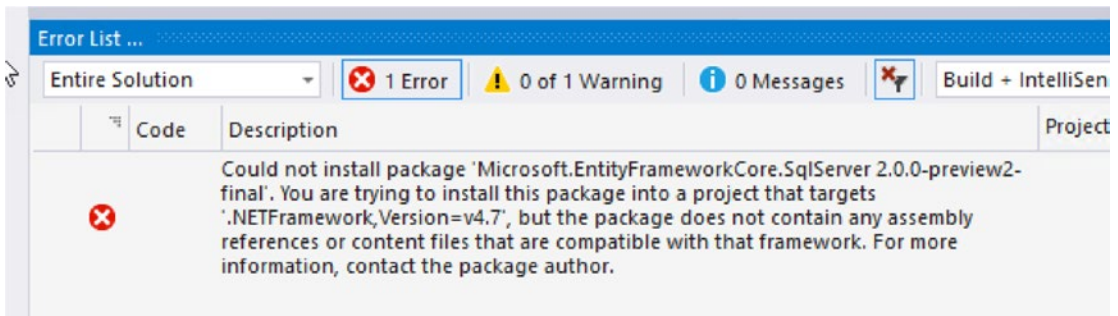

Figure 2-9. Error message when updating to Entity Framework Core 2.0

Tip When upgrading from Entity Framework Core 1.x to version 2.0, you will need remove the reference to `Microsoft.EntityFrameworkCore.SqlServer.Design` manually.

```
uninstall-package Microsoft.EntityFrameworkCore.SqlServer.Design
```

If you also have a reference to the package `Microsoft.EntityFrameworkCore.Relational.Design`, then remove this (Figure 2-10):

```
uninstall-package Microsoft.EntityFrameworkCore.Relational.Design
```

In Entity Framework Core 2.0, Microsoft has moved the content of the NuGet packages with the suffix `.Design` into the eponymous packages without this suffix.

If you still have packages named `Microsoft.AspNetCore. . .`, even though you are not using an ASP.NET Core-based web application, you can remove them as well. These references are a relic from the first versions of the Entity Framework Core tools:

```
uninstall-package Microsoft.AspNetCore.Hosting.Abstractions
```

```
uninstall-package Microsoft.AspNetCore.Hosting.Server.Abstractions
```

```
uninstall-package Microsoft.AspNetCore.Http.Abstractions
```

```
uninstall-package Microsoft.AspNetCore.Http.Feature
```

```
uninstall-package System.Text.Encodings.Web
```

```

Tip In a .NET Standard Library, Entity Framework Core 2.0 can be installed only if it is set to .NET Standard 2.0 as the target framework. Otherwise, you will see this error: “Package Microsoft.EntityFrameworkCore.SqlServer 2.0.0 is not compatible with netstandard1.6 (.NETStandard,Version=v1.6). Package Microsoft.EntityFrameworkCore.SqlServer 2.0.0 supports: netstandard2.0 (.NET Standard,Version=v2.0).” Similarly, Entity Framework Core 2.0 cannot be used in a .NET Core 1.x project, but only in .NET Core 2.0 projects. The projects may need to be upgraded beforehand (see Figure 2-13 and Figure 2-14).

CHAPTER 3

Concepts of Entity Framework Core

Framework Core

In this chapter, you will learn about the core concepts of Entity Framework Core, broken down according to the procedural models and artifacts of Entity Framework Core.

Process Models for Entity Framework Core

Entity Framework Core supports the following:

- Reverse engineering of existing databases (an object model is created from an existing database schema)
- Forward engineering of databases (a database schema is generated from an object model).

Reverse engineering (often referred to as *database first*) is useful if you already have a database or if developers choose to create a database in a traditional way. The second option, called *forward engineering*, gives the developer the ability to design an object model. From this, the developer can then generate a database schema.

For the developer, forward engineering is usually better because you can design an object model that you need for programming.

Forward engineering can be used at development time (via so-called schema migrations) or at runtime. A *schema migration* is the creation of the database with an initial schema or a later extension/modification of the schema.

At runtime, this means the database is created (`EnsureCreated()`) or updated (`Migrate()`) when the Entity Framework Core-based application is running.

Reverse engineering always takes place during development.

The ADO.NET Entity Framework, the predecessor of Entity Framework Core, supported four process models, as shown here:

- Reverse engineering with EDMX files (aka Database First)
- Reverse engineering with Code First
- Forward engineering with EDMX files (aka Model First)
- Forward engineering with Code First

Because there is no EDMX in Entity Framework Core, two of the models have been eliminated. Reverse engineering and forward engineering in Entity Framework Core are the successors of the corresponding Code First practices. However, Microsoft no longer speaks of Code First because this name suggests to many developers forward engineering. Microsoft generally references *code-based modeling*. Figure 3-1 illustrates forward engineering and reverse engineering.

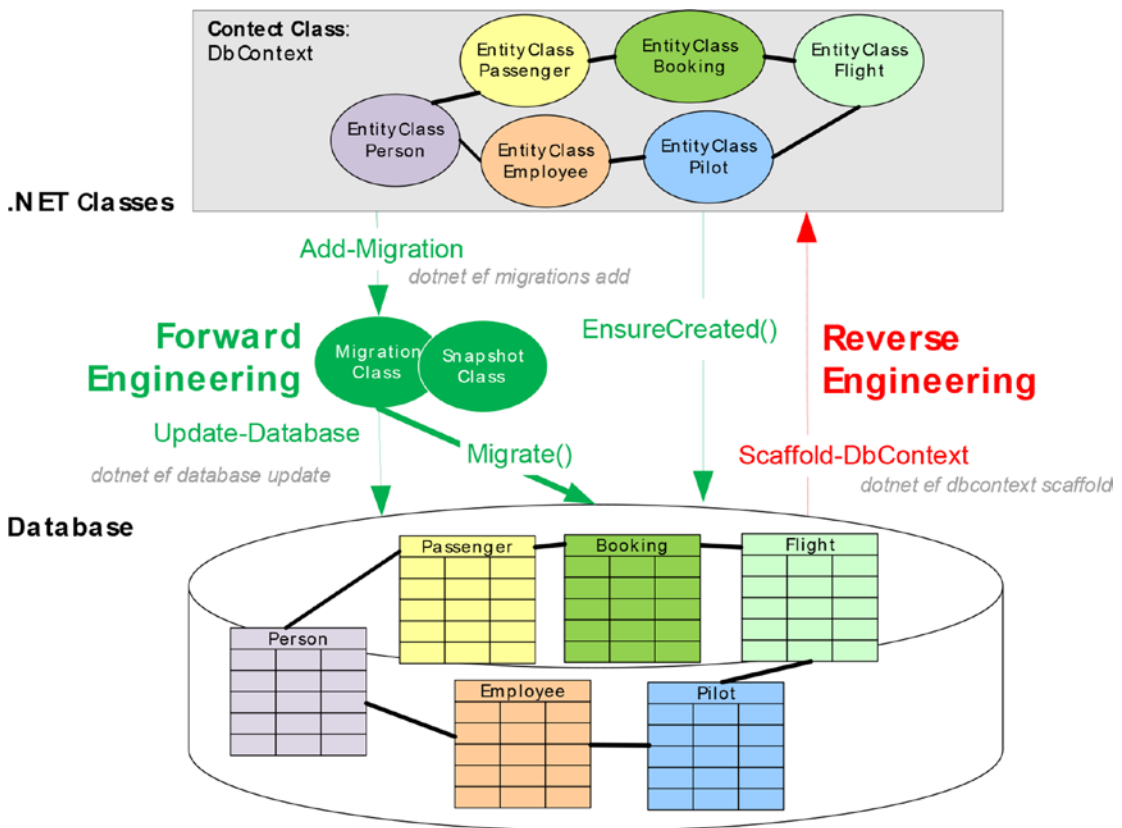

Figure 3-1. Forward engineering versus reverse engineering for Entity Framework Core

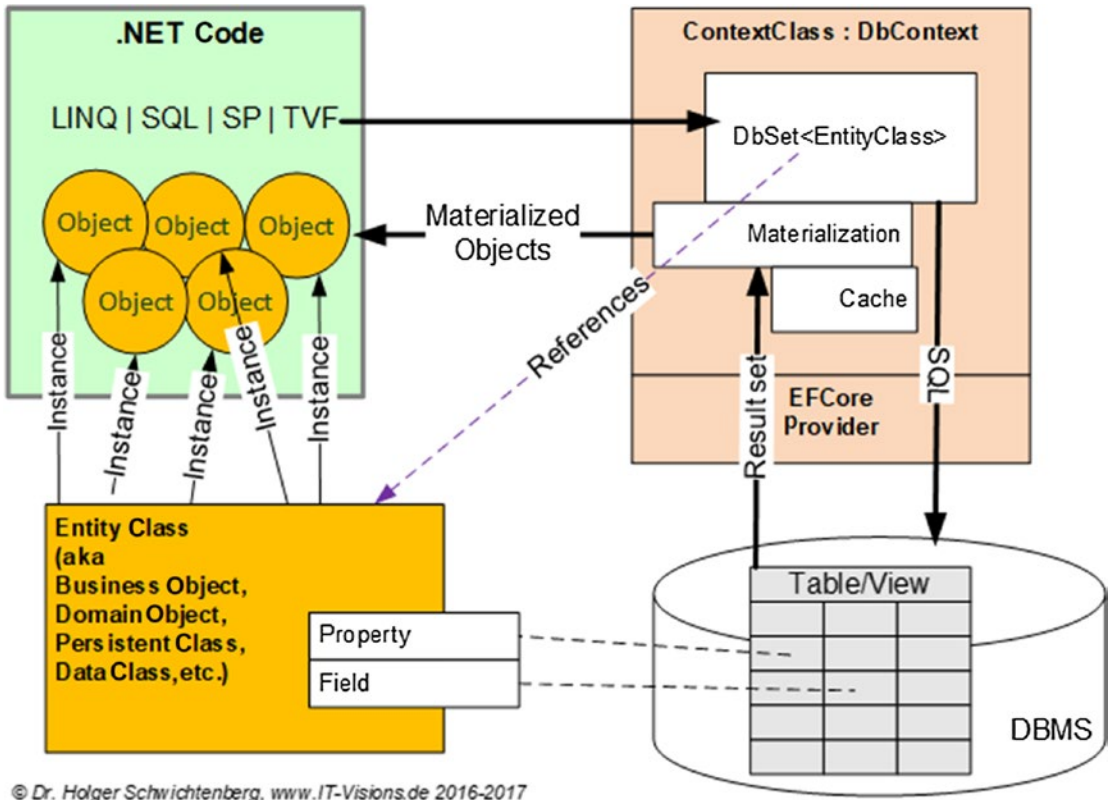

Table 3-1 compares the features of the two process models in Entity Framework Core.

Components of Entity Framework Core

© Dr. Holger Schwichtenberg, www.IT-Visions.de 2016-2017

Figure 3-2. The central artifacts in Entity Framework Core and their context

The database management system (DBMS) contains a database with tables and views.

Note Currently only tables with primary keys or with views that include a primary key can be used. In Entity Framework Core version 2.1, there will be the option to read (but not change) tables without a primary key (see Appendix C).

Entity classes (aka domain object classes, business object classes, data classes, or persistent classes) are representations of tables and views. They contain properties or fields that are mapped to columns of the tables/views. Entity classes can be plain old CLR objects (POCO classes); in other words, they need no base class and no interface. However, you cannot access the database with only these objects.

Best Practice Although the use of fields is possible, you should work only with properties because a lot of other libraries and frameworks require properties.

A *context class* is a class always derived from the `DbContext` base class. It has properties of type `DbSet<EntityClass>` for each of the entity classes. The context class or `DbSet` properties take the commands of the self-created program code in the form of LINQ commands, SQL commands, stored procedure and table-valued function (TVF) calls, or special API calls for append, modify, and delete. The context class sends the commands to the DBMS-specific provider, which sends the commands to the database via `DbCommand` objects and receives result sets in a `DataReader` from the database. The context class transforms the contents of the `DataReader` object into instances of the entity class. This process is called *materialization*.

CHAPTER 4

Reverse Engineering of Existing Databases (Database First Development)

This chapter discusses the reverse engineering of existing databases. Reverse engineering is when an object model is created from an existing database schema.

This chapter covers the simpler version 1 of the World Wide Wings database schema. You can install this database schema with the SQL script `WWWings66.sql`, which also provides the data (10,000 flights and 200 pilots).

Using Reverse Engineering Tools

Out of the box there are no visual tools for this process, but future releases from Microsoft might include options. In Chapter 19, I will introduce a few additional tools that might assist you with this process, as described here:

- PowerShell cmdlets for the NuGet Package Manager Console (PMC) within the Visual Studio development environment. These commands can be used not only in .NET core projects but also in “full” .NET Framework projects.
- The command-line .NET Core tool (called `dotnet.exe` in Windows), which can also be used independently of Visual Studio and Windows. However, this is available only for .NET Core or ASP.NET Core-based projects.

Reverse Engineering with PowerShell Cmdlets

For reverse engineering, two NuGet packages are relevant in Entity Framework Core 2.0.

- The package `Microsoft.EntityFrameworkCore.Tools` is needed at development time in the current startup project of Visual Studio.
- The package for each Entity Framework Core database driver (for example, `Microsoft.EntityFrameworkCore.SqlServer` or `Microsoft.EntityFrameworkCore.Sqlite`) is needed in the project where the program code was generated and in the project with the tools.

Tip While it is theoretically possible to work with only one project and include both packages, you should in practice create your own project for the Entity Framework Core tools. At the moment, only the Entity Framework Core tools are used. The startup project is made but otherwise remains unused. Alternatively, it is also possible to uninstall the Entity Framework Core tools after the program code generation. This keeps your projects cleaner and more focused.

For the example in this chapter, go ahead and create these two projects:

- `EFC_Tools.csproj` exists only for the tools. This project will be a .NET Framework console application (EXE).
- The program code is generated in `EFC_WWWingsV1_Reverse.csproj`. This project is a .NET Standard 2.0 library and thus can be used in the .NET Framework as well as .NET Core, Mono, and Xamarin.

In this case, you have to install the packages first, so do the following in `EFC_Tools.csproj`:

```
Install-Package Microsoft.EntityFrameworkCore.Tools Install-package  
Microsoft.EntityFrameworkCore.SqlServer
```

Do the following in `EFC_WWWingsV1_Reverse.csproj`:

```
Install-package Microsoft.EntityFrameworkCore.SqlServer
```

Or do the following for SQLite:

```
Install-package Microsoft.EntityFrameworkCore.Sqlite
```

Note In Entity Framework Core 1.x, you must also include the package `Microsoft.EntityFrameworkCore.SqlServer.Design` or `Microsoft.EntityFrameworkCore.Sqlite.Design` in the tool project. These packages are no longer needed in Entity Framework Core 2.0.

When you run the package installation commands for the tools, a total of 33 assembly references will be added to a .NET 4.7 project (see Figure 4-1). In Entity Framework Core 1.x, there were even more, including ASP.NET Core assemblies, even though you were not in an ASP.NET Core project at all.

```

Figure 4-1. The `Microsoft.EntityFrameworkCore.Tools` package will add 33 more packages!

If a code generation command was executed without the previous package installation, the developer sees an error in the Package Manager Console (see Figure 4-2).

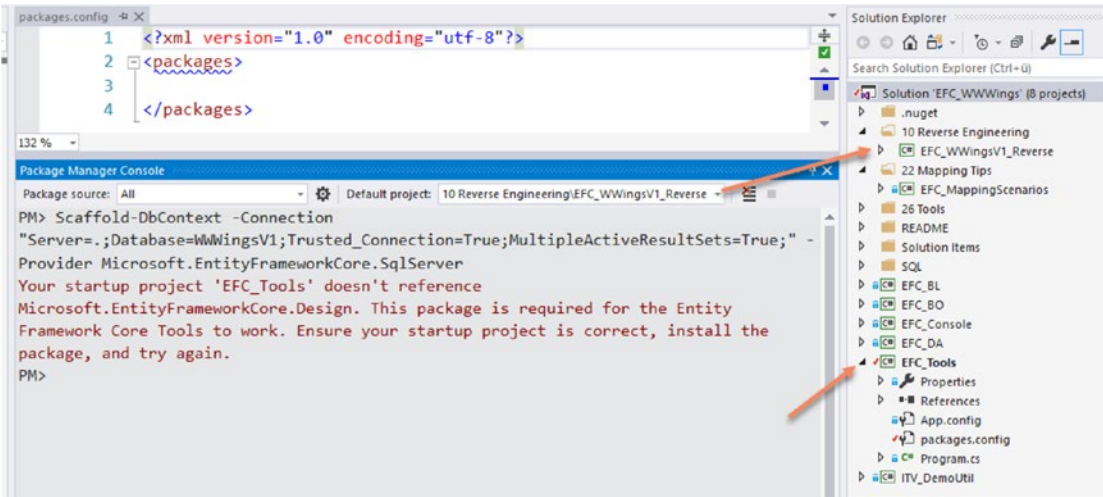

Figure 4-2. Scaffold-DbContext without previous package installation

Generating Code

The actual code generation then runs after the installation of the two packages via the Scaffold-DbContext cmdlet, to which at least the name of the database provider and a connection string have to be transferred by the developer.

```
Scaffold-DbContext -Connection "Server=DBServer02;Database=WWings;Trusted_Connection=True;MultipleActiveResultSets=True;" -Provider Microsoft.EntityFrameworkCore.SqlServer
```

This command creates classes for all the tables in this database in the project that is set as the current target project in the NuGet Package Manager Console. For database columns that could not be mapped, Scaffold-DbContext issues warnings (see Figure 4-3).

Figure 4-3. Scaffold-DbContext warns that a column of type Geography has been ignored

Alternatively, you can use a schema or tables to limit the generation to specific database schema names or table names. For both parameters, you can specify several names separated by semicolons.

```
Scaffold-DbContext -Connection "Server=DBServer02;Database=WWWingsV1;Trusted_Connection=True;MultipleActiveResultSets=True;" -Provider Microsoft.EntityFrameworkCore.SqlServer -Tables Flight,Person,Pilot,Passenger,Airport,Employee,Flight_Passenger -force
```

You can use the table names with or without schema names (in other words, you can use `Flight` or `operation.Flight`). But beware that if a table with the same name exists in multiple schemas, then a specification without a schema name will generate entity classes for all tables of that name from all schemas.

By default, the code is generated in the project currently selected in the NuGet Package Manager Console in its root directory using the default namespace of that project. With the parameters `-Project` and `-OutputDir`, the developer can influence the project and the output folder. Unfortunately, with the existing parameters, it is not possible to direct the code generation of the entity class and the context class into different projects.

With respect to the data model shown in Figure 4-4, the `Scaffold-DbContext` cmdlet now generates the following outputs:

- One entity class each in POCO style is generated for each of the six tables, including the N:M intermediate table `Flight_Passenger`, which has always eliminated the classic Entity Framework in the object model. Unfortunately, Entity Framework Core version 2.0 does not yet support N:M relationships; it only replicates them with two 1:N relationships, as does the relational model.
- A context class derived by the base class `Microsoft.EntityFrameworkCore.DbContext` is derived. Unlike before, this class is no longer a wrapper around the `ObjectContext` class but a whole new, stand-alone implementation. The name of this class can be influenced by the developer with the command-line parameter `-Context`. Unfortunately, specifying a namespace is not possible here. Using points in the parameter value is acknowledged by Visual Studio with “The context class name passed in is not a valid C# identifier.”

- If code generation is not possible for individual columns, there will be a yellow alert output in the Package Manager Console. This happens for the Geometry and Geography data types, for example, because Entity Framework Core is not yet supported.

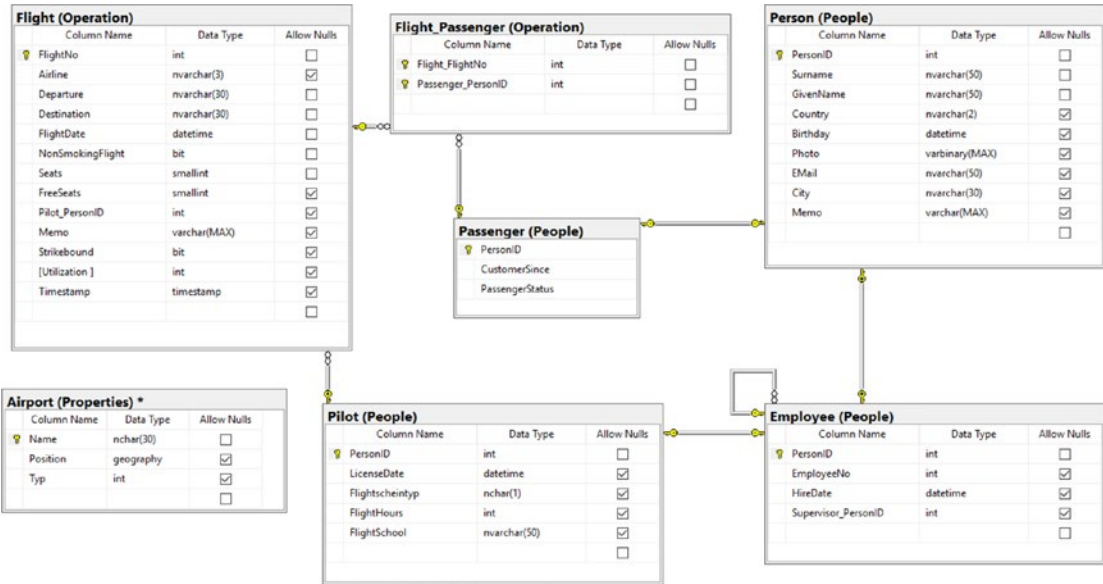

Figure 4-4. Example database for the Word Wide Wings airline (version 1)

Figure 4-5 shows the generated classes for the sample database from Figure 4-4, and Figure 4-6 shows the object model.

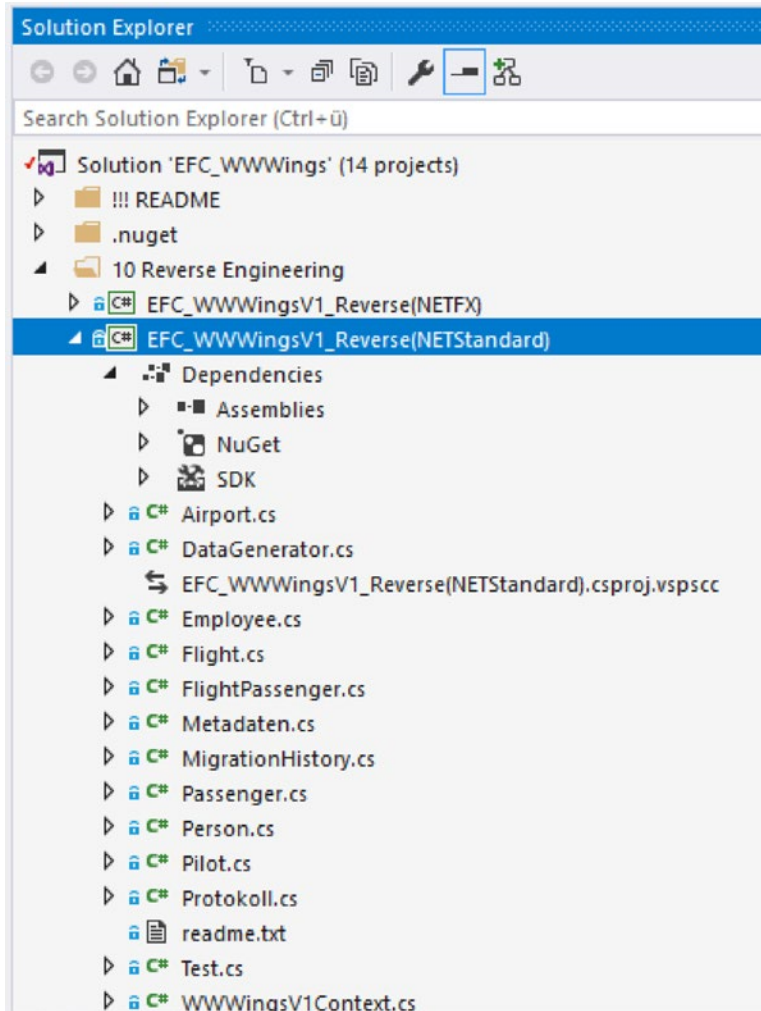

Figure 4-5. Project with the generated classes for the sample database from Figure 4-4

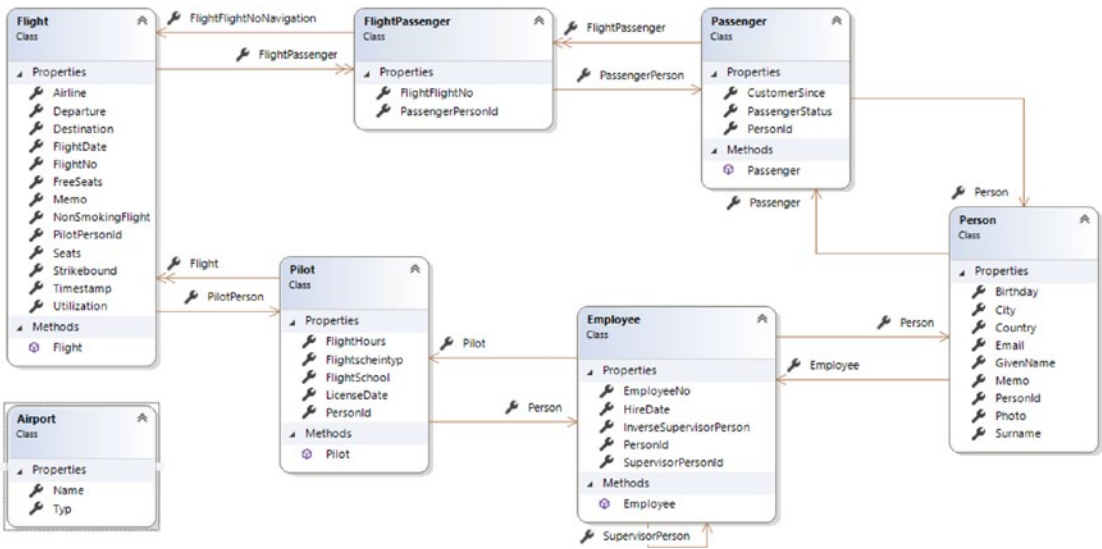

Figure 4-6. Object model of the generated classes

Unfortunately, you cannot give the code generator of Entity Framework Core any settings for the namespaces; it always uses the project’s default namespace for both the generated entity classes and the context class. Therefore, you should set the default namespace in the generation project so that it fits at least to the entity classes. Then you just have to manually change the namespace of the context class.

Unlike in reverse engineering with the ADO.NET Entity Framework, the Entity Framework Core does not automatically include the connection string in the application configuration file `app.config` or `web.config`. The connection string is in the `OnConfiguring()` method of the context class after generation, and it is up to the software developer to find a suitable and possibly backed-up location for it.

A *pluralization* (in other words, changing the table names to plural in the class names) does not take place. So far, there is no option in Entity Framework Core to do this; however, this is not a big loss because the pluralization service works only for English table names.

Looking at the Generated Program Code

The following listings show the program code generated by Scaffold-DbContext for the context class and, by way of example, for the entity classes `Flight` and `Passenger`.

The definition of how the object model is mapped to the database schema continues as in the classic Entity Framework in these three ways:

- Conventions that are applied by Entity Framework Core automatically
- Data annotations that are applied by the entity classes and their members
- Fluent API used in the `OnModelCreating()` method of the `DbContext` class

The code generated by the Entity Framework Core tools focuses on the third way. The `OnModelCreating()` method in the context class is accordingly full of Fluent API calls. But conventions continue to work, for example, that the properties of the class in the standard have the same names as the columns in the table.

So far, the assistant for the classic Entity Framework in Visual Studio also used data annotations, which are now no longer used in the generated program code. If you want to get the old behavior back, you can use the parameter `-DataAnnotations` in `Scaffold-DbContext`.

The Fluent API contains the following definitions:

- It defines the table names in the database if they differ or if they have a schema name different from `dbo`, using `ToTable()`.
- It defines names for primary key columns and indexes, using `HasName()`.
- It defines column types and column properties if the .NET type names are not unique to a data type in the database management system, using `HasColumnType()`, `IsRequired()`, `HasMaxLength()`.
- It defines default values for columns, using `HasDefaultValueSql()` or `HasDefaultValue()`.
- It defines the cardinalities between tables and their foreign keys, using `HasOne()`, `HasMany()`, `WithOne()`, `WithMany()`, `HasForeignKey()`, and `HasConstraintName()`.
- It defines the indices, using `HasIndex()`.

- It determines whether a column's content must be reread after inserting or modifying an Entity Framework Core record because it is generated by the database management system, using `ValueGeneratedOnAddOrUpdate()` and `ValueGeneratedOnAdd()` and `ValueGeneratedNever()`.
- It sets cascading delete settings, using `OnDelete()`.

In the source code, the Fluent API configuration is organized by classes, as shown here:

```
modelBuilder.Entity<Person>(entity => {...});
```

Within these method calls you will find the configuration for the individual columns of these tables.

```
entity.Property(e => e.PersonId)...
```

Compared to the previous ADO.NET Entity Framework, there are some syntactical changes and also improvements. So, the index configuration is now much more concise.

The following features are just like the classic Entity Framework:

- The reverse engineering code generator does not create inheritance relationships between entity classes, even though this would be possible as in the case of `Passenger` ► `Person`, `Employee` ► `Person`, and `Pilot` ► `Employee`. Instead, the code generator always generates associations and associated navigation properties. Such inheritance relationships must be defined by the developer later and then remove the navigation properties.
 - For example, the navigation properties in the entity classes are declared `virtual`, even though the Entity Framework Core lazy loading does not yet support what `virtual` is necessary for.
 - For example, navigation properties for sets are declared with `ICollection<T>` and are then filled in the constructor with the new `HashSet<T>()`.
- For each entity class, there is a `DbSet<T>` property in the context class.

The generated source code can be changed (see Listings 4-1, Listing 4-2, and Listing 4-3), such as if you want to have property names other than column names in the database in the object model. You would do this with the Fluent API method `HasColumnName("column name")` or the data annotation `Column("column name")`.

Seeing an Example Client

The program shown in Listing 4-4 uses the generated Entity Framework context class and the entity class Passenger.

The method illustrated creates a new passenger, attaches the passenger to the `DbSet<Passenger>`, and then stores the new passenger in the database using the `SaveChanges()` method.

Then all passengers are loaded for control, and their numbers are printed. Listing 4-4 shows a version of all passengers with the name Schwichtenberg. This filtering then takes place in RAM with LINQ to Objects over the previously loaded passengers. Figure 4-7 shows the output on the screen.

Note The commands used in this example are of course described in more detail in later chapters in this book. However, this listing is didactically necessary here to prove the functionality of the Entity Framework Core context class created.

```
Start...
Number of changes: 2
Number of passengers: 1
0: Holger Schwichtenberg
Done!
```

Listing 4-4. Program Code That Uses the Created Entity Framework Core Model

```
public static void Run()
{
    Console.WriteLine("Start...");
    using (var ctx = new WWingsV1Context())
    {
        // Create Person object
        var newPerson = new Person();
        newPerson.GivenName = "Holger";
        newPerson.Surname = "Schwichtenberg";
        // Create Passenger object
        var newPassenger = new Passenger();
        newPassenger.PassengerStatus = "A";
        newPassenger.Person = newPerson;
        // Add Passenger to Context
        ctx.Passenger.Add(newPassenger);
        // Save objects
        var count = ctx.SaveChanges();
        Console.WriteLine("Number of changes: " + count);
        // Get all passengers from the database
```

```

var passengerSet = ctx.Passenger.Include(x => x.Person).ToList();
Console.WriteLine("Number of passengers: " + passengerSet.Count);
// Filter with LINQ-to-Objects
foreach (var p in passengerSet.Where(x=>x.Person.Surname ==
"Schwichtenberg").ToList())
{
    Console.WriteLine(p.PersonId + ": " + p.Person.GivenName + " " +
    p.Person.Surname);
}
}
Console.WriteLine("Done!");
Console.ReadLine();
}

```

Using the .NET Core Tool dotnet

When developing .NET Core projects, the command-line tool dotnet (also known as the .NET Core command-line interface [CLI]) from the .NET Core SDK can be used as an alternative to the PowerShell cmdlets (<https://www.microsoft.com/net/download/core>). Unlike the PowerShell cmdlets, dotnet is available not only for Windows but also for Linux and macOS.

This form of generation works for the following:

- .NET Core console applications
- ASP.NET Core projects based on .NET Core or the .NET Framework 4.6.2 and later

First, the package `Microsoft.EntityFrameworkCore.Tools.DotNet` has to be installed, which does not work via a command-line tool but only through a manual entry in the XML-based `.csproj` project file (see Figure 4-8):

```

<ItemGroup>
  <DotNetCliToolReference Include="Microsoft.EntityFrameworkCore.Tools.DotNet"
    Version="2.0.1" />
</ItemGroup>

```

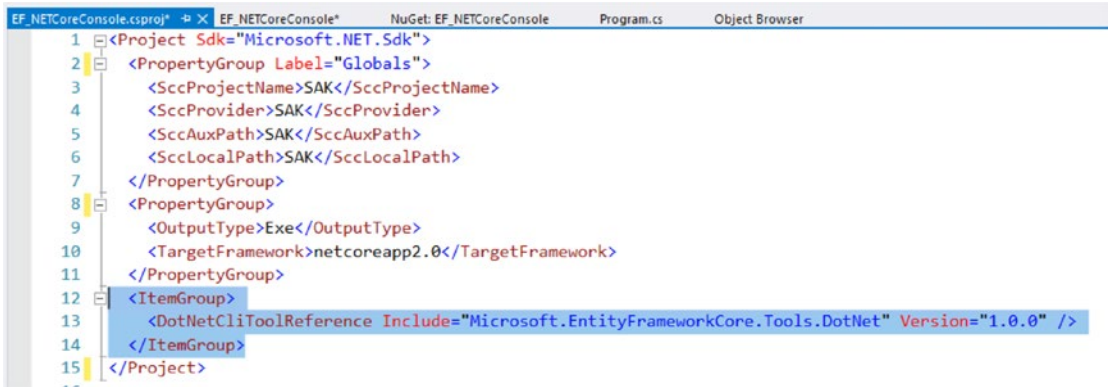

Figure 4-8. Manual extension of the .csproj file

Then you have to add the following package:

```

<ItemGroup>
  <PackageReference Include="Microsoft.EntityFrameworkCore.Design"
Version="2.0.1" />
</ItemGroup>

```

However, this is also possible via the command line in the project directory, as shown here:

```
dotnet add package Microsoft.EntityFrameworkCore.design
```

Now add the desired Entity Framework Core provider, shown here:

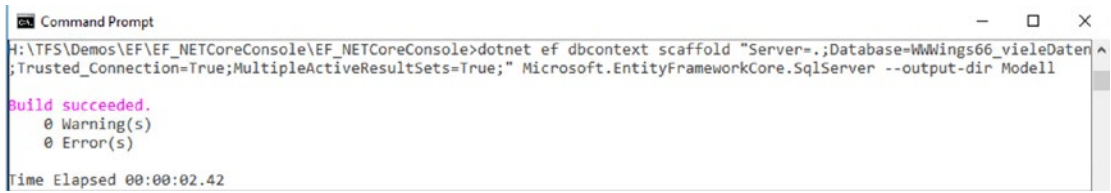

```
dotnet add package Microsoft.EntityFrameworkCore.SqlServer
```

The following package was also necessary in Entity Framework Core 1.x but is not needed anymore in Entity Framework Core 2.0:

```
dotnet add package Microsoft.EntityFrameworkCore.SQL Server.design
```

Then you can do the code generation (see Figure 4-9).

```
dotnet ef dbcontext scaffold "server =.; Database = WWWings66; Trusted_
Connection = True; MultipleActiveResultSets = True; "Microsoft.
EntityFrameworkCore.SqlServer --output-dir model
```

```
Command Prompt
H:\TFS\Demos\EF\EF_NETCoreConsole\EF_NETCoreConsole>dotnet ef dbcontext scaffold "Server=.;Database=MMWings66_vieleDaten;Trusted_Connection=True;MultipleActiveResultSets=True;" Microsoft.EntityFrameworkCore.SqlServer --output-dir Modell
Build succeeded.
    0 Warning(s)
    0 Error(s)
Time Elapsed 00:00:02.42
```

Figure 4-9. Reverse engineering with dotnet.exe

Note Microsoft did not release the final version of dotnet.exe 1.0 until March 6, 2017, as part of Entity Framework Core 1.1.1 and Visual Studio 2017. Previously, there were only “preview” versions. These preview versions used a project.json file. If you still use this outdated format, you do not have to make the entries in the .csproj file; you have to do it in the project.json file!

Understanding the Weaknesses of Reverse Engineering

As in the classic Entity Framework, you can create entity types only for tables with primary keys. Composite primary keys, however, are not a problem for Entity Framework Core.

Note Microsoft will introduce the mapping of a table without a primary key in version 2.1; see Appendix C for more information.

In the case of the temporal tables (called *system-versioned* tables) added in SQL Server 2016, the history tables cannot be mapped using Entity Framework Core. However, this is already possible for the actual table, whereby querying the historical values is possible only via SQL and so far not via LINQ.

For database views and stored procedures, in contrast to the classic Entity Framework, classes and functions cannot be generated.

Once the object model is generated using the Entity Framework Core command-line tools, you cannot update it. The Update Model from Database command available for the Database First approach is currently not implemented. You can only restart the generation. If the classes to be generated already exist, the cmdlet Scaffold-DbContext complains about it. With the additional parameter `-force`, the cmdlet will overwrite existing files. However, any manually made changes to the source code files will be lost.

If in a new Scaffold-DbContext command you let not all previously generated tables be generated, but only a few selected ones, then in the context class the `DbSet<T>` declarations and the Fluent API configurations are missing for all the tables that are now no longer generated. Once again, this is a reason to generate a project from which you can then copy the generated parts you need to another project. However, Microsoft has announced (at <https://github.com/aspnet/EntityFramework/wiki/Roadmap>) that it plans to improve the tools and provide an Update Model from Database feature.

Until then, it's the best way to at least limit the code generation that occurs in changes to new tables; the changes for new, changed, or deleted columns are better made manually in the source code. Or, after a reverse engineering of a database, you can switch to forward engineering; in that case, changes will be recorded in the object model and used to generate DDL commands for changing the database schema.

CHAPTER 5

Forward Engineering for New Databases

Although Entity Framework Core supports the reverse engineering of existing database models, the ideal process model is forward engineering, where the database model is generated from an object model. This is because the developer can design the object model according to the needs of the business case.

Forward engineering is available in the classic Entity Framework in two variants: Model First and Code First. In Model First, you graphically create an entity data model (EDM) to generate the database schema and .NET classes. In Code First, you write classes directly, from which the database schema is created. The EDM is invisible. In the redesigned Entity Framework Core, there is only the second approach, which however is not called Code First but *code-based modeling* and no longer uses an invisible EDM.

Two Types of Classes

Code-based modeling in Entity Framework Core happens through these two types of classes:

- You create entity classes, which store the data in RAM. You create navigation properties in the entity classes that represent the relationships between the entity classes. These are typically plain old CRL objects (POCOs) with properties for each database column.
- You write a context class (derived from `DbContext`) that represents the database model, with each of the entities listed as a `DBSet`. This will be used for all queries and other operations.

Ideally, these two types of classes are implemented in different projects (DLL assemblies) because entity classes are often used in several or even all layers of the software architecture, while the context class is part of the data access layer and should be used only by the layer above it.

Examples in This Chapter

This chapter shows how to create a preliminary edition of the World Wide Wings object model in version 2. Initially, you will consider only the entities Person, Employee, Pilot, Passenger, Flight, and Booking. You will set only the minimum options needed to create a database schema from the object model. You will expand and refine the object model in the following chapters. You can find the program code in the solution EFC_WWWings. The entity classes are in a DLL project named EFC_BO_Step1 (for business objects), and the context class is in a DLL project named EFC_DA_Step1 (for data access). The startup application is a console application (EFC_Konsole). This includes the data access code and screen output. See Figure 5-1.

Note To keep the examples simple and focused on using the Entity Framework Core API, I am not doing any further delineation of business logic or creating a dedicated data access layer above the context class. This is not an architectural example; those types of examples will follow later in this book.

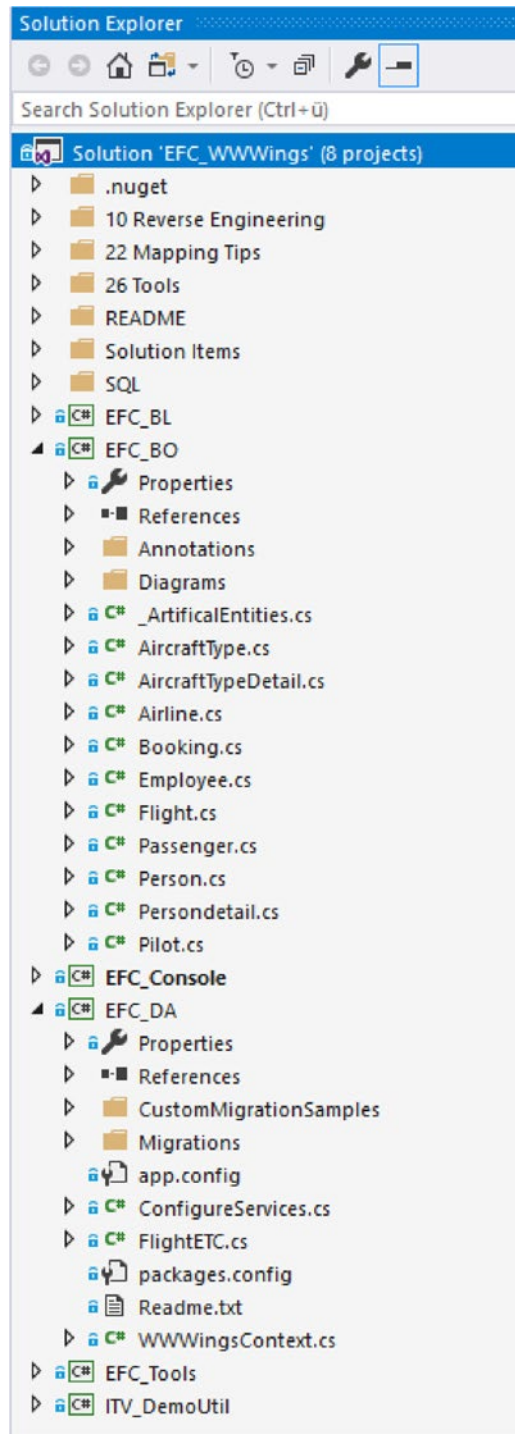

Figure 5-1. Solution for the example in this and the following chapters

Rules for Self-Created Entity Classes

As mentioned, the entity classes are POCOs. In other words, they do not have to inherit from a base class or implement an interface. However, there must be a parameterless constructor that Entity Framework Core can use to create the instances when database table rows are materialized.

Note This chapter initially describes only a typical basic configuration for the entity classes. You will find adaptations in Chapter 12.

NuGet Packages

You do not need to reference any Entity Framework Core NuGet packages to implement the entity classes. However, using data annotations such as `[Key]` and `[StringLength]` requires a reference to `System.ComponentModel.Annotations.dll` in the classic .NET Framework or the NuGet package `System.ComponentModel.Annotations` (<https://www.nuget.org/packages/System.ComponentModel.Annotations>) in .NET Core and .NET Standard.

Data Annotation Properties

Each column to be created in the database table must be represented by a property. The properties can be automatic properties with `{get; set;}` or explicit properties with getter and setter implementations (see the property `Memo` in class `Flight`). A class may also own fields; however, these fields are not mapped to columns. In other words, the information in these fields is not persisted by default. In addition, properties that have no setter are not persisted either, such as the property `Fullname` in the class `Person`.

Data Types

The .NET primitive data types (`String`, `DateTime`, `Boolean`, `Byte`, `Byte[]`, `Int16`, `Int32`, `Int64`, `Single`, `Double`, `Decimal`, and `System.Guid`) are allowed. `Nullable<T>` may indicate that the corresponding column in the database table may be left empty (`NULL`). Enumeration types are also allowed; for example, see `PilotLicenseType` in class `Pilot`.

The data types `DbGeometry` and `DbGeography`, which have been supported in the classic Entity Framework since version 5.0, unfortunately do not exist in Entity Framework Core for now.

Relationships (Master-Detail)

There may also be properties that are declared as different entity types. These are called *navigation properties*, and they express the relationships between two entity classes. Entity Framework Core supports the following:

- *1:0/1 relationships*: Here, the property is declared to a single object of the related type (see `Pilot` and `Copilot` in the `Flight` class).

Important For a single object, it is semantically wrong to assign an instance of the related type in the navigation property declaration or in the constructor because an OR mapper, such as the Entity Framework Core, sees a new entity object. This instantiation makes sense only if a new top object always requires a new subobject. In the case of `Flight` and `Pilot`, this is not so since a new pilot is not set for each flight.

- *1:0 / N relations*: Here, the property is declared to a collection type of a related type (see `List<Flight>` for `FlightAsPilotSet` and `FlightAsCopilotSet` in the `Pilot` class). It is allowed to declare the navigation property as `ICollection` or any other interface based on it (like `IList`) or as an `ICollection<T>` class (like `List<T>` or `HashSet<T>`).

Important It is usually a good idea to assign concrete set types directly in the declaration or in the constructor so that the calling program code does not have to do this. Entity Framework Core handles set instantiation within relationship fixup. Since only an empty list is created here, Entity Framework Core will not want to persist anything here, as long as the list is not filled.

Note Entity Framework Core does not currently support N:M relationships. More specifically, Entity Framework Core does not support the abstraction of representing two 1:N relationships with an intermediate table in the object model as N:M. Neither does the relational database model support N:M relationships; it needs an intermediate table for two 1:N relationships, where the intermediate table contains a composite primary from the primary keys of the entities to be joined. In Entity Framework Core, you have an intermediate class for the intermediate table in the object model and, just like in the relational model, two 1:N relationships instead of an N:M relationship. Such an intermediate entity class can be seen in the class `Booking`. It is referenced by a `booking set` in class `Flight` and class `Passenger`.

The navigation properties must be labeled `virtual` in the classic Entity Framework Core for lazy loading to work. Since there is no lazy loading in Entity Framework Core 1.x/2.0, this edition is no longer required. Lazy loading will come in a later version in Entity Framework Core; so far, it is still unclear whether Microsoft will require this again as a label. But it does not hurt to declare the navigation properties as `virtual` today.

Navigation properties can be bidirectional, as the entity classes `Flight` and `Pilot` show. The 0/1 pages of a navigation property may have (but not need) explicit foreign key properties (see `PilotId` and `CopilotId`).

Inheritance

Entity classes can inherit from each other. This can be seen in the classes `Pilot` and `Passenger`, which inherit from the class `Person`. In this case, `Person` is an abstract class. But it could also be a class with instances.

Primary Key

Another prerequisite for Entity Framework Core is that each entity class must have a primary key (PK) made up of one or more simple properties. In the simplest case, according to a convention, you create a property with the name `ID` or `Id` or `classnameID` or `classnameId`. The case sensitivity of the `ID` and the class name is not relevant here, even if the still incomplete documentation of Entity Framework Core at www.efproject.net/en/latest/modeling/keys.html suggests differently.

Note If you want to rename the primary key or define a composite primary key, then you must explicitly configure it, as you'll learn in Chapter 12.

Rules for the Self-Created Context Class

The context class is the linchpin for Entity Framework Core programming, and there are a few rules to follow when implementing it.

Note This chapter only describes a typical basic configuration for the context class. You will find adaptations in Chapter 12.

Installing the NuGet Packages

For the realization of the context class, you need a NuGet package for your respective database management system (see Table 5-1). For example, enter the following in the NuGet Package Manager Console:

```
Install-Package Microsoft.EntityFrameworkCore.SqlServer
```

For SQLite, enter the following:

```
Install-Package Microsoft.EntityFrameworkCore.Sqlite
```

For Oracle, enter the following:

```
Install-Package Devart.Data.Oracle.EFCore
```

While in the classical Entity Framework just two assemblies had to be referenced (and these references had to be created manually), the new NuGet package (in the sense of the modularization of the core products) entails a jumble of 32 references (see the project DAL), which you do not want to have to create manually. For the project B0, no reference to an Entity Framework DLL is necessary!

Table 5-1. *The Entity Framework Core Providers Available on nuget.org*

Database Management System	NuGet Package
Microsoft SQL Server Express, Standard, Enterprise, Developer, LocalDB 2008+	Microsoft.EntityFrameworkCore.SqlServer
Microsoft SQL Server Compact 3.5	EntityFrameworkCore.SqlServerCompact35
Microsoft SQL Server Compact 4.0	EntityFrameworkCore.SqlServerCompact40
SQLite	Microsoft.EntityFrameworkCore.sqlite
PostgreSQL	Npgsql.EntityFrameworkCore.PostgreSQL
In memory (for unit tests)	Microsoft.EntityFrameworkCore.InMemory
MySQL	MySQL.Data.EntityFrameworkCore
Oracle (DevArt)	Devart.Data.Oracle.EFCore

Base Class

The context class is not a POCO class. It must inherit from the base class `Microsoft.EntityFrameworkCore.DbContext`. The alternative base class `ObjectContext`, which existed in the classic Entity Framework, no longer exists.

Constructor

The context class must have a parameterless constructor to use the schema migration tools in Visual Studio or the command line because these tools must instantiate the context class at design time. It does not require a parameterless constructor if the database schema is to be generated exclusively at application startup. Then the developer has the opportunity to call the context class with constructor parameters.

Note Without an explicit constructor, C# automatically has a parameterless constructor.

References to Entity Classes

The developer must create a property of type `DbSet<EntityType>` for each entity class, like so:

```
public DbSet<Flight> FlightSet {get; set; }
public DbSet<Pilot> PilotSet {get; set; }
```

Caution By default, Entity Framework Core uses the property names shown here for the table names in the database schema. You will learn later how to change this behavior.

Provider and Connection String

The connection string for the database to be addressed had to be passed in the classic Entity Framework via the constructor to the local implementation of the base class `DbContext`. Entity Framework Core has a different approach, namely, a new method called `OnConfiguring()`, which has to be overridden. This method is called by Entity Framework Core for the first instantiation of the context in a process. The method `OnConfiguring()` receives as a parameter an instance of `DbContextOptionsBuilder`. In `OnConfiguring()`, you then invoke an extension method on this instance of `DbContextOptionsBuilder`, which determines the database provider and the connection string. The extension method to be invoked is provided by the Entity Framework Core database provider. In the case of Microsoft SQL Server, it is named `UseSqlServer()` and expects the connection string as a parameter. It is up to you to move the connection string to a suitable location (for example, the configuration file) and to load from there.

Note While having a connection string in the code is a bad practice for real projects, it is the best solution here to make the example clear. Therefore, many listings in this book save the connection string within the code. In real projects, you should read the connection string from a configuration file.

The ability to outsource configuration data is highly dependent on the type of project, and a solution like the one shown here would not run in any other type of project. The treatment of various configuration systems and associated APIs is not part of this book. Please refer to basic documentation on .NET, .NET Core, UWP, and Xamarin.

The connection string must contain `MultipleActiveResultSets = True` because otherwise Entity Framework Core may not work correctly in some cases; you'll get the following error message: "There is already an open `DataReader` associated with this `Command` which must be closed first."

```
builder.UseSqlServer(@"Server=MyServer;Database=MyDatabase;Trusted_Connection=
True;MultipleActiveResultSets=True");
```

Attention If no `UseXY()` method is called in `OnConfiguring()`, then the following runtime error appears: "No database provider has been configured for this `DbContext`. A provider can be configured by overriding the `DbContext.OnConfiguring` method or by using `AddDbContext` on the application service provider. If `AddDbContext` is used, then also ensure that your `DbContext` type accepts a `DbContextOptions<TContext>` object in its constructor and passes it to the base constructor for `DbContext`."

Seeing an Example

Listing 5-7 shows the context class of the World Wide Wings sample in a basic configuration.

Listing 5-7. Context Class

```

using BO;
using Microsoft.EntityFrameworkCore;

namespace DA
{
    /// <summary>
    /// EFCore context class for World Wings Wings database schema version 7.0
    /// </summary>
    public class WWingsContext : DbContext
    {
        #region Tables
        public DbSet<Flight> FlightSet { get; set; }
        public DbSet<Pilot> PilotSet { get; set; }
        public DbSet<Passenger> PassengerSet { get; set; }
        public DbSet<Booking> BookingSet { get; set; }
        #endregion

        public static string ConnectionString { get; set; } =
        @"Server=.;Database=WWingsV2_EN_Step1;Trusted_Connection=True;Multiple
        ActiveResultSets=True;App=Entityframework";

        public WWingsContext() { }

        protected override void OnConfiguring(DbContextOptionsBuilder builder)
        {
            builder.UseSqlServer(ConnectionString);
        }
    }
}

```

Your Own Connections

UseSqlServer() and other drivers can also receive a connection object (an instance of the class DbConnection) instead of the connection string. The connection does not necessarily have to be opened beforehand. It can be open, and then the existing connection is used. The Entity Framework Core context does not close it either. If it is not open, the Entity Framework Core context opens and closes the connection as needed.

Best Practice Basically, you should keep away from Entity Framework Core connection management! Only in exceptional cases, where this is absolutely necessary (for example, transactions across multiple context instances), should you open the connection yourself!

Thread Safety

The `DbContext` class is not thread-safe, meaning that the self-created context class inherited from `DbContext` must under no circumstances be used in several different threads. Each thread needs its own instance of the context class! Those who disregard this risk unpredictable behavior and strange runtime errors in Entity Framework Core! For those using dependency injection, `DbContext` should be scoped as a `Transient` object.

Note This, of course, also applies to `DbContext` classes generated using reverse engineering.

Rules for Database Schema Generation

Entity Framework Code then generates a database schema from the entity classes and the context class capable of storing all instances of the entity classes. The structure of the database schema is based on conventions and configurations. The principle of convention before configuration applies here.

There are numerous conventions. The following are the most important:

- From each entity class, for which there is a `DbSet<T>` in the context class, a table is created. In the classic Entity Framework, the class name of the entity class was plural in the standard system. In Entity Framework Core, the standard now uses the name of the `DbSet<T>` property in the context class.
- Each elementary property in an entity class becomes a column in the table.

- Properties named ID or classes named ID automatically become primary keys with auto-increment values.
- For every 1/0 side of a navigation property, an additional foreign key column is created, even if there is no explicit foreign key property.
- Properties that are named as navigation properties plus the suffix ID represent automatically generated foreign key columns.
- Enumerated types become int columns in the database.

Note While in many cases these conventions suffice to create a database schema from an object model, the conventions in this case are not sufficient. Unfortunately, you will not detect this at compile time; you will detect it only when executing program code that uses the context class.

Looking at an Example Client

The program in Listing 5-8 now uses the Entity Framework context class created and the entity class `Passenger`. First, by calling the `EnsureCreated()` method the program makes sure that the database is created, if it does not already exist. The database initialization classes known from the classic Entity Framework no longer exist in Entity Framework Core.

Thereafter, the program creates a new passenger, attaches the passenger to the `DbSet<Passenger>`, and then stores the new passenger in the database using the `SaveChanges()` method.

Then all passengers are loaded, and their numbers are printed. Finally, a version of all passengers with the name Schwichtenberg follows. This filtering then takes place in RAM with LINQ to Objects over the previously loaded passengers.

Note The commands used in this example are of course described in more detail in later chapters in this book. However, this discussion is didactically necessary to prove the functionality of the Entity Framework Core context class created.

The example is unfortunately not yet running error-free. In the next chapter, you will learn why this is so and how to fix the problems.

Listing 5-8. Program Code That Uses the Created Entity Framework Core Model

```

using DA;
using BO;
using System;
using System.Linq;

namespace EFC_Console
{
    class SampleClientForward
    {
        public static void Run()
        {
            Console.WriteLine("Start...");
            using (var ctx = new WWWingsContext())
            {
                // Create database at runtime, if not available!
                var e = ctx.Database.EnsureCreated();
                if (e) Console.WriteLine("Database has been created!");
                // Create passenger object
                var newPassenger = new Passenger();
                newPassenger.GivenName = "Holger";
                newPassenger.Surname = "Schwichtenberg";
                // Append Passenger to EFC context
                ctx.PassengerSet.Add(newPassenger);
                // Save object
                var count = ctx.SaveChanges();
                Console.WriteLine("Number of changes: " + count);
                // Read all passengers from the database
                var passengerSet = ctx.PassengerSet.ToList();
                Console.WriteLine("Number of passengers: " + passengerSet.Count);
                // Filter with LINQ-to-Objects
                foreach (var p in passengerSet.Where(x => x.Surname ==
                    "Schwichtenberg").ToList())
                {

```

```

    Console.WriteLine(p.PersonID + ": " + p.GivenName + " " + p.Surname);
  }
}
Console.WriteLine("Done!");
Console.ReadLine();
}
}

```

Adaptation by Fluent API (OnModelCreating())

When you start the program code in Listing 5-8, the `EnsureCreated()` method first encounters the following runtime error: “Unable to determine the relationship represented by navigation property `Flight.Pilot`’ of type `Pilot`. Either manually configure the relationship, or ignore this property using the `[NotMapped]`’ attribute or by using `EntityTypeBuilder.Ignore`’ in `OnModelCreating`.”

By this the Entity Framework Core tells you that in the case of the two-way relationship between `Flight` and `Pilot` (with the properties `Pilot` and `Copilot`), it does not know which of the two navigation properties on the `Pilot` side (`FlightsAsPilotSet` and `FlightAsCopilotSet`) correspond to the navigation properties `Pilot` and `Copilot` on the `Flight` side.

To clarify this, there is the so-called Fluent API in Entity Framework Core, which was available in Code First in the classic Entity Framework. The Fluent API consists of the method protected override `void OnModelCreating(ModelBuilder modelBuilder)`, which is to be overridden in the context class. On the `modelBuilder` object, you then make the configuration in call chains of methods.

```

protected override void OnModelCreating(ModelBuilder builder)
{
  ...
}

```

In the case of the two-way relationship between Pilot and Flight, the following two chains of methods are to be entered in `OnModelCreating()`, where the pilot clearly associates with `FlightAsPilot` and where Copilot associates with `FlightAsCopilot`:

```
modelBuilder.Entity<Pilot>().HasMany(p => p.FlightAsPilotSet).WithOne(p =>
p.Pilot).HasForeignKey(f => f.PilotId).OnDelete(DeleteBehavior.Restrict);
modelBuilder.Entity<Pilot>().HasMany(p => p.FlightAsCopilotSet).WithOne
(p => p.Copilot).HasForeignKey(f => f.CopilotId).OnDelete(DeleteBehavior.
Restrict);
```

With `.OnDelete(DeleteBehavior.Restrict)`, you turn off the cascading deletion, which makes no sense in this case.

If you start the program again afterward, you get the runtime error “The entity type ‘BO.Booking’ requires a key to be defined.” Entity Framework Core does not know what the primary key is in the intermediate class `booking` because there is no property there by convention that can be the primary key. There should be a composite primary key. Therefore, you have to add the following in the Fluent API:

```
modelBuilder.Entity<Booking>().HasKey(b => new { b.FlightNo, b.PassengerID });
```

Entity Framework is still not satisfied and complains at the next start of the program about a missing primary key in the classes `Flight`, `Passenger`, and `staff`. In `Flight` this is clear because `FlightNr` does not correspond to the convention (that would be `FlightID`). So, add the following:

```
modelBuilder.Entity<Flight>().HasKey(x => x.FlightNo);
```

Passengers and employees, however, inherit the primary key `PersonID` of the base class `Person`. Unfortunately, Entity Framework Core is not smart enough to notice. Therefore, it should also be added.

```
modelBuilder.Entity<Employee>().HasKey(x => x.PersonID);
modelBuilder.Entity<Passenger>().HasKey(x => x.PersonID);
```

Thus, the program code is finally executable!

Now the question arises why Entity Framework Core does not complain that there is no primary key for `Pilot`. This is because of the way Entity Framework Core maps inheritance in the database. The pilots are not stored in a separate table but are in the same table with the employees. Therefore, Entity Framework Core does not complain for the pilots.

Listing 5-9 shows the improved version of the context class. With this version, the program is now executing as expected. Figure 5-2 shows the output.

Viewing the Generated Database Schema

Figure 5-3 shows the resulting database.

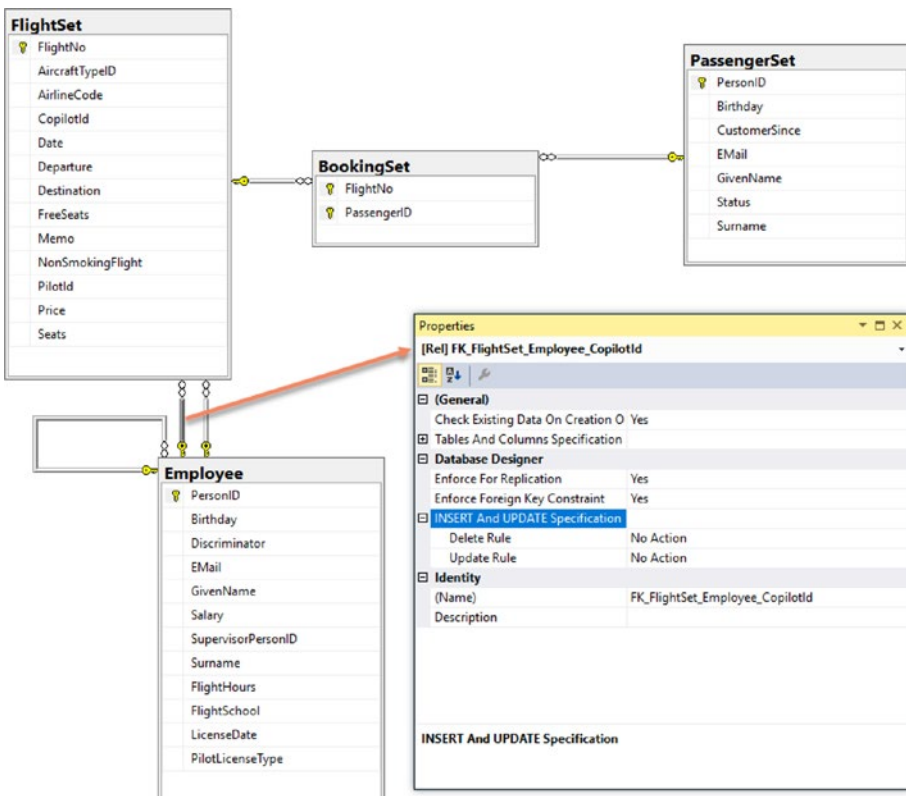

Figure 5-3. The resulting database model

As you can see, Entity Framework Core generates only four tables in the database from the six entity classes (Person, Employee, Pilot, Passenger, Flight, and Booking). Entity Framework Core mixes the inheritance mapping strategies table per concrete type (TPC) and table per hierarchy (TPH).

- There is no table Person. All properties of the abstract entity class Person have been moved to the Passenger and Employee tables.
- The table Employee also includes instances of the entity class Pilot according to the TPH principle. There is a column Discriminator that automatically populates Entity Framework Core with the value Pilot or Employee.

So far, developers using Entity Framework Core have very little influence on the inheritance mapping strategy. You can only indirectly influence the decision between TPC and TPH. If there were a `DbSet<Person>` and `DbSet<Employee>` in the context class, Entity Framework Core would have completely applied the table by hierarchy (TPH) strategy, in other words, made only a single table out of Person, Employee, Pilot, and Passenger. Then no explicit key specification in the Fluent API for employees and passengers must be made!

Note The table by type (TPT) inheritance mapping strategy does not yet exist in the Entity Framework Core.

As in the classic Entity Framework, Entity Framework Core creates indexes for all primary and foreign keys. As in the classic Entity Framework, Entity Framework Core sets the string columns in the standard as `nvarchar(max)`. This still needs to be adjusted. Better than the classic Entity Framework is that Entity Framework Core creates the date columns with the data type `DateTime2(7)` instead of `DateTime` as before. So, there is no longer the problem that in .NET valid dates are rejected by SQL Server before version 1.1.1601.

CHAPTER 6

Customizing the Database Schema

In many cases, Entity Framework Core can create a database schema in forward engineering based solely on conventions from an object model. However, the previous chapter has already shown that conventions are not always enough to create a valid database schema. The computer needed tutoring by the software developer to create composite primary keys, to create primary keys for inheriting classes, and to deactivate the cascading deletion; otherwise, the database results in circular deletion operations.

In other cases, although Entity Framework Core can create a database schema, the result is unsatisfactory. Both of these cases were shown in the previous chapter (see the table names and lengths of the character string columns).

In this chapter, you will learn how to override or supplement the conventions by explicitly configuring via data annotations in the entity classes or via the Fluent API in the `OnModelCreating()` method.

Examples in This Chapter

While the previous chapter used a preliminary stage of the World Wide Wings object model version 2, the book will now cover the complete object model version 2. You will find the program code in the project folder `EFC_WWWings` in the projects `EFC_GO`, `EFC_DA`, and `EFC_Console` (see Figure 6-1).

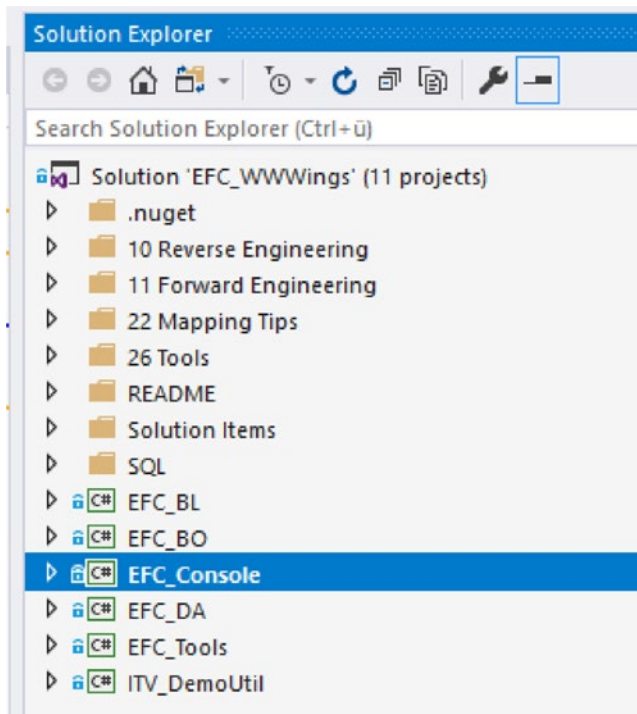

Figure 6-1. Solution EFC_WWWings

Convention vs. Configuration

There are two ways to configure the database schema in Entity Framework Core.

- With data annotations in the entity classes
- With the Fluent API in the `OnModelCreating()` method in the context class

There are three basic rules, listed here:

- Configuration via data annotations or the Fluent API weighs heavier than the conventions. In other words, configuration overrides conventions for individual cases. Microsoft speaks about Entity Framework Core using “convention before configuration.” However, this means that the goal is to make the explicit configuration as far as possible superfluous by conventions.

- When there are conflicting data annotations and Fluent API calls, the Fluent API call always wins.
- You can express all configuration options via the Fluent API. A subset of this is also possible via data annotations.

Persistent vs. Transient Classes

A *persistent class* is a class from the object model whose instances are stored in the database. Within Entity Framework Core, persistent classes are also called *entity classes*. By contrast, transient classes have only volatile instances that are purely in main memory.

Basically, every .NET class is transient. Entity Framework Core makes a class persistent if any of the following are true:

- There is a `DbSet<EntityClass>` in the context class
- There is a call to `modelBuilder.Entity<EntityClass>()` in the Fluent API
- Another persistent class refers to this class by navigation property

Using the second option usually makes no sense because without a `DbSet<EntityClass>` or a navigation property, the data access class through Entity Framework Core is not available.

A developer may sometimes want to define deviations from the third rule if a persistent class is to have a relation to a transient class. In this case, the developer must annotate the related class that is to remain transient with `[NotMapped]` or `modelBuilder.Ignore<Class>()` in the Fluent API.

`[NotMapped]` can also be used at the level of properties of the class if you do not want to persist individual properties of a persistent class in the database because by default Entity Framework Core persists all properties of an entity class that have a getter and a setter. The Fluent API uses the `Ignore()` method for this, but this time it does so after calling `Entity<T>(): modelBuilder.Entity<EntityClass>().Ignore(x => x.Property)`.

An entity class property, in particular, must be ignored if the property has a more complex .NET data type that Entity Framework Core cannot map. This applies, for example, to the class `system.Xml.XmlDocument`. Entity Framework Core fails

to generate a database schema and gives the following error: “The key {‘TempId’} contains properties in shadow state and is referenced by a relationship from ‘XmlSchemaCompilationSettings’ to ‘XmlSchemaSet.CompilationSettings’. Configure a non-shadow principal key for this relationship.” Although there is an XML data type in Microsoft SQL Server and other database management systems, in Entity Framework Core a mapping to the .NET class `System.Xml.XmlDocument` is not realized yet.

Names in the Database Schema

By convention, Entity Framework Core assigns the following:

- Each table gets the name of the property used in the context class for the `DbSet<EntityClass>`.
- For each entity class for which there is no `DbSet <entity class>`, Entity Framework Core uses the class name as the table name.
- Each column gets the name of the property in the entity class.

To change this, you can use the options described in Table 6-1.

Table 6-1. *Changing Conventionally Specified Table and Column Names in the Database Schema*

	Data Annotation	Fluent API
Table name	In front of a class: <code>[Table("TableName")]</code> or with additional specification of the schema name: <code>[Table("TableName", schema = "SchemaName")]</code> Without the schema name, the table always ends up in the default schema, which is <code>dbo</code> .	<code>modelBuilder. Entity<EntityClass>(). ToTable("TableName");</code> or <code>modelBuilder. Entity<EntityClass>(). ToTable("TableName", schema: "SchemaName");</code>
Column name	In front of a property: <code>[Column("ColumnName")]</code>	<code>modelBuilder. Entity<EntityClass>(). Property(b => b.Property). HasColumnName("Column Name");</code>

Order of Columns in a Table

Entity Framework Core sorts the columns in a table as follows:

1. First the primary key columns appear in alphabetical order.
2. Then all other columns appear in alphabetical order.
3. Columns added later are not sorted in the order but added at the back.

Unlike the classic Entity Framework, Entity Framework Core does not follow the order of the properties in the source code. Microsoft explains this at <https://github.com/aspnet/EntityFramework/issues/2272> with the following: “In EF6 we tried having column order match the order of properties in the class. The issue is that reflection can return a different order on different architectures.”

In the classic Entity Framework, the order could be configured by the annotation `[Column(Order = Number)]`. However, this affects only the first time the table is created, not columns that are added later, because sorting new columns between existing columns in many database management systems requires a table rebuild. According to Microsoft, “There isn’t any way to do this since SQL Server requires a table rebuild (rename existing table, create new table, copy data, delete old table) to re-order the columns” (<https://github.com/aspnet/EntityFramework/issues/2272>). Microsoft has therefore decided not to respect the `Order` property of the annotation `[Column]` in Entity Framework Core.

Column Types/Data Types

The database type used in the database schema for a .NET type is not determined by Entity Framework Core but by the database provider. For example, Table 6-2 shows what is selected by default in Microsoft SQL Server, SQLite, and the DevArt Oracle provider.

Note While there are fixed mappings of column types to .NET data types in Entity Framework Core 2.0, Microsoft will introduce value converters in Entity Framework Core 2.1; see Appendix C. A value converter allows property values to be converted when reading from or writing to the database.

Table 6-2. Mapping .NET Data Types to Column Types

.NET Data Type	Microsoft SQL Server Column Type	SQLite Column Type	Oracle Column Type

(continued)

Table 6-2. (continued)

.NET Data Type	Microsoft SQL Server Column Type	SQLite Column Type	Oracle Column Type
Other array types, such as <code>short[]</code> , <code>int[]</code> , and <code>string[]</code>	Mapping is not yet supported by Entity Framework Core. You will get the following error: “The property ‘xy’ could not be mapped, because it is of type ‘Int16[]’ which is not a supported primitive type or a valid entity type. Either explicitly map this property, or ignore it using the ‘[NotMapped]’ attribute or by using ‘EntityTypeBuilder.Ignore’ in ‘OnModelCreating’.”		
Char	Mapping is not yet supported by Entity Framework Core. You will get the following error: “The property ‘xy’ is of type ‘char’ which is not supported by current database provider. Either change the property CLR type or ignore the property using the ‘[NotMapped]’ attribute or by using ‘EntityTypeBuilder.Ignore’ in ‘OnModelCreating’.”	INTEGER	Mapping is not yet supported by Entity Framework Core. You will get the following error: “The property ‘xy’ is of type ‘char’ which is not supported by current database provider. Either change the property CLR type or ignore the property using the ‘[NotMapped]’ attribute or by using ‘EntityTypeBuilder.Ignore’ in ‘OnModelCreating’.”
XmlDocument	Mapping is not yet supported by Entity Framework Core. You will get the following error: “The entity type ‘XmlSchemaCompilationSettings’ requires a primary key to be defined.”		

If you do not agree with this data type equivalent, you must use the data annotation `[Column]` or use `HasColumnType()` in the Fluent API.

Here's an example:

```
[Column(TypeName = "varchar(200)")]
modelBuilder.Entity<Entitätsklasse>()
    .Property(x => x.Destination).HasColumnType("varchar(200)")
```

Caution The `DbGeometry` and `DbGeography` classes, which have been supported by the classic Entity Framework since version 5.0, cannot yet be used in Entity Framework Core. So far, there is no mapping for the SQL Server `Geometry` and `Geography` column types.

Mandatory Fields and Optional Fields

The convention states that only those columns in the database are to be created as “nullable”, in which the .NET type in the object model can also tolerate a null (or nothing in Visual Basic .NET). In other words, it can take `string`, `byte[]`, and the explicit nullable value types `Nullable<int>`, `int?`, `Nullable<DateTime>`, `DateTime?`, and so on.

With the annotation `[Required]` or with `modelBuilder.Entity<EntityClass>().Property(x => x. Propertyname).IsRequired()`, you determine that a property should not be nullable in the database, even if the property actually allows a null or nothing in your code. It is not possible to enforce a nullable column using an annotation or the Fluent API; if the database allows null values in a column but the corresponding property your code is not nullable, you get runtime errors.

Note Because of the behavior of .NET value types, it may be necessary to declare a column as `int?` with a `[Required]` attribute to ensure that the value is actually provided and not just set to the .NET default of 0.

Field Lengths

A significant weakness in the generated database schema in Chapter 5 was that all character string columns with the long data type `nvarchar(max)` were generated. Entity Framework Core limits a string column that is a primary key to 450 characters by default.

You can define a length limitation with the annotation `[MaxLength(number)]` or `[StringLength(number)]` or with `modelBuilder.Entity<EntityClass>().Property(x => x.PropertyName).HasMaxLength(number)`.

Primary Keys

By convention, the primary key of a table is a property named `ID` or `Id` or `ClassNameID` or `ClassNameId`. The case of these names is not relevant. Unfortunately, if you use more than one of these variants in a class (all four are possible in C#, but only two are possible in Visual Basic .NET because the language is case-insensitive), Entity Framework Core takes the first matching property in that order as it stands in the program code. All other properties corresponding to this convention become normal columns of the table.

If another property is to become a primary key, you must annotate it with `[Key]` or write it in the Fluent API: `modelBuilder.Entity<EntityClass>().HasKey(x => x.Property)`. As opposed to the classic Entity Framework, composite primary keys can no longer be specified in Entity Framework Core via data annotations; they can be specified only via the Fluent API, as in `builder.Entity<Booking>().HasKey(x => new { x.FlightNo, x.Passenger ID })`.

For primary keys that are integers (byte, short, int, long), Entity Framework Core creates default identity columns (also known as *auto-increment columns*) in the database schema. The documentation says this: “By convention, primary keys that are of an integer or GUID data type will be set up to have values generated on add” (<https://docs.microsoft.com/en-us/ef/core/modeling/generated-properties>). *Integer* is a misleading generic term (because the sentence is also true for byte, short, and long). If you do not want auto-increment columns, use the annotation `[DatabaseGenerated(DatabaseGeneratedOption.None)]` in front of the property or use `modelBuilder.Entity<class>().Property(x => x.PropertyName).ValueGeneratedNever()` in `OnModelCreating()`.

Relationships and Foreign Keys

Entity Framework Core automatically treats properties that reference one or more instances of another entity class as navigation properties. This allows you to create relationships between entities (master-detail relationships such as 1:1 and 1:N).

For sets, the developer can use `ICollection` or any other interface based on it (such as `IList`), as well as any `ICollection<T>`-implementing class (such as `List<T>` or `HashSet<T>`). Entity Framework Core automatically creates a foreign key column in the database schema in the table in these spots:

- On the N side of a 1:N relationship
- On one side of a 1:0/1 relationship

The foreign key column contains the name of the navigation property plus the name of the primary key of the related entity class. For each foreign key column, Entity Framework Core automatically generates an index in the database.

For the program code in Listing 6-1 (which introduces the entity type `AircraftType` into the World Wide Wings sample), the foreign key column `AircraftTypeId` is created in the `Flight` table (`Type` occurs twice because it belongs to both the class name and the name of the primary key). To get Entity Framework Core to use a simpler name, you use the annotation `[ForeignKey("AircraftTypeId")]` on the navigation property. In the Fluent API, this is a bit more complicated because you have to explicitly formulate the cardinality with `HasOne()`, `HasMany()`, `WithOne()`, and `WithMany()` before calling the method `HasForeignKey()` to get the name of the Set foreign key column.

```
builder.Entity<Flight>().HasOne(f => f. AircraftType).WithMany(t=>t.
FlightSet).HasForeignKey("AircraftTypeId");
```

You have the choice to determine from which direction you want to formulate the relationship. Therefore, the following command line is equivalent to the previous one. Having both instructions in program code is not an error but unnecessary.

```
builder.Entity<AircraftType>().HasMany(t => t.FlightSet).WithOne(t => t.
AircraftType).HasForeignKey("AircraftTypeId");
```

This foreign key column can also be explicitly mapped in the object model by a foreign key property (see `public byte AircraftTypeID {get; set;}` in Listing 6-1). However, this explicit mapping is not mandatory.

Tip The advantage of displaying the foreign key column by a property in the object model is that relationships can be established via the foreign key without having to load the complete, related object. By convention, Entity Framework Core automatically treats a property as a foreign key property if it matches the name Entity Framework Core chooses by default for the foreign key column.

Optional Relationships and Mandatory Relationships

Listing 6-1 introduces the entity types `AircraftType` and `AircraftTypeDetail`. An `Aircraft` has exactly one `AircraftType`, and one `AircraftType` has exactly one `AircraftTypeDetail`.

Listing 6-1. New Entity Classes `AircraftType` and `AircraftTypeDetail` with the Relevant Cutouts from the Related `Flight` and `Pilot` Classes

}

```

In Listing 6-1, the relationship between Flight and AircraftType is a mandatory relationship, i.e. each flight must be assigned exactly one AircraftType, because the foreign key property AircraftTypeID must be assigned a value. See Figure 6-2.

To make this relationship optional, i.e. permit Flight objects that have no assigned AircraftType, the property has to allow zero or nothing for the foreign key column. In this case, there would have to be: public byte? Aircraft TypeNr {get; set; }. You can also create a mandatory relationship with IsRequired() in the Fluent API, even if the foreign key column allows null or nothing, as shown here:

```
builder.Entity<Flight>()
    .HasOne(f => f.AircraftType)
    .WithMany(t => t.FlightSet)
    .IsRequired()
    .HasForeignKey("AircraftTypeID");
```

Note If there is no explicit foreign key property, the relationship is optional by default. Again, you need to call the method IsRequired() to force a mandatory relationship.

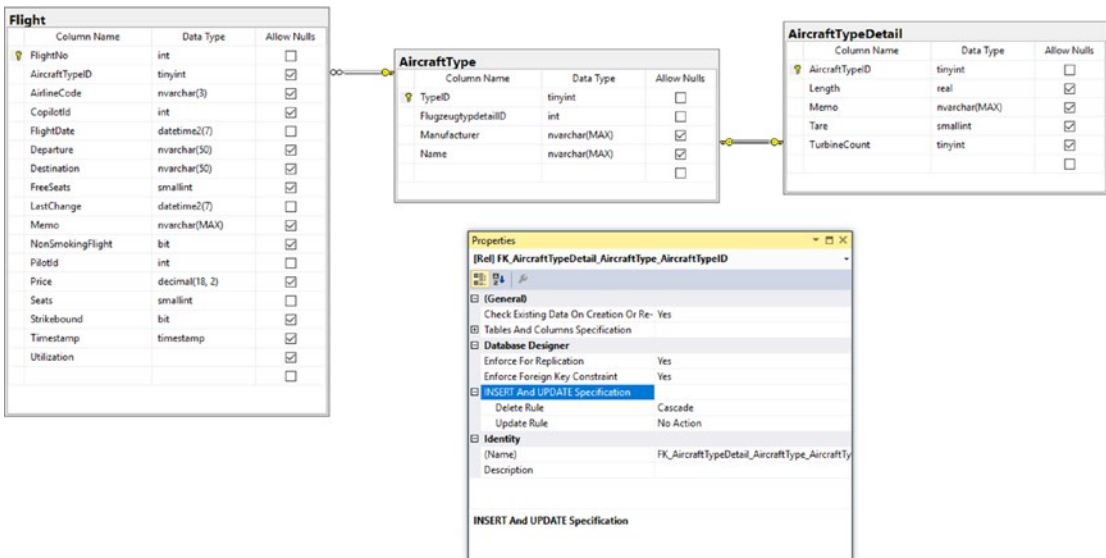

Figure 6-2. Relationship between Flight and AircraftType and AircraftTypeDetail

Unidirectional and Bidirectional Relationships

Relations between two entity classes can be bidirectional in the object model; that is, there are two-way navigation properties, both from `Flight` to `AircraftType` (via the `AircraftType` property in class `Flight`) and from `AircraftType` to `Flight` (via the `FlightSet` property in class `AircraftType`). Alternatively, unidirectional relationships are allowed because of simply omitting navigation in one of the two classes (see the relationship between `AircraftTypeDetail` and `AircraftTypeDetail`, which is unidirectional).

Listing 6-1 showed that `AircraftType` has a navigation property named `Detail` that refers to an `AircraftTypeDetail` object. However, in the implementation of `AircraftTypeDetail`, there is no navigation property to `AircraftType`. Bidirectional relationships, however, usually make sense, so the object model is easier to use, especially since they consume no additional space in the database and only minimal space in the main memory.

In bidirectional relationships, Entity Framework Core uses convention to find the two matching navigation properties and their cardinalities. So, if `Flight` has a navigation property of type `AircraftType` and `AircraftType` has a navigation property of type `List<Flight>`, then Entity Framework Core automatically assumes a 1:N relationship.

However, this convention-based mechanism is not possible for the `Flight <-> Pilot` relationship because there are two navigation property of type `Pilot` (named `Pilot` and `Copilot`) in the `Flight` class and two navigation properties of type `List<Flight>` (`FlightAsPilotSet` and `FlightAsCopilotSet`) in the class `Pilot`. At this point, you must give the Entity Framework Core pertinent hints about what belongs together. This is done either via the data annotation `[InverseProperty("FlightAsPilotSet")]` or `[InverseProperty("FlightAsCopilotSet")]` or via the Fluent API, as shown here:

```
builder.Entity<Pilot>().HasMany(p => p.FlightAsCopilotSet)
    .WithOne(p => p.Copilot).HasForeignKey(f => f.CopilotId);
builder.Entity<Pilot>().HasMany(p => p.FlightAsPilotSet)
    .WithOne(p => p.Pilot).HasForeignKey(f => f.PilotId);
```

In the World Wide Wings example, the relationship between `Flight` and `Pilot` over the navigation property `Pilot` is a mandatory relationship; `Copilot` is optional.

Abolishing the copilot and landing the plane by the flight attendant in an emergency (as in the movie *Turbulence* from 1997) incidentally was a real proposal of Michael O’Leary, the boss of the Irish airline Ryanair in the year 2010 (see www.dailymail.co.uk/news/article-1308852/Let-stewardesses-land-plane-crisis-says-Ryanair-boss-Airline-wants-ditch-pilots.html).

1:1 Relationships

Listing 6-1 also shows the 1:1 relationship between `AircraftType` and `AircraftTypeDetail`. This is a mandatory relationship; that is, there must be exactly one `AircraftTypeDetail` object for each `AircraftType` object because the relationship between the classes is not backed by a foreign key column. `AircraftType` and `AircraftTypeDetail` have a primary key property that is identical in name and type. The relationship thus arises from `AircraftType.TypeID` to `AircraftTypeDetail.AircraftTypeID`.

`AircraftType.TypeID` is created as an auto-increment value. Entity Framework Core is smart enough to also create `AircraftTypeDetail.AircraftTypeID` as an auto-increment value because these two numbers must indeed correspond so that the relationship works.

If `AircraftType.TypeID` is not an auto-increment value, Entity Framework Core would make one for `AircraftTypeDetail.AircraftTypeID`, which leads to problems. `AircraftType.TypeNr` has no auto-increment value, but Entity Framework Core still does not store the value that was explicitly assigned in the source code. Entity Framework Core then uses for `AircraftType.TypeID` the auto-increment value, which `AircraftTypeDetail.AircraftTypeID` has specified. Only if both `AircraftType.TypeID` and `AircraftTypeDetail.AircraftTypeID` are set to `ValueGeneratedNever()` you can set the values freely. Here you would have to help a bit and configure `AircraftTypeDetail.AircraftTypeID` as having no auto-increment value.

```
builder.Entity<AircraftTypeDetail>().Property(x => x.AircraftTypeID).
ValueGeneratedNever().
```

If the entity class `AircraftTypeDetail` had a different primary key name (for example, `No`), Entity Framework Core would have created this primary key column as the auto-increment value column and added a foreign key column in the `AircraftType` table (named `DetailNo`). This relationship would then be a 1:0/1 relationship, so there could be `AircraftType` objects without an `AircraftTypeDetail` object. Then you could not easily see the relationship from the data; for example, `AircraftType` object #456 may be associated with `AircraftTypeDetail` object #72.

A `DbSet<AircraftTypeDetail>` does not have to exist in the context class. In addition, the relationship between `AircraftType` and `AircraftTypeDetail` is a unidirectional relationship since there is only one navigation type from `AircraftType` to `AircraftTypeDetail`, but not from `AircraftTypeDetail` to `AircraftType`. From

the point of view of Entity Framework Core, this is fine, and in this case it is technically quite appropriate that `AircraftTypeDetail` exists as a purely `AircraftType`-dependent object.

Indexes

Entity Framework Core automatically assigns an index to all foreign key columns. In addition, you can assign arbitrary indices with the method `HasIndex()` in the Fluent API (possibly with the addition of `IsUnique()` and `ForSqlServerIsClustered()`). The syntax is simpler than the classic Entity Framework. However, unlike the classic Entity Framework, you cannot use data annotations in Entity Framework Core for indexes.

Here are some examples:

```
// Index with one column
modelBuilder.Entity<Flight>().HasIndex(x => x.FreeSeats).
// Index with two columns
modelBuilder.Entity<Flight>().HasIndex(f => new {f.Departure, f.Destination});
// Unique Index: Then there could be only one Flight on each Flight route ...
modelBuilder.Entity<Flight>().HasIndex(f => new {f.Departure,
f.Destination}).IsUnique();
// Unique Index and Clustered Index: there can only be one CI per table
(usually PK)
modelBuilder.Entity<Flight>().HasIndex (f => new {f.Departure,
f.Destination}).IsUnique().ForSqlServerIsClustered();
```

Entity Framework Core names the indexes in the database with the prefix `IX_`.

Tip With `HasName()`, you can influence the name of an index in the database, as in `modelBuilder.Entity<Flight>().HasIndex(x=>x.FreeSeats).HasName("Index_FreeSeats");`

In Figure 6-3, there are three foreign key relationship indexes, with one based on the primary key. The remaining two are created manually.

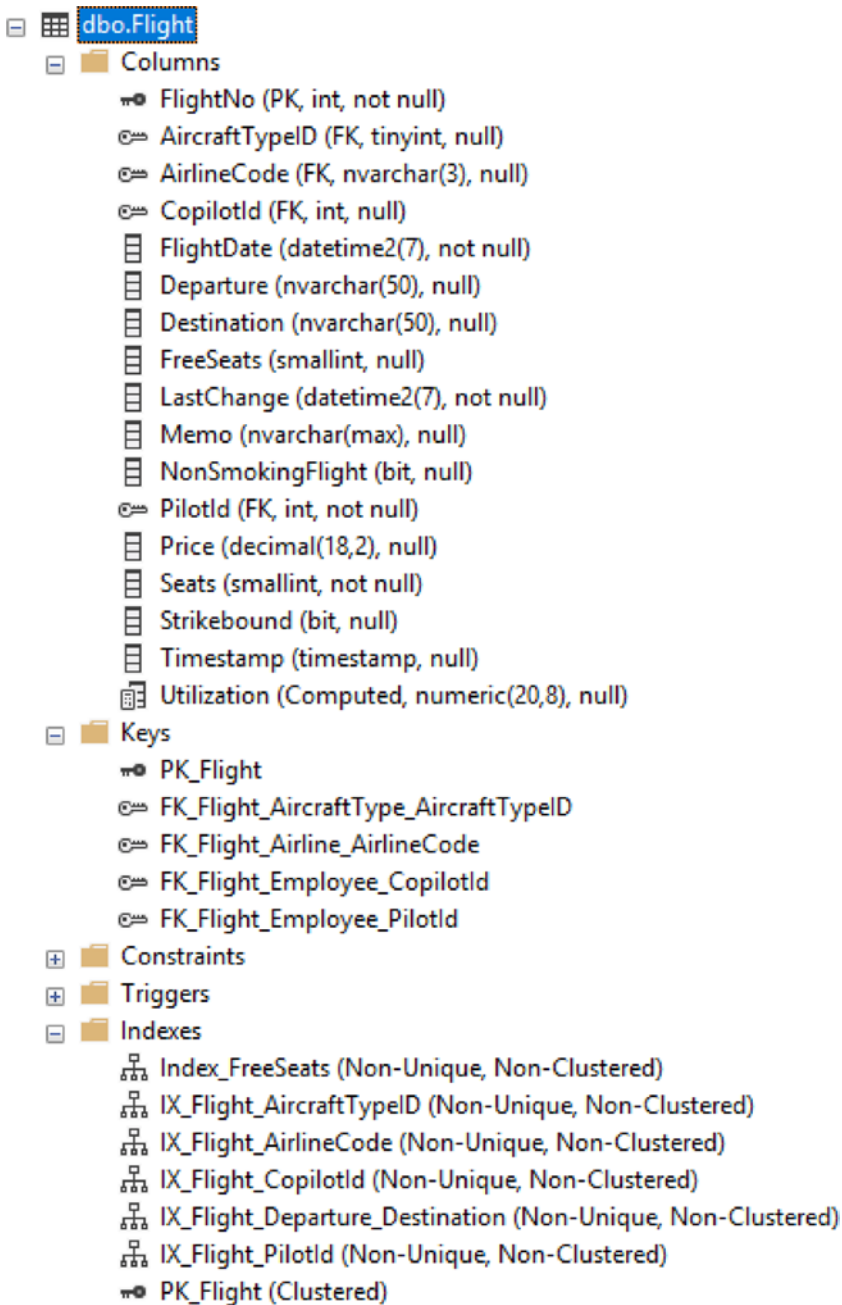

Figure 6-3. *Indexes in SQL Server Management Studio*

Syntax Options for the Fluent API

For larger object models, the Fluent API configuration in the `OnModelCreating()` method in the Entity Framework Core context class can become very large. Entity Framework Core therefore offers various options for structuring the content differently instead of the sequential calls shown up to now.

Sequential Configuration

The starting point for the statements is the sequential configuration of the entity class `Flight` shown in Listing 6-2.

Listing 6-2. Fluent API Calls for the Entity Class `Flight` Without Structuring

```
modelBuilder.Entity<Flight>().HasKey(f => f.FlightNo);
modelBuilder.Entity<Flight>().Property(b => b.FlightNo).
ValueGeneratedNever();

// ----- Length and null values
modelBuilder.Entity<Flight>().Property(f => f.Memo).HasMaxLength(5000);
modelBuilder.Entity<Flight>().Property(f => f.Seats).IsRequired();

// ----- Calculated column
modelBuilder.Entity<Flight>().Property(p => p.Utilization)
    .HasComputedColumnSql("100.0-(((FreeSeats]*1.0)/[Seats])*100.0");

// ----- Default values
modelBuilder.Entity<Flight>().Property(x => x.Price).
HasDefaultValue(123.45m);
modelBuilder.Entity<Flight>().Property(x => x.Departure).
HasDefaultValue("(not set)");
modelBuilder.Entity<Flight>().Property(x => x.Destination).
HasDefaultValue("(not set)");
modelBuilder.Entity<Flight>().Property(x => x.Date).HasDefaultValueSql
("getdate()");
```

```

//// ----- Indexes
//// Index over one column
modelBuilder.Entity<Flight>().HasIndex(x => x.FreeSeats).HasName("Index_
FreeSeats");
//// Index over two columns
modelBuilder.Entity<Flight>().HasIndex(f => new { f.Departure,
f.Destination });

```

Structuring by Lambda Statement

This structuring form eliminates the constant repetition of `modelBuilder.Entity<Flight>()` by entering a lambda expression with a command sequence in the method `Entity()`; see Listing 6-3.

Listing 6-3. Fluent API Calls Structured by Lambda Statement

```

modelBuilder.Entity<Flight>(f =>
{
// ----- PK
f.HasKey(x => x.FlightNo);
f.Property(x => x.FlightNo).ValueGeneratedNever();
//// ----- Length and null values
f.Property(x => x.Memo).HasMaxLength(5000);
f.Property(x => x.Seats).IsRequired();
// ----- Calculated column
f.Property(x => x.Utilization)
.HasComputedColumnSql("100.0-(([FreeSeats]*1.0)/[Seats])*100.0");

// ----- Default values
f.Property(x => x.Price).HasDefaultValue(123.45m);
f.Property(x => x.Departure).HasDefaultValue("not set");
f.Property(x => x.Destination).HasDefaultValue("not set");
f.Property(x => x.Date).HasDefaultValueSql("getdate()");

// ----- Indexes
// Index with one column
f.HasIndex(x => x.FreeSeats).HasName("Index_FreeSeats");

```

```
// Index with two columns
f.HasIndex(x => new { x.Departure, x.Destination });
});
```

Structuring by Subroutines

In the structured form shown in Listing 6-4, the configuration for an entity class is stored in a subroutine.

Listing 6-4. Fluent API Calls Structured by Subroutine

```
modelBuilder.Entity<Flight>(ConfigureFlight);

private void ConfigureFlight(EntityTypeBuilder<Flight> f)
{
    // ----- PK
    f.HasKey(x => x.FlightNo);
    f.Property(x => x.FlightNo).ValueGeneratedNever();
    /// ----- Length and null values
    f.Property(x => x.Memo).HasMaxLength(5000);
    f.Property(x => x.Seats).IsRequired();
    // ----- Calculated column
    f.Property(x => x.Utilization)
        .HasComputedColumnSql("100.0-(([FreeSeats]*1.0)/[Seats])*100.0");

    // ----- Default values
    f.Property(x => x.Price).HasDefaultValue(123.45m);
    f.Property(x => x.Departure).HasDefaultValue("(not set)");
    f.Property(x => x.Destination).HasDefaultValue("(not set)");
    f.Property(x => x.Date).HasDefaultValueSql("getdate()");

    // ----- Indexes
    // Index with one column
    f.HasIndex(x => x.FreeSeats).HasName("Index_FreeSeats");
    // Index with two columns
    f.HasIndex(x => new { x.Departure, x.Destination });
}
```

Structuring Through Configuration Classes

With Entity Framework Core 2.0, Microsoft has introduced another structuring option. Following the outsourcing of configuration in the `EntityTypeConfiguration<T>` inheriting classes that exist in the classic Entity Framework, Entity Framework Core now provides the `IEntityTypeConfiguration <EntityType>` interface with which you can implement a separate configuration class for an entity type; see Listing 6-5.

Listing 6-5. Fluent API Calls Structured by `IEntityTypeConfiguration`

```
using B0;
using Microsoft.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore.Metadata.Builders;

namespace DA
{
    /// <summary>
    /// Configuration Class for Entity Class Flight
    /// EFCore >= 2.0
    /// </summary>
    class FlightETC : IEntityTypeConfiguration<Flight>
    {
        public void Configure(EntityTypeBuilder<Flight> f)
        {
            // ----- PK
            f.HasKey(x => x.FlightNo);
            f.Property(x => x.FlightNo).ValueGeneratedNever();
            //// ----- Length and null values
            f.Property(x => x.Memo).HasMaxLength(5000);
            f.Property(x => x.Seats).IsRequired();
            // ----- Calculated column
            f.Property(x => x.Utilization)
                .HasComputedColumnSql("100.0-(((FreeSeats)*1.0)/[Seats])*100.0");

            // ----- Default values
            f.Property(x => x.Price).HasDefaultValue(123.45m);
            f.Property(x => x.Departure).HasDefaultValue("not set");
        }
    }
}
```

```

f.Property(x => x.Destination).HasDefaultValue("(not set)");
f.Property(x => x.Date).HasDefaultValueSql("getdate()");

// ----- Indexes
// Index with one column
f.HasIndex(x => x.FreeSeats).HasName("Index_FreeSeats");
// Index with two columns
f.HasIndex(x => new { x.Departure, x.Destination });
}
}
}

```

You can use this configuration class by calling `modelBuilder.ApplyConfiguration<EntityClass>(ConfigurationObject)` in `OnModelCreating()`, as shown here:

```
modelBuilder.ApplyConfiguration<Flight>(new FlightETC());
```

Bulk Configuration with the Fluent API

Another option in the Fluent API is not to configure each individual entity classes but instead configure several at once. The subobject `Model` of the passed `ModelBuilder` object provides a list of all entity classes in the form of objects with the interface `IMutableEntityType` via `GetEntityTypes()`. This interface provides access to all configuration options for an entity class. The example in Listing 6-6 shows the following:

- It prevents the convention that all table names are named as the property name of `DbSet<EntityClass>` in the context class. With `entity.Relational().TableName = entity.DisplayName()`, all tables are named as the entity classes. Exceptions are only those classes that have a `[Table]` annotation, so you have the opportunity to set individual deviations from the rule.
- You ensure that properties ending in the letters `NO` automatically become the primary key and there are no auto-increment values for these primary keys.

Listing 6-6. Bulk Configuration in the Fluent API

```

protected override void OnModelCreating (ModelBuilder builder)
{
...
    #region Bulk configuration via model class for all table names
    foreach (IMutableEntityType entity in modelBuilder.Model.GetEntityTypes())
    {
        // All table names = class names (~ EF 6.x),
        // except the classes that have a [Table] annotation
        var annotation = entity.ClrType.GetCustomAttribute<TableAttribute>();
        if (annotation == null)
        {
            entity.Relational().TableName = entity.DisplayName();
        }
    }
...
    #region Bulk configuration via model class for primary key
    foreach (IMutableEntityType entity in modelBuilder.Model.GetEntityTypes())
    {
        // properties ending in the letters "NO" automatically become the primary
        // key and there are no auto increment values for these primary keys.
        var propNr = entity.GetProperties().FirstOrDefault(x => x.Name.
            EndsWith("No"));
        if (propNr != null)
        {
            entity.SetPrimaryKey(propNr);
            propNr.ValueGenerated = ValueGenerated.Never;
        }
    }
}

```

CHAPTER 7

Database Schema Migrations

Entity Framework Core contains tools to create a database from an object model at the time of development or runtime of the application and to change the schema of an existing database (in simple cases without data loss).

By default, Entity Framework Core assumes at startup that the database to be addressed exists and is in the correct schema version. There is no check to see whether this is really true. For example, if a table or column is missing or a relationship does not exist as intended, then you will get a runtime error (for example, “Invalid object name ‘AircraftType’”) when you access the object in the database.

Creating the Database at Runtime

At program start, you can call the `EnsureCreated()` method in the Database subobject of the context class (see Listing 7-1); this method creates the complete database in the sense of forward engineering if it does not exist and creates the tables with the associated keys and indexes.

However, if the database already exists, `EnsureCreated()` leaves it as is. The method `EnsureCreated()` does not then check whether the database schema is correct, meaning whether it corresponds to the current object model. Instead, `EnsureCreated()` uses the following command:

```
IF EXISTS (SELECT * FROM INFORMATION_SCHEMA.TABLES WHERE TABLE_TYPE = 'BASE
TABLE') SELECT 1 ELSE SELECT 0
```

This checks whether there is any table in the database at all. If there is no table, all tables are created. However, as soon as there is any table in the database, nothing happens, and the program fails at runtime. You get more “intelligence” with the schema migrations described in the next section.

Listing 7-1. Using EnsureCreated()

```
using DA;
using ITVisions;
using Microsoft.EntityFrameworkCore;

namespace EFC_Console
{
    class CreateDatabaseAtRuntime
    {
        public static void Create()
        {
            CUI.MainHeadline("----- Create Database at runtime");
            using (var ctx = new WWingsContext())
            {
                // GetDbConnection() requires using Microsoft.EntityFrameworkCore !
                CUI.Print("Database: " + ctx.Database.GetDbConnection().ConnectionString);
                var e = ctx.Database.EnsureCreated();
                if (e)
                {
                    CUI.Print("Database has been created");
                }
                else
                {
                    CUI.Print("Database exists!");
                }
            }
        }
    }
}
```

Schema Migrations at the Time of Development

In the 4.3 version of the classic Entity Framework, Microsoft introduced schema migrations. These schema migrations are now (with slight differences) also available in Entity Framework Core.

Schema migrations allow you to do the following:

- Change the database schema at a later date while retaining the existing data
- Reverse the changes, if necessary
- Run the migration either at development time or at the start of the application

Commands for the Schema Migrations

As in the classic Entity Framework, there is no graphical user interface (GUI) for performing migrations. Rather, you execute all actions within a command-line interface, either via a PowerShell cmdlet within the Package Manager Console of Visual Studio or via the external command-line tool `dotnet.exe` (or `dotnet` on other operating systems).

To use these commands, install a NuGet package.

```
Install-Package Microsoft.EntityFrameworkCore.Tools
```

Unfortunately, this package brings a lot of new assembly references into the project, which will not be needed at runtime later. However, since the NuGet packages are needed only in the startup project of the application and not in other projects, a simple solution is available to not inflate the actual startup project. Follow these steps:

1. Create a new console application project, such as with the name `EFC_Tools`.
2. Install the Entity Framework Core tools package (Microsoft.EntityFrameworkCore.Tools).
3. From the `EFC_Tools` project, refer to the project in which the context class is located.

4. Make this EFC_Tools project the startup project.
5. Execute the required migration commands here.
6. Change the startup project again.

You can refrain from changing the startup project if you specify what the startup project should be in the cmdlets using the parameter `-startupproject`.

Note The project EFC_Tools does not need to be deployed to users later.

Microsoft has changed some of the details of the procedure for creating and using schema migrations in Entity Framework Core compared to the classic Entity Framework. You do not need to run the `Enable-Migrations` command at the beginning; you can start the project directly with `Add-Migration`. The `Command-Enable-Migrations` command still exists, but it only returns the following message: “Enable-Migrations is obsolete. Use Add-Migration to start using Migrations.” Automatic migrations, without calling `Add-Migration`, are no longer available in Entity Framework Core. Updating the database is done as before with `Update-Database`. If you prefer a SQL script for your own execution, you will now receive it with `Script-Migration` instead of with the `Update-Database` script (see Figure 7-1).

ef.exe

Internally, the PowerShell cmdlets use a classic command-line utility called `ef.exe` (the Entity Framework Core command-line tools), which is part of the NuGet package `Microsoft.EntityFrameworkCore.Tools` and is located in the `Tools` folder. Figure 7-2 shows help for the command.

Add-Migration

For Entity Framework Core, you start a schema migration (even the first one) within Visual Studio with the PowerShell cmdlet `Add-Migration`. This is done via the NuGet Package Manager Console (PMC).

1. The Entity Framework Core tools are actually installed in the current startup project.
2. That this project is selected as the default project in which the context class is located.
3. That all projects can be compiled in the solution.

The case of the cmdlet name is not relevant, as with all PowerShell cmdlets. To make it easy for you, you should have only one context class in each project. Otherwise, the Entity Framework Core tools do not know which context class is meant (you'll get this error message: "More than one DbContext was found. Specify which one to use. Use the '-Context' parameter for PowerShell commands and the '--context' parameter for dotnet commands."). You always have to solve this by specifying the additional parameter `-Context` for each command.

You have to specify a freely selectable name for, for example, `Add-Migration v1`. Executing this command in the Package Manager Console creates a `Migrations` folder in the project of the context class with three files and two classes (see Figure 7-3).

- A class is created named as specified in `Add-Migration`. This class has two files, one with the addition of `.designer`. These files also carry a timestamp in the name, which indicates the time at which the migration was created. This class inherits from the base class `Microsoft.EntityFrameworkCore.Migrations.Migration`. It is hereafter referred to as a *migration class*.
- A class is created that takes the name of the context class with the addition of `ModelSnapshot` and inherits from `Microsoft.EntityFrameworkCore.Infrastructure.ModelSnapshot`. This class is hereafter referred to as a *snapshot class*.

The migration class has three methods. The `Up()` method moves the database schema to its new state (if there is no previous migration, the program code creates the database in its default state), and the `Down()` method undoes the changes. The method `BuildTargetModel()` returns the state of the object model at the time the migration was created. `BuildTargetModel()` uses an instance of `ModelBuilder` passed from Entity Framework Core, just like the `OnModelCreating()` method in the context class.

In the classic Entity Framework, Microsoft stored the current state of the object model in an XML resource file (`.resx`) with a binary representation of the current state in an embedded BLOB. However, such a binary representation was not suitable for comparisons in source control systems and therefore presented challenges when multiple developers created schema migrations. Entity Framework Core can still be a source of conflict in team environments, but these conflicts can now be solved more easily through the source control system because snapshots are now kept in C# (or Visual Basic .NET).

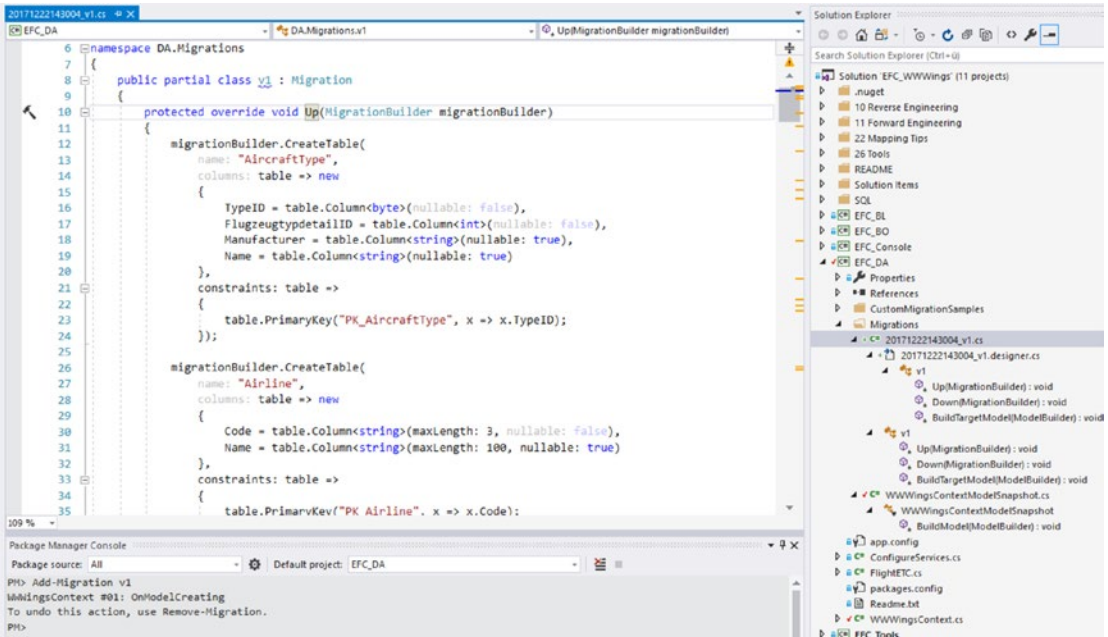

Figure 7-3. File created by Add-Migration

The Snapshot class contains a `BuildModel()` method that contains the same program code as `BuildTargetModel()` on the first migration. The Snapshot class always reflects the last state of the object model, while `BuildTargetModel()` refers to the time the migration was created. Common to both methods is that they express the entire object model in Fluent API syntax, not just the content of `OnModelCreating()`; they also formulate the conventions and the data annotations via the Fluent API. Here you can see that the Fluent API really offers all the configuration options of Entity Framework Core (see www.n-tv.de/mediathek/videos/wirtschaft/Ryanair-will-Co-Piloten-abschaffen-article1428656.html).

Developers can extend the `Up()` and `Down()` methods themselves and perform their own steps here. In addition to `CreateTable()`, `DropTable()`, `AddColumn()`, and `DropColumn()`, further operations are available such as `CreateIndex()`, `AddPrimaryKey()`, `AddForeignKey()`, `DropTable()`, `DropIndex()`, `DropPrimaryKey()`, `DropForeignKey()`, `RenameColumn()`, `RenameTable()`, `MoveTable()`, and `Sql()`. With the latter operation, you can execute any SQL command, for example, to update values or create records. A `Seed()` method for populating the database tables as in the classic Entity Framework does not exist in Entity Framework Core. See Figure 7-4.

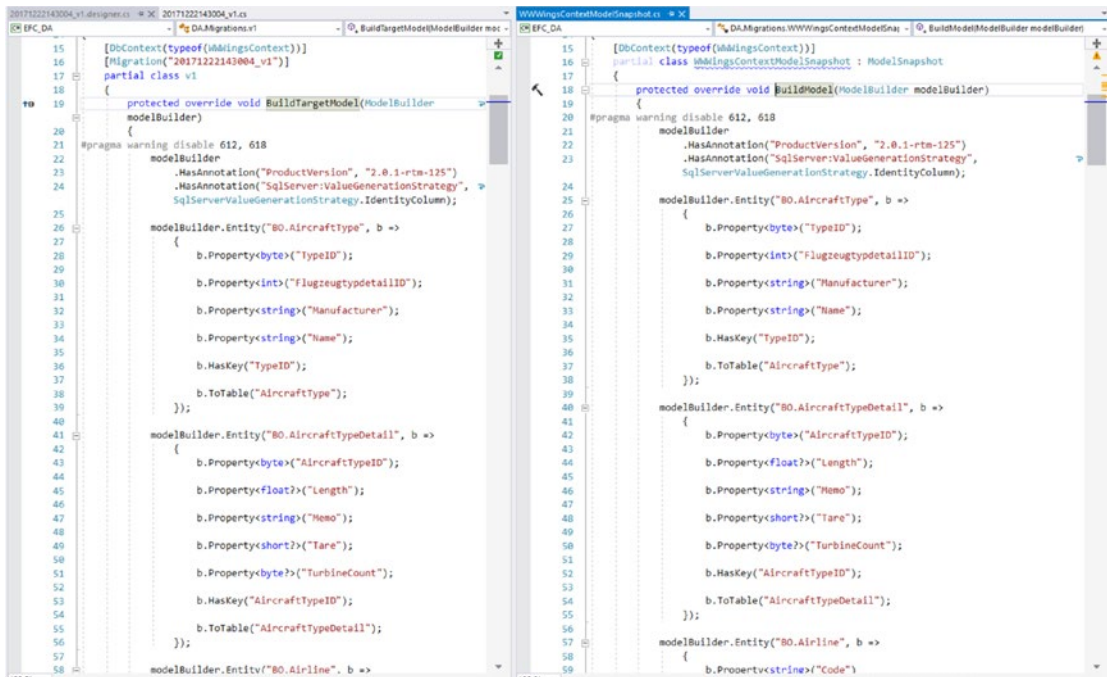

Figure 7-4. Content of *BuildModel()* vs. *BuildTargetModel()* on first migration

Add-Migration does not create a database and does not read the database. Add-Migration solely decides what to do based on the current snapshot class. Thus, in Entity Framework Core you can create multiple migrations one after the other without actually having to update the database in between.

In the classic Entity Framework this was different. Here, Add-Migration always looked first in the database to see whether it was up-to-date. If it was not, the error “Unable to generate an explicit migration because of the following explicit migrations are pending” appeared. Unfortunately, this meant you could not create multiple schema migrations one after the other without updating your own database in between. Although it is advisable to create schema migrations in small steps, you don’t want to be forced to update the database every time.

Attention You might see the following error message: “No DbContext was found in assembly. Ensure that you’re using the correct assembly and that the type is neither abstract nor generic.” This means you have chosen the wrong assembly to run `Add-Migration`. It also can mean that there is a (small) inconsistency in the version numbers. If, for example, in the context class project (EFC_DA) Entity Framework Core 2.0 is used but the version 2.0.1 of the tools is installed in the EFC_Tools project, this misleading error message occurs.

Listing 7-2 shows the migration v2, which was created after v1 and after I added the property `Plz`, forgotten in the class `Persondetail`. The `Up()` method adds the column `AddColumn()`, and `Down()` clears it with `DropColumn()`.

Listing 7-2. The Migration v2 Complements the Column `Plz` in the Table `Persondetail`

```
using Microsoft.EntityFrameworkCore.Migrations;
using System;
using System.Collections.Generic;

namespace DA.Migrations
{
    public partial class v2 : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.AddColumn<string>(
                name: "Postcode",
                table: "Persondetail",
                maxLength: 8,
                nullable: true);
        }
    }
}
```

```

protected override void Down(MigrationBuilder migrationBuilder)
{
    migrationBuilder.DropColumn(
        name: "Postcode",
        table: "Persondetail");
}
}
}

```

Update-Database

The command `Update-Database` then brings the database into the state described by the migration steps any time you want. It is important that at this time, in the `OnConfiguring()` method of the context class, you pass the correct connection string to the desired database to the Entity Framework Core database provider via `UseSqlServer(Connection string)`. `Update-Database` will instantiate the context class at development time, and `OnConfiguring()` will execute it. `Update-Database` will create the database (if it's not there yet), as well as all tables, according to the `Up()` methods of all the not yet executed schema migrations. Figure 7-5 shows that two schema migrations (v1 and v2) are executed.

Figure 7-5. Execution of `Update-Database`

`Update-Database` also creates an additional `__EFMigrationsHistory` table in the database with the `MigrationId` and `ProductVersion` columns. `MigrationId` corresponds to the file name of the migration class without the file name extension (e.g., `20171222143004_v1`), and `ProductVersion` is the version number of Entity Framework Core (for example, `2.0.1-rtm-125`). In the classic Entity Framework, the table was named `__MigrationHistory` and also contained a BLOB of the object model state. See Figure 7-6.

	MigrationId	ProductVersion
1	20171219200937_v1	2.0.1-rtm-125
2	20171222091949_v2	2.0.1-rtm-125

Figure 7-6. Content of the Table `__EFMigrationsHistory`

If the database already exists, Entity Framework Core looks to see whether the `__EFMigrationsHistory` table already exists. If there is the table and there are all migration steps recorded, nothing happens. Repeated execution of `Update-Database` does not generate an error (execution is idempotent). Entity Framework Core does not check whether the actual database schema fits. So, if someone has deleted a table (via SQL Management Studio or similar), the problem arises only when the program is running and Entity Framework Core wants to access that table.

If the `__EFMigrationsHistory` table does not exist, Entity Framework Core creates it, but at the same time it assumes that the database schema does not yet exist and performs all the migration steps. However, if there are already tables with those names, `Update-Database` fails (with the error message “There is already an object named ‘xy’ in the database.”). So, if someone deletes the `__EFMigrationsHistory` table because they think it is superfluous, it destroys the ability to load more schema migrations.

Script-Migration

While forward engineering with Entity Framework Core is adequate for executing the PowerShell commandlet `Update-Database` or the equivalent command-line command `dotnet ef database update` for importing schema changes directly to a development system, you will need other mechanisms when distributing the applications. For most companies, it will be necessary to use a SQL script that database administrators (after careful scrutiny) install on the well-shielded database server. Such a SQL script is obtained through the `Script-Migration` command line or via the command line with `dotnet ef migrations script`.

`Script-Migration` creates a SQL Data Definition Language (DDL) script with the migration actions. `Script-Migration` does not look in the database and therefore does not know what its status is. The cmdlet always creates a SQL script for all migration

steps after the first one, without further specification of parameters. If you only want individual migration steps as an SQL script, you must specify this with `-from` and `-to`. Here's an example:

```
Script-Migration -from 20170905085855_v2 -to 20170905090511_v3
```

There are two “difficulties” built into this cmdlet.

- You can't use the self-assigned name (e.g., `v2`); you have to use the complete migration name including the timestamp given by Entity Framework Core. The value `0` in the parameter `-from` is a fixed name for the initial state.
- The migration step specified in the parameter `-from` is also executed. So, the previous command does not create a SQL script with the differences between `v2` and `v3`, but a SQL script with the differences between `v1` and `v3`.

Further Migration Steps

Even after importing one or more migration steps, you can create additional migration steps at any time. `Update-Database` detects whether a migration step has not been recorded yet and then performs it.

Migration Scenarios

The question arises for which types of schema changes Entity Framework Core can automatically generate appropriate schema migrations. Schema changes that add tables or columns are not critical. Columns are always added at the end of the table, regardless of the alphabetical order used (otherwise the entire table would have to be deleted and re-created, which would require that the data be saved in a temporary table beforehand).

When you create migration steps that delete tables or columns, `Add-Migration` warns you with this message: “An operation was scaffolded that may result in the loss of data. Please review the migration for accuracy.”

Sometimes you want to do something else besides adding tables and columns. When renaming a table or column, for example, you must intervene manually. Here, `Add-Migration` generates some program code that contains the old table or column deletes, and a new table or column is created because there is no feature of a .NET class or property that is preserved when renamed. The data was lost during this migration. Now, here in the migration class, you have to change by your own a `DropTable()` or a `CreateTable()` to a `RenameTable()` as well as a `DropColumn()` and a `CreateColumn()` to a `RenameColumn()` methods.

Note Since Entity Framework Core version 2.0, Entity Framework Core regards deleting a property and adding a property of the same data type and length as a rename operation and thus creates a `RenameColumn()` method in the migration class. That may be correct; you might have wanted to delete a column and create a new one instead. Again, you must carefully examine the generated migration classes.

When changing a data type (for example, reducing an `nvarchar` column from eight to five characters), `Migration` aborts `Update-Database` if there are longer strings in the database (you get this error message: "String or binary data would be truncated."). In this case, you must first prune the data. For example, you can shorten the `Postcode` column from eight to five characters by adding this:

```
migrationBuilder.Sql("update Persondetail set Postcode = left(Postcode, 5)")
```

to the `Up()` method before the execution of this:

```
migrationBuilder.AlterColumn<string>(name: "Postcode", table:
"Persondetail", maxLength: 5, nullable: true).
```

Schema migrations that change cardinalities are difficult. For example, say you must suddenly build a 1:N relationship from the 1:0/1 relationship between `Passenger` and `Persondetail` because the requirement has changed so that each `Passenger` now may have multiple addresses. With this cardinality change, Entity Framework Core can no longer maintain a consistent data state. While there was previously a `DetailID` column in the `Passenger` table that referred to a record in the `Persondetail` table, there must

be a `PersonID` column after the schema construction in `PersonDetail` that references `Passenger`. Although Entity Framework Core deletes one column and creates the other new one, it does not fill the new column with the appropriate values. Here, you must manually copy the values using the `Sql()` method in the migration class.

Unfortunately, the Entity Framework Core tools also generate migration code that first deletes the `DetailID` column and then re-creates `PersonID` in the `PersonDetails` table. Obtaining the data of course will not work here. Listing 7-3 shows the correct solution with a different order and uses the `Sql()` method to copy the keys.

Listing 7-3. `Up()` Migration Class Method for a Cardinality Change from 1:0/1 to 1:N

```
namespace EFC_DA.Migrations
{
    public partial class Kardinaliaet11wird1N : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            // First create a new column on the N-side
            migrationBuilder.AddColumn<int>(
                name: "PassengerPersonID",
                table: "Persondetail",
                nullable: true);

            // Now copy the values from the 1-side
            migrationBuilder.Sql("update Persondetail set PassengerPersonID =
            Passenger.PersonID FROM Passenger INNER JOIN Persondetail ON Passenger.
            DetailID = Persondetail.ID");

            // Then delete the column on the 1-side first
            migrationBuilder.DropForeignKey(
                name: "FK_Passenger_Persondetail_DetailID",
                table: "Passenger");

            migrationBuilder.DropIndex(
                name: "IX_Passenger_DetailID",
                table: "Passenger");
        }
    }
}
```

```

migrationBuilder.DropColumn(
    name: "DetailID",
    table: "Passenger");

// Then create index and FK for new column
migrationBuilder.CreateIndex(
    name: "IX_Persondetail_PassengerPersonID",
    table: "Persondetail",
    column: "PassengerPersonID");

migrationBuilder.AddForeignKey(
    name: "FK_Persondetail_Passenger_PassengerPersonID",
    table: "Persondetail",
    column: "PassengerPersonID",
    principalTable: "Passenger",
    principalColumn: "PersonID",
    onDelete: ReferentialAction.Restrict);
}
}

```

More Options

With Update-Database, you can also return to a previous state of the database schema. For example, you can return to version 2 after importing version 3 with the following command:

```
Update-Database-Migration v2
```

Update-Database uses the `Down()` method of the migration class. With Script-Migration, you can also create a script for the “down” case. Here’s an example:

```
Script-Migration -from v3 -to v2
```

Remove-Migration allows you to remove the migration class from Visual Studio for the most recent migration step.

Important You should not delete the migration class manually because the snapshot class will no longer be up-to-date. As a result, the next time you create a migration, the manually deleted migration steps would be disregarded. If you manually delete the migration class, you must also manually adjust the snapshot class.

Remove-Migration checks whether the last migration step has already been applied in the database. If so, deleting the migration class and changing the snapshot class will not occur. The error message is as follows: “The migration has already been applied to the database. Unapply it and try again. If the migration has been applied to other databases, consider reverting its changes using a new migration.” You can bypass this check with the parameter `-force`. Without manual intervention in the database schema, you may then no longer be able to create new migration steps in the database because there is a risk that these steps will try to re-create previously created tables or columns.

Add-Migration, Remove-Migration, Update-Database, and Script-Migration each have three common parameters, listed here:

- `-StartupProject`: Sets the Visual Studio project containing the Entity Framework Core tool packages if you do not want to change the startup project
- `-Project`: Specifies the Visual Studio project in which the context class resides
- `-Context`: Sets the context class (with namespace) if there are multiple context classes in the Visual Studio project

Here’s an example:

```
Update-Database v2 -StartupProject EFC_Tools -Project EFC_DA -Context  
WWWingsContext
```

To avoid the repeated use of these parameters in cmdlets, you can set these values with the cmdlet `Use-DbContext` and thus ensure that all subsequent cmdlet calls use these values.

```
Use-dbContext -StartupProject EFC_Tools -Project EFC_DA -context  
WWWingsContext
```

Problems with Schema Migration in Connection with TFS

In combination with the version management system of Team Foundation Server (TFS)—at least in the classic variant with Server Workspace, which works with write protection to files—the tools of Entity Framework Core have difficulties. It reports that it is not possible to modify the files in the migration folder. You'll get the following error: "Access to the path ...WWWingsContextModelSnapshot.cs' is denied." In this case, before running the command, you should unlock the migration folder with Check Out for Edit.

Another issue is that Remove-Migration deletes files on disk, but not from TFS versioning. You have to manually select the Visual Studio-Command "Undo" in the Pending Changes window.

Schema Migrations at Runtime

On rare occasions, a small application (e.g., a console application) will be issued that imports the schema changes to the target database. These cases include the following:

- Providing a tool for inexperienced database administrators or customer service reps who are unfamiliar with SQL
- Installing or updating databases as part of automated integration testing in release pipelines
- Installing or updating local databases on end-user systems (if it is a mobile app, you should install the schema migration directly into the actual app at startup)

For cases where a program execution schema migration is appropriate, Entity Framework Core provides the methods `ctx.Database.GetMigrations()`, `ctx.Database.GetAppliedMigrations()`, and `ctx.Database.Migrate()`. These methods can save developers from having to write a tool that determines which schema migrations are pending and then inject the appropriate SQL scripts.

Unlike the classic Entity Framework, Entity Framework Core does not check whether the schema is up-to-date during the first database access of an application. The program may run on an error (for example, "Invalid column name 'Postcode'"). By calling the method `Migrate()` in the Database object of the context class, you can ensure at startup

that the database schema is up-to-date (see Listing 7-4). `Migrate()` may execute missing migration steps, which is possible because the migration classes are part of the compilation of the project, which contains the context class.

Note For a schema migration at runtime, the NuGet package `Microsoft.EntityFrameworkCore.Tools` is not needed.

Listing 7-4. Running a Schema Migration at Runtime Using the `Migrate()` Method

```
using (var ctx = new WWingsContext())
{
    ctx.Database.Migrate();
}
```

It is forbidden to use `EnsureCreated()` and `Migrate()` together. Even the tooltip of method `Migrate()` warns against it. If you still want to try it, you'll be rewarded with the unremarkable runtime error "An item with the same key has already been added."

Note If the schema is already in the necessary state, the startup costs of `Migrate()` are very low. A schema migration might take some seconds; however, without the migration, your code will likely fail.

CHAPTER 8

Reading Data with LINQ

Like the classic Entity Framework, Entity Framework Core allows you to write database queries with Language Integrated Query (LINQ).

LINQ is a common query language for different data stores introduced in 2007 in .NET Framework 3.5; it also exists in .NET Core as well as Mono and Xamarin. Microsoft has used LINQ since the beginning in the classic Entity Framework, where it's implemented as LINQ to Entities. Microsoft no longer uses this term in Entity Framework Core; it's just called LINQ. There are some positive and negative differences in LINQ execution between the classic Entity Framework and Entity Framework Core.

Context Class

The starting point for all LINQ queries in Entity Framework Core is the context class that you create either during the reverse engineering of an existing database or manually while forward engineering. The context class in Entity Framework Core always inherits from the base class `Microsoft.EntityFrameworkCore.DbContext`. The alternative base class of `ObjectContext`, which exists in the classic Entity Framework, has been deleted from Entity Framework Core. Accordingly, you have to use `DbContext` for all LINQ operations. But even the base class `DbContext` has changed a bit in Entity Framework Core.

The `DbContext` class implements the `IDisposable` interface. As part of the `Dispose()` method, `DbContext` frees all allocated resources, including references to all objects loaded with change tracking.

Tip Therefore, it is important that the context class user always calls `Dispose()` once the work is done. It's best to use a `using(){ ... }` block!

LINQ Queries

After instantiating the context class, you can formulate a LINQ query. This query is not necessarily executed immediately; it is initially in the form of an object with the interface `IQueryable<T>`. In the sense of so-called deferred execution, the LINQ query is executed when the result is actually used (for example, in a `foreach` loop) or when converted to another collection type. You can force the execution of the query with a LINQ conversion operator, in other words, `ToList()`, `ToArray()`, `ToLookup()`, `ToDictionary()`, `Single()`, `SingleOrDefault()`, `First()`, `FirstOrDefault()`, or an aggregate operator such as `Count()`, `Min()`, `Max()`, or `Sum()`.

Since `IQueryable<T>` is a subtype of `IEnumerable<T>`, you can start a `foreach` loop over an object with `IQueryable<T>`. This causes the query to run immediately. In addition, Entity Framework Core keeps the database connection open until the last object has been fetched, which can lead to unwanted side effects. You should therefore always explicitly use one of the previous conversions or aggregate operators before using the data in RAM because in this case Entity Framework Core will close the database connection. However, because Entity Framework Core is based on ADO.NET, the database connection is not actually closed immediately but returned to the ADO.NET connection pool. Also, data binding to an object with interface `IQueryable<T>` triggers a retrieval of the data.

Figure 8-1 shows the internal processing for a LINQ query. First, the LINQ query is converted into an expression tree. The expression tree creates a SQL command that Entity Framework Core sends to the database management system using a `Command` object from ADO.NET. Entity Framework Core has a cache for the SQL commands to prevent the overhead of converting from LINQ to SQL to the same commands twice.

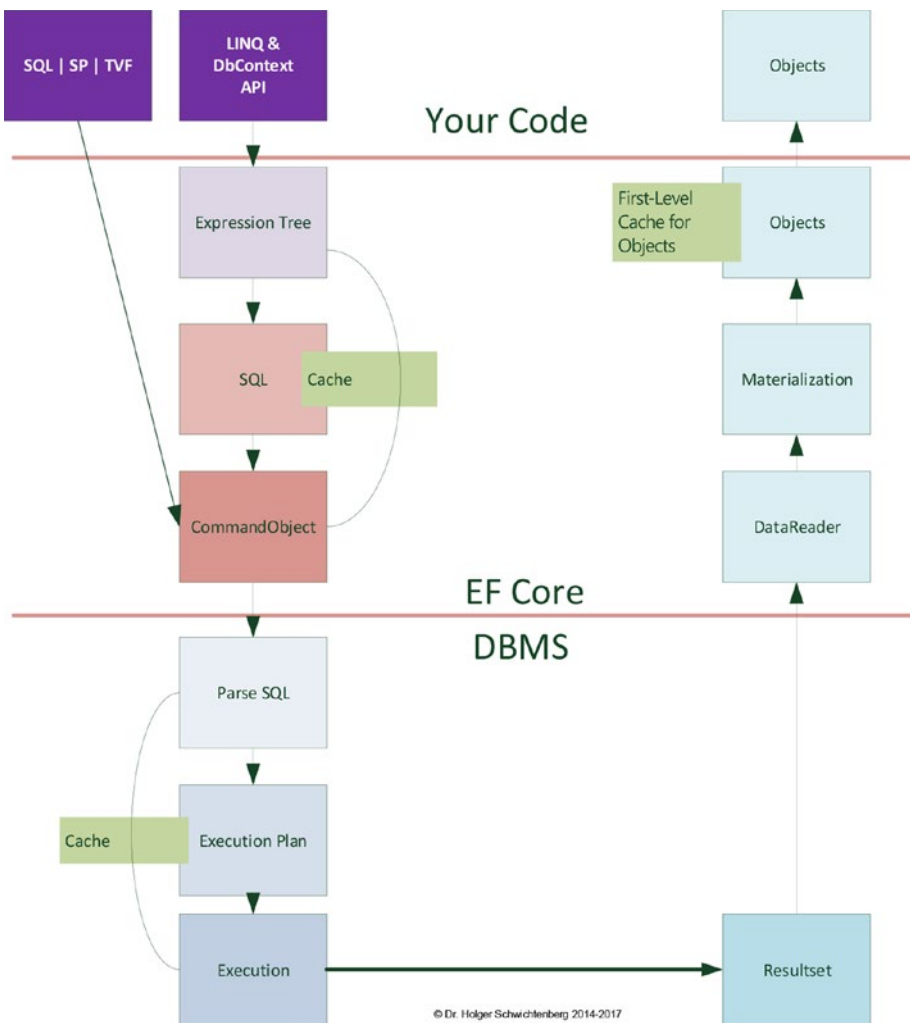

Figure 8-1. Internals for running a LINQ command through Entity Framework Core

The database management system analyzes the query and checks whether there is already a suitable execution plan for it. If none exists in the cache, it will be created. Thereafter, the database management system executes the query and delivers a result set to Entity Framework Core. Then Entity Framework Core uses a `DataReader` object to read the result set, but the user code does not see it because Entity Framework Core materializes the `DataReader` lines into objects. Except in no-tracking mode, Entity Framework Core looks to see whether the objects to be materialized are already in the first-level cache of the Entity Framework Core context. If the objects are there, the materialization is eliminated. However, this also means that if an object is in RAM, the

user will not get the current state of the record from the database but instead get the object from the cache, despite the renewed execution of a SQL command.

Listing 8-1 shows a simple LINQ query that returns all unbooked flights from a departure location, sorted by date and departure. `ToList()` turns `IQueryable<Flight>` into a `List<Flight>` with interface `IEnumerable<T>`. Instead of the concrete type name, however, the keyword `var` is often used in the program code in practice.

Listing 8-1. LINQ Query That Returns All Nonbooked Flights from a Departure Location

```
public static void Linq_List()
{
    var city = "Berlin";

    // Instantiate context
    using (var ctx = new WWingsContext())
    {
        // Define queries, but do not execute yet
        IQueryable<Flight> query = (from x in ctx.FlightSet
                                   where x.Departure == city &&
                                         x.FreeSeats > 0
                                   orderby x.Date, x.Departure
                                   select x);

        // Run query now
        List<Flight> flightSet = query.ToList();

        // Count loaded objects
        var count = flightSet.Count;
        Console.WriteLine("Number of loaded flights: " + count);

        // Print results
        foreach (var f in flightSet)
        {
            Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
                               {f.Destination} has {f.FreeSeats} free seats!");
        }
    } // End using-Block -> Dispose() will be called
}
```

A more concise formulation in the method syntax of LINQ is possible, as shown here:

```
var query2 = ctx.FlightSet.Where(x => x.Departure == city && x.FreeSeats > 0)
    .OrderBy(x => x.Date).ThenBy(x => x.Departure);
```

Of course, it is also possible to combine the call to `ToList()` with the definition of the LINQ query and thus execute the LINQ query immediately.

```
var flightSet2 = (from x in ctx.FlightSet
    where x.Departure == city &&
           x.FreeSeats > 0
    orderby x.Date, x.Departure
    select x).ToList();
```

However, the advantage of split notation is that you can attach more operations before executing the query.

The following is the executed SQL query:

```
SELECT [x].[FlightNo], [x].[AircraftTypeID], [x].[AirlineCode], [x].
[CopilotId], [x].[FlightDate], [x].[Departure], [x].[Destination], [x].
[FreeSeats], [x].[LastChange], [x].[Memo], [x].[NonSmokingFlight], [x].
[PilotId], [x].[Price], [x].[Seats], [x].[Strikebound], [x].[Timestamp],
[x].[Utilization]
FROM [Flight] AS [x]
WHERE ([x].[Departure] = @__city_0) AND ([x].[FreeSeats] > 0)
ORDER BY [x].[FlightDate], [x].[Departure]
```

Note Theoretically, you can call the method `query.Count()` instead of the property `flightSet.Count`. However, this produces a new database query that provides the number of records. This is superfluous because the objects are already materialized and can be counted quickly in RAM. Accessing the DBMS with `query.Count()` makes sense only if you want to determine whether the number of records in the database has changed.

Step-by-Step Composition of LINQ Queries

Listing 8-2 shows how to attach an extra condition on the departure or destination to the basic query `FreeSeats > 0` on a case-by-case basis if the variables for the values do not contain zero or an empty string. This is the typical scenario for user-set filters. If users do not enter anything in a filter field, then they do not want to see those records where the value is empty and want this filter to be ignored during the query.

Listing 8-2. LINQ Query That Returns All Unbooked Flights on a Route, with Both Departure and Destination Optional

```
public static void LINQ_Composition()
{
    var departure = "";
    var destination = "Rome";

    // Create context instance
    using (var ctx = new WWWingsContext())
    {
        // Define query, but do not execute yet
        IQueryable<Flight> query = from x in ctx.FlightSet
            where x.FreeSeats > 0
            select x;

        // Conditional addition of further conditions
        if (!String.IsNullOrEmpty(departure)) query = query.Where(x =>
            x.Departure == departure);
        if (!String.IsNullOrEmpty(destination)) query = query.Where(x =>
            x.Destination == destination);

        // now use sorting, otherwise there will be problems with variable
        query type (IQueryable<Flight> vs. IOrderedQueryable<Flight>)
        var querySorted = from x in query // IOrderedQueryable<Flight>
            orderby x.Date, x.Departure
            select x;

        // Execute query now
        List<Flight> flightSet = querySorted.ToList();
    }
}
```

```

// Count loaded objects
long c = flightSet.Count;
Console.WriteLine("Number of loaded flights: " + c);

// Print result
foreach (var f in flightSet)
{
    Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
    {f.Destination} has {f.FreeSeats} free seats!");
}
} // End using-Block -> Dispose()

```

Use of var

In practice, instead of the specific type names such as `IQueryable<Flight>`, the keyword `var` is used when using LINQ. There are still a lot of arguments among developers regarding the keyword `var` (specifically when using `Dim` without a type in Visual Basic .NET). In conjunction with LINQ, `var` often simplifies the coding. With LINQ, using some operators such as `orderby` changes the return type. Without `orderby`, you get an object that implements `IQueryable<Flight>`. With `orderby`, it is an `IOrderedQueryable<Flight>`. So, you often have to change the variable type when changing LINQ queries. This is not necessary when using the keyword `var`.

Repository Pattern

Except in small applications, you should not keep the data access code in the user interface. The repository pattern has been established to encapsulate the data access code for one or more (connected) tables. A repository class provides methods that return individual objects or sets of objects or return methods that allow you to insert, delete, and modify records.

An `IQueryable<T>` can also be used as the return value of a method so that the caller of the method can also extend the query. However, this makes sense only if the context instance still survives after the end of the method and thus can execute the query later. Therefore, you must hold the context instance as an attribute of the class and provide

the `IDisposable` interface for later destruction of the context instance when calling `Dispose()` (see Listing 8-3 with class `FlightManager` in repository style). The caller can then expand the query and should use the class `FlightManager` with a `using()` block to ensure the call to `Dispose()`. See Listing 8-4.

Note You can see the repository pattern in action in Appendix A of this book. There you will also see how to use a common base class for all repository classes, reducing the code in the repository classes.

        // Execute the query now
        var flightSet = query.ToList();
        Console.WriteLine("Number of loaded flights: " + flightSet.Count);
    }
}
}

```

LINQ Queries with Paging

Paging means that only one specific range of records should be delivered from a result set. This can be realized in LINQ with the methods `Skip()` and `Take()` (or the language elements `Skip` and `Take` in Visual Basic .NET).

Listing 8-5 shows a more complex LINQ query. It will search the flights in which

- There is at least one free seat
- There is at least one booking
- There is a passenger named Müller
- The pilot was born before January 1, 1972
- There is a copilot

From the result set, the first 50 data records are then skipped by paging in the database management system, and only the following 10 data records are delivered (that is, data records 51 to 60).

Listing 8-5. Complex LINQ Query

```
[EFCBook("Paging")]
public static void LINO_QueryWithPaging()
{
    CUI.MainHeadline(nameof(LINO_QueryWithPaging));
    string name = "Müller";
    DateTime date = new DateTime(1972, 1, 1);
    // Create context instance
    using (var ctx = new WWingsContext())
    {
        // Define query and execute
        var flightSet = (from f in ctx.FlightSet
                        where f.FreeSeats > 0 &&
                              f.BookingSet.Count > 0 &&
                              f.BookingSet.Any(b => b.Passenger.Surname ==
                                                    name) &&
                              f.Pilot.Birthday < date &&
                              f.Copilot != null
                        select f).Skip(5).Take(10).ToList();

        // Count number of loaded objects
        var c = flightSet.Count;
        Console.WriteLine("Number of found flights: " + c);
    }
}
```

```

// Print objects
foreach (var f in flightSet)
{
    Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
    {f.Destination} has {f.FreeSeats} free seats!");
}
} // End using-Block -> Dispose()
}

```

The following SQL command is the SQL command sent in Listing 8-5, which is much more complex than its LINQ counterpart. This command was sent to Microsoft SQL Server 2017 and was retrieved using the SQL Server Profiler tool included with SQL Server. The SQL Server version is actually important here; the row-limiting clauses with the keywords OFFSET, FETCH FIRST, and FETCH NEXT from the 2008 SQL ANSI standard (http://www.iso.org/iso/home/store/catalogue_tc/catalogue_tc_browse.htm?commid=45342) have been supported by Microsoft SQL Server since version 2012. Oracle has been offering this support since version 12c (released on 1.7.2013). For DBMSs that do not support this new syntax, Entity Framework Core needs to create an even more complex query with the `rownumber()` function and subselects to implement `Skip()`.

Note An nice improvement in Entity Framework Core is the use of the variable names from the LINQ query (here `f` and `b`) in the SQL command. In the classic Entity Framework, names such as `extend1`, `extend2`, `extend3`, and so on, were used instead. If Entity Framework Core in SQL needs an alias multiple times for a table, the ORM appends a number to the variable name (see `[b0]` in the following SQL code).

```

exec sp_executesql N'SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].
[AirlineCode], [f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].
[Destination], [f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].
[NonSmokingFlight], [f].[PilotId], [f].[Price], [f].[Seats], [f].
[Strikebound], [f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
INNER JOIN [Employee] AS [f.Pilot] ON [f].[PilotId] = [f.Pilot].[PersonID]

```

```

WHERE ([f.Pilot].[Discriminator] = N'Pilot') AND (((([f].[FreeSeats] > 0)
AND ((
    SELECT COUNT(*)
    FROM [Booking] AS [b]
    WHERE [f].[FlightNo] = [b].[FlightNo]
) > 0)) AND EXISTS (
    SELECT 1
    FROM [Booking] AS [b0]
    INNER JOIN [Passenger] AS [b.Passenger] ON [b0].[PassengerID] =
    [b.Passenger].[PersonID]
    WHERE ([b.Passenger].[Surname] = @__name_0) AND ([f].[FlightNo] =
    [b0].[FlightNo]))) AND ([f.Pilot].[Birthday] < @__date_1)) AND [f].
[CopilotId] IS NOT NULL)
ORDER BY (SELECT 1)
OFFSET @__p_2 ROWS FETCH NEXT @__p_3 ROWS ONLY',N'@__name_0
nvarchar(4000),@__date_1 datetime2(7),@__p_2 int,@__p_3 int',
@__name_0=N'Müller',@__date_1='1972-01-01 00:00:00',@__p_2=5,@__p_3=10

```

Projections

In a relational database, the restriction to selected columns is referred to as a *projection* (see https://en.wikipedia.org/wiki/Set_theory). It is often a serious performance error to load all the columns of a table if not all columns are really needed.

Projection to an Entity Type

The LINQ queries shown so far always actually load and materialize all columns of the Flight table. Listing 8-6 shows a projection with `select new Flight()` and only the desired columns. After executing the `ToList()` method, you receive a list of Flight objects that have all the properties (since the class is defined as such), but only the specified properties are filled.

Listing 8-6. LINQ Query with Projection

```

public static void Projection_Read()
{
    using (var ctx = new WWingsContext())
    {
        CUI.MainHeadline(nameof(Projection_Read));

        var query = from f in ctx.FlightSet
                    where f.FlightNo > 100
                    orderby f.FlightNo
                    select new Flight()
                    {
                        FlightNo = f.FlightNo,
                        Date = f.Date,
                        Departure = f.Departure,
                        Destination = f.Destination,
                        FreeSeats = f.FreeSeats
                    };

        var flightSet = query.ToList();

        foreach (var f in flightSet)
        {
            Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
                               {f.Destination} has {f.FreeSeats} free seats!");
        }
    }
}

```

The following SQL output of Listing 8-6 proves that Entity Framework Core is indeed requesting the desired columns in the database management system only:

```

SELECT [f].[FlightNo], [f].[FlightDate] AS [Date], [f].[Departure], [f].
[Destination], [f].[FreeSeats]
FROM [Flight] AS [f]
WHERE [f].[FlightNo] > 100
ORDER BY [f].[FlightNo]

```

Note The direct support of projections to an entity class is a major advantage of Entity Framework Core over the classic Entity Framework. In the classic Entity Framework, projections were not possible for entity classes and complex types; only anonymous types and nonentity classes could be used with projections. Because of the limitation of anonymous types (instances are read-only and cannot be used in methods as a return value), it was usually necessary to copy in instances of the entity class. For this you could use the NuGet package AutoMapper.EF6 (<https://github.com/AutoMapper/AutoMapper.EF6>) with the extension method `ProjectTo<T>()`.

Projections to an Anonymous Type

A projection to an anonymous type is possible. In this case, no class name should be specified after the `new` operator. If the names of the properties will not change, then in the initialization block instead of the assignment `{Departure = f.Departure, ...}` only a simple mention of the properties is necessary, as follows: `{f.Departure, f.Destination, ...}`.

Note The anonymous type is unknown to Entity Framework Core. If you try to query for an anonymous state with `ctx.Entry(f).State` or call `ctx.Attach(f)`, you get the following runtime error: “The entity type ‘<>f__AnonymousType8<int, DateTime, string, string, Nullable<short>, byte[]>’ was not found. Ensure that the entity type has been added to the model.”

```
f.FreeSeats--
```

Chapter 20 covers how to map anonymous types to other types using object-to-object mapping. Listing 8-7 shows the projection to an anonymous type.

Listing 8-7. Projection to an Anonymous Type

```
public static void Projection_AnonymousType()
{
    using (var ctx = new WWingsContext())
```

```

{
    CUI.MainHeadline(nameof(Projection_AnonymousType));

    var q = (from f in ctx.FlightSet
            where f.FlightNo > 100
            orderby f.FlightNo
            select new
            {
                FlightID = f.FlightNo,
                f.Date,
                f.Departure,
                f.Destination,
                f.FreeSeats,
                f.Timestamp
            }).Take(2);

    var flightSet = q.ToList();

    foreach (var f in flightSet)
    {
        Console.WriteLine($"Flight Nr {f.FlightID} from {f.Departure} to
        {f.Destination} has {f.FreeSeats} free seats!");
    }

    Console.WriteLine("Number of flights: " + flightSet.Count);

    foreach (var f in flightSet)
    {
        Console.WriteLine(f.FlightID);
        // not possible: Console.WriteLine("Before attach: " + f + " State: " +
        ctx.Entry(f).State + " Timestamp: " + ByteArrayToString(f.Timestamp));
        // not possible: ctx.Attach(f);
        // not possible: Console.WriteLine("After attach: " + f + " State: " +
        ctx.Entry(f).State + " Timestamp: " + ByteArrayToString(f.Timestamp));
        // not possible:
        // f.FreeSeats--;
        // not possible: Console.WriteLine("After Änderung: " + f + " State: " +
        ctx.Entry(f).State + " Timestamp: " + ByteArrayToString(f.Timestamp));
    }
}

```

```

var count = ctx.SaveChanges(); // no changes can be saved
Console.WriteLine("Number of saved changes: " + count);
// not possible: Console.WriteLine("After saving: " + f + " State: " +
ctx.Entry(f).State + " Timestamp: " + ByteArrayToString(f.Timestamp));
}
}
}

```

Projections to an Arbitrary Type

The target of the projection can also be any other class that, depending on the structure of the software architecture, would be called a *business object* (BO) or *data transfer object* (DTO). You have to mention the class name after `new` as with the entity class projection, and full assignments are necessary for the initialization, as follows: `{Departure = f.Departure, ...}`. Listing 8-8 shows the projection to a DTO.

Note As with anonymous types, Entity Framework Core does not know the class in this case. Asking for the state with `Attach()` and saving changes is therefore not possible.

Listing 8-8. Projection to a DTO

```

class FlightDTO
{
    public int FlightID { get; set; }
    public DateTime Date { get; set; }
    public string Departure { get; set; }
    public string Destination { get; set; }
    public short? FreeSeats { get; set; }
    public byte[] Timestamp { get; set; }
}

```

```

public static void Projection_DTO()
{
    using (var ctx = new WWWingsContext())
    {
        CUI.MainHeadline(nameof(Projection_DTO));

        var q = (from f in ctx.FlightSet
                where f.FlightNo > 100
                orderby f.FlightNo
                select new FlightDTO()
                {
                    FlightID = f.FlightNo,
                    Date = f.Date,
                    Departure = f.Departure,
                    Destination = f.Destination,
                    FreeSeats = f.FreeSeats,
                    Timestamp = f.Timestamp
                }).Take(2);

        var flightSet = q.ToList();

        foreach (var f in flightSet)
        {
            Console.WriteLine($"Flight Nr {f.FlightID} from {f.Departure} to
            {f.Destination} has {f.FreeSeats} free seats!");
        }

        Console.WriteLine("Number of flights: " + flightSet.Count);

        foreach (var f in flightSet)
        {
            Console.WriteLine(f.FlightID);
            // not possible: Console.WriteLine("Before attach: " + f + " State: " +
            ctx.Entry(f).State + " Timestamp: " + ByteArrayToString(f.Timestamp));
            // not possible: ctx.Attach(f);
            // not possible: Console.WriteLine("After attach: " + f + " State: " +
            ctx.Entry(f).State + " Timestamp: " + ByteArrayToString(f.Timestamp));
        }
    }
}

```

```

// not possible:

Console.WriteLine("Number of saved changes: " + anz);
// not possible: Console.WriteLine("After saving: " + f + " State: " +

}
}
}

```

Querying for Single Objects

LINQ offers four operations to select the first or only element of a set, listed here:

- `First()`: The first element of a set. If there are multiple elements in the set, all but the first are discarded. If there is no element, a runtime error occurs.
- `FirstOrDefault()`: The first element of a set or a default value (for reference types `null` or `Nothing`) when the amount is empty. If there are multiple elements in the set, all but the first are discarded.
- `Single()`: The only element of a set. If there is no element or there are multiple elements in the set, a runtime error occurs.
- `SingleOrDefault()`: The only element of a set. If there is no element, the default value (for reference types `null` or `Nothing`) is returned. If there are multiple items in the set, a runtime error occurs.

`First()` and `FirstOrDefault()` limit the output quantity on the database side with the SQL operator `TOP(1)`. `Single()` and `SingleOrDefault()` use `TOP(2)` to determine whether there is more than one element, which results in a runtime error. Listing 8-9 shows the code for the LINQ query.

Listing 8-9. LINQ Query for a Single Object with SingleOrDefault()

```

public static void LINQ_SingleOrDefault()
{
    using (var ctx = new WWingsContext())
    {
        var FlightNr = 101;

        var f = (from x in ctx.FlightSet
                where x.FlightNo == FlightNr
                select x).SingleOrDefault();

        if (f != null)
        {
            Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
                               {f.Destination} has {f.FreeSeats} free seats!");
        }
        else
        {
            Console.WriteLine("Flight not found!");
        }
    } // End using-Block -> Dispose()
}

```

Loading Using the Primary Key with Find()

The `DbSet<T>` class in the classic Entity Framework offers a `Find()` method as an alternative to loading an object using the primary key with LINQ. `Find()` passes the value of the primary key. If there is a multipart primary key, you can also pass several values, such as `Find("Holger", "Schwichtenberg", 12345)` if the primary key consists of two strings and one number. `Find()` was not available in Entity Framework Core version 1.0 but has already been integrated into version 1.1. Listing 8-10 shows the LINQ query.

Note Find() has the special behavior of first looking for an object in the first-level cache of the Entity Framework Core context and starting a database query only if the object is not there. The methods Single(), SingleOrDefault(), First(), and FirstOrDefault() always ask the database, even if the object exists in the local cache!

Listing 8-10. LINQ Query for a Single Object with Find

```
public static void LINQ_Find()
{
    CUI.MainHeadline(nameof(LINQ_Find));
    using (var ctx = new WWingsContext())
    {
        ctx.FlightSet.ToList(); // Caching all flights in context (here as an
                                // example only to show the caching effect!)

        var FlightNr = 101;
        var f = ctx.FlightSet.Find(FlightNr); // Flight is loaded from cache!

        if (f != null)
        {
            Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
                                {f.Destination} has {f.FreeSeats} free seats!");
        }
        else
        {
            Console.WriteLine("Flight not found!");
        }
    } // End using-Block -> Dispose()
}
```

Using LINQ in RAM Instead of in the Database (Client Evaluation)

Listing 8-11 shows a LINQ query with grouping using the LINQ grouping operator (`group by` or `GroupBy()`). This query provides the desired result (the number of flights per departure), but the query takes a lot of time for large amounts of data. When researching causes, you will find out that in the SQL command sent to the database management system, the grouping is completely missing. Entity Framework Core has loaded all records and grouped them in RAM, which is bad and unexpected.

Attention In fact, Entity Framework Core versions 1.x and 2.0 do not support the translation of a LINQ grouping into the `GROUP BY` syntax of SQL, which is a frightening gap in Entity Framework Core (see the “Working Around the GroupBy Problem” section). An improvement is planned for version 2.1 of Entity Framework Core; see Appendix C.

Listing 8-11. Determine the Number of Flights per Departure

```
using (var ctx = new WWWingsContext())
{
    Console.WriteLine(ctx.Database.GetType().FullName);
    ctx.Log();

    var groups = (from p in ctx.FlightSet
                  group p by p.Departure into g
                  select new { City = g.Key, Count = g.Count() }).Where
        (x => x.Count > 5).OrderBy(x => x.Count);

    // First roundtrip to the database (done intentionally here!)
    var count = groups.Count();
    Console.WriteLine("Number of groups: " + count);
    if (count == 0) return;
}
```

```
// Second roundtrip to the database
foreach (var g in groups.ToList())
{
    Console.WriteLine(g.City + ": " + g.Count);
}
}
```

Listing 8-11 shows the SQL command sent to the database management system (twice: once for `Count()` and once for `ToList()`).

```
SELECT [p0].[FlightNo],
       [p0].[AircraftTypeID],
       [p0].[AirlineCode],
       [p0].[CopilotId],
       [p0].[FlightDate],
       [p0].[Departure],
       [p0].[Destination],
       [p0].[FreeSeats],
       [p0].[LastChange],
       [p0].[Memo],
       [p0].[NonSmokingFlight],
       [p0].[PilotId],
       [p0].[Price],
       [p0].[Seats],
       [p0].[Strikebound],
       [p0].[Timestamp],
       [p0].[Utilization]
FROM   [Flight] AS [p0]
ORDER BY [p0].[Departure]
```

Unfortunately, there are a number of other cases where Entity Framework Core performs the operations in RAM rather than in the database.

For the following query, in Entity Framework Core 1.x, only filtering via `FlightNo` took place in the database.

```
var q2 = from f to ctx.FlightSet
        where f.FlightNo > 100
        && f.FreeSeats.ToString().Contains("1")
        orderby f.FlightNo
        select f;
```

`ToString().Contains()` could not be translated and executes this condition in RAM. In version 2.0, the entire LINQ command is translated to SQL.

For the following query, `AddDays()` could not be translated in Entity Framework Core 1.x, so only the filter on the free seats, but not the date filter, took place in the database management system.

```
var q3 = from f to ctx.FlightSet
        where f.FreeSeats > 0 &&
        f.Date > DateTime.Now.AddDays (10)
        orderby f.FlightNo
        select f;
```

This is also fixed in Entity Framework Core 2.0.

Unfortunately, the following query with the LINQ operator `Union()` also happens in RAM in Entity Framework Core 2.0:

```
var all places = (from f in ctx.FlightSet select f.Departure.Union(from f
in ctx.FlightSet select f.Destination)).Count();
```

Although here only one number is needed, Entity Framework Core will execute the following:

```
SELECT [f]. [Departure]
FROM [Flight] AS [f]
SELECT [f0]. [Destination]
FROM [Flight] AS [f0]
```

Note It should be mentioned that some of the previous LINQ queries were not executable at all in the classic Entity Framework. They were compiled but caused runtime errors. It's arguable whether the new solution in Entity Framework Core is a better solution. Although the orders are now possible, there is a big trap lurking. After all, Microsoft has announced in the road map (<https://github.com/aspnet/EntityFrameworkCore/wiki/Roadmap>) that in future versions of Entity Framework Core you can perform more operations in the database management system.

When running in RAM, significant performance problems threaten because too many records are loaded. Developers can run into a hard case if they use such a query and then do not test with a large number of records. This is all the more surprising since Microsoft always talks about Big Data but then with LINQ in Entity Framework Core provides a tool that is just not Big Data capable in some respects.

Such RAM operations are possible only in Entity Framework Core through a new provider architecture, which leaves the provider with the decision to perform certain operations in RAM. Microsoft calls this *client evaluation*.

Software developers can protect against these performance issues by turning off client evaluation. This is possible with the `ConfigureWarnings()` method, which provides the `DbContextOptionsBuilder` object that the developer gets in the `OnConfiguring()` method. The following configuration causes each client evaluation to trigger a runtime error, as shown in Figure 8-2. By default, Entity Framework Core logs client evaluation only (see Chapter 12 Logging).

```
protected override void OnConfiguring(DbContextOptionsBuilder builder)
{
    builder.UseSqlServer(_DbConnection);

    builder.ConfigureWarnings(warnings => warnings.Throw(RelationalEventId.
        QueryClientEvaluationWarning));
}
```

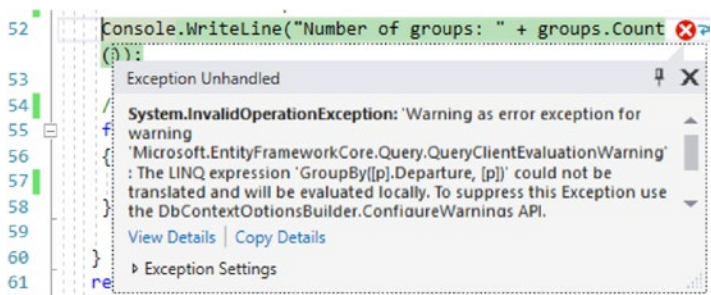

Figure 8-2. Runtime error raised on a client evaluation if disabled

Using the Wrong Order of Commands

Sometimes, however, software developers themselves make operations in RAM rather than in the database management system. In Listing 8-12, `ToList()` is called too early, and the query contains an object of the type `List<Flight>` instead of the type `IQueryable<Flight>`. As a result, the filters based on the place of departure and destination and sorting occur in the RAM with LINQ to Object.

Note LINQ uses the same syntax for queries in RAM (LINQ to Objects) and LINQ in Entity Framework/Entity Framework Core. Therefore, you cannot see in a program code line, whether it is executed in RAM or in the database management system. This always depends on the data type of the base set (that is, what is after `in` in the LINQ query).

Listing 8-12. `ToList()` Is Set Too Early and Causes the Following Queries to Execute in RAM

```
public static void LINQ_CompositionWrongOrder()
{
    CUI.MainHeadline(nameof(LINQ_Composition));

    var departure = "";
    var destination = "Rome";

    // Create context instance
    using (var ctx = new WWingsContext())
```

```

{
    // Define query (ToList() ist WRONG here!)
    var query = (from x in ctx.FlightSet
        where x.FreeSeats > 0
        select x).ToList();

    // Conditional addition of further conditions
    if (!String.IsNullOrEmpty(departure)) query = query.Where(x =>
        x.Departure == departure).ToList();
    if (!String.IsNullOrEmpty(destination)) query = query.Where(x =>
        x.Destination == destination).ToList();

    // Sorting
    var querySorted = from x in query
        orderby x.Date, x.Departure
        select x;

    // The query shoud execute here, but it is already executed
    List<Flight> flightSet = querySorted.ToList();

    // Count loaded objects
    long c = flightSet.Count;
    Console.WriteLine("Number of loaded flights: " + c);

    // Print result
    foreach (var f in flightSet)
    {
        Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
            {f.Destination} has {f.FreeSeats} free seats!");
    }
} // End using-Block -> Dispose()
}

```

Using Custom Function in LINQ

The new provider architecture in Entity Framework Core opens up the possibility of incorporating your own functions in LINQ queries. Of course, this part of the query is executed in RAM. For example, the query in Listing 8-13 includes its own `GetNumberOfDaysUntil()` method. Also, in this case, only the filter is executed over the `FreeSeats` column in the database.

Note Local functions that have existed since C# 6.0 cannot be called in LINQ commands.

Listing 8-13. Custom Functions in LINQ

```
private static int GetNumberOfDaysUntil(DateTime t)
{
    return (t - DateTime.Now).Days;
}

public static void LINQ_CustomFunction()
{
    CUI.MainHeadline("Query with Custom Function - RAM :-(");
    using (var ctx = new WWWingsContext())
    {
        var q4 = from f in ctx.FlightSet
                where f.FreeSeats > 0 &&
                    GetNumberOfDaysUntil(f.Date) > 10
                orderby f.FlightNo
                select f;

        List<Flight> l4 = q4.Take(10).ToList();

        Console.WriteLine("Count: " + l4.Count);
    }
}
```

```

foreach (var f in l4)
{
    Console.WriteLine(f);
}
}
}

```

Working Around the GroupBy Problem

The lack of translation of LINQ groupings to SQL in Entity Framework Core 1.x and 2.0 and the grouping of the records in RAM instead are absolutely unacceptable for many real-world scenarios.

In practice, a solution is needed that executes the grouping in the respective database management system. Unfortunately, with LINQ, this cannot be done in Entity Framework Core 1.x and 2.0. But the use of SQL also presents a challenge because Entity Framework Core does not yet support the mapping of results from SQL queries to any type, but only to entity classes.

Note Microsoft will introduce the GroupBy translation in version 2.1 of Entity Framework Core (see Appendix C), which will make these work-arounds obsolete.

Mapping to Nonentity Types

The code in Listing 8-14 using `FromSql()` is unfortunately not a solution. It fails to execute `FromSql()` and results in this runtime error: “Cannot create a DbSet for ‘DepartureGroup’ because this type is not included in the model for the context.” However, the error message suggests another trick that works (See Below “Challenge: Migrations” section).

Listing 8-14. No Solution to the GroupBy Issue

```

public static void GroupBy_SQL_NonEntityType()
{
    // Get the number of flights per departure
    using (var ctx = new WWWingsContext())

```

```

{
    // Map SQL to non-entity class
    Console.WriteLine(ctx.Database.GetType().FullName);
    ctx.Log();
    var sql = "SELECT Departure, COUNT(FlightNo) AS FlightCount FROM Flight
GROUP BY Departure";
    // ERROR!!! Cannot create a DbSet for 'Group' because this type is not
    included in the model for the context."
    var groupSet = ctx.Set<DepartureGroup>().FromSql(sql);
    // Output
    foreach (var g in groupSet)
    {
        Console.WriteLine(g.Departure + ": " + g.FlightCount);
    }
}
}

```

Creating an Entity Class for the Database View Result

Because the mapping with `FromSql()` is not realized on nonentity types, you must create a pseudo-entity class for the result of the grouping whose name and type attributes must match the columns of the grouping result. This entity class also requires a primary key that conforms to the convention (an ID of `classnameID`), or it must be specified using `[Key]` or the Fluent API's `HasKey()`. See Listing 8-15.

Listing 8-15. Entity Class with Two Properties for the Grouping Result

```

namespace B0
{
    public class DepartureGrouping
    {
        [Key] // must have a PK
        public string Departure { get; set; }
        public int FlightCount { get; set; }
    }
    ...
}

```

Including the Entity Class in the Context Class

The pseudo-entity class for the grouping result has to be included as an entity class in the context class via `DbSet<T>`, as shown in Listing 8-16.

Listing 8-16. Including the Entity Class for the Database View in the Context Class

```
public class WWWingsContext: DbContext
{
    #region tables
    public DbSet<Flight> FlightSet {get; set; }
    public DbSet<Pilot> PilotSet {get; set; }
    public DbSet<Passenger> PassengerSet {get; set; }
    public DbSet<Airport> AirportSet {get; set; }
    public DbSet<Booking> BookingSet {get; set; }
    public DbSet<AircraftType> AircraftTypeSet {get; set; }
    #endregion

    #region grouping results (pseudo-entities)
    public DbSet<DepartureGrouping> DepartureGroupingSet {get; set; }
    // for grouping
    #endregion ...
}
```

Using the Pseudo-Entity Class

The entity class `DepartureGrouping` can now be used as the return type in `FromSQL()`, as shown in Listing 8-17.

Listing 8-17. Use of the Pseudo-Entity Class

```
public static void GroupBy_SQL_Trick()
{
    // Get the number of flights per departure
    using (var ctx = new WWWingsContext())
    {
```

```

Console.WriteLine(ctx.Database.GetType().FullName);
ctx.Log();

// Map SQL to entity class
var sql = "SELECT Departure, COUNT(FlightNo) AS FlightCount FROM Flight
GROUP BY Departure";
var groupSet = ctx.Set<BO.DepartureGrouping>().FromSql(sql).Where(x=>x.
FlightCount>5).OrderBy(x=>x.FlightCount);

// Output
foreach (var g in groupSet)
{
    Console.WriteLine(g.Departure + ": " + g.FlightCount);
}
}
}

```

Figure 8-3 shows the output.

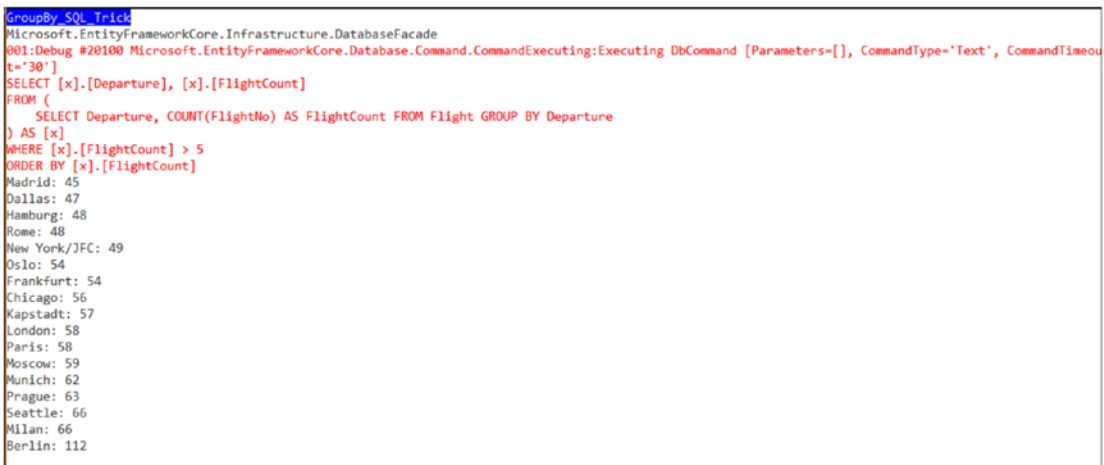

Figure 8-3. Output of Listing 8-17

Challenge: Migrations

As you've seen, some manual work is necessary to use the grouping result. Unfortunately, there is another challenge in database schema migrations beyond the typing work.

If you create a schema migration class after adding the database view's pseudo-entity class in the context, you will notice that Entity Framework Core undesirably wants to create a table for the pseudo-entity class in the database (see `CreateTable()` in Listing 8-18). This is correct in that I pretended that `DepartureGrouping` would be a table. However, it is not desirable to create a table for the grouping result.

Listing 8-18. Entity Framework Core Creates a `CreateTable()` for the Pseudo-Entity in the Schema Migration (Not Desirable)

```
using Microsoft.EntityFrameworkCore.Migrations;
using System;
using System.Collections.Generic;

namespace DA.Migrations
{
    public partial class v3 : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "DepartureGrouping",
                columns: table => new
                {
                    Departure = table.Column<string>(nullable: false),
                    FlightCount = table.Column<int>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_DepartureGrouping",
                        x => x.Departure);
                });
        }
    }
}
```

```

protected override void Down(MigrationBuilder migrationBuilder)
{
    migrationBuilder.DropTable(
        name: "DepartureGrouping");
}
}
}

```

There are three possible solutions in this situation:

- You can create the table and just not use it.
- You can manually delete `CreateTable()` in the `Up()` method and the corresponding `DropTable()` in `Down()` from the migration class.
- You can trick Entity Framework Core so that it ignores the entity class `DepartureStatistics` when creating the migration step at development time but not at runtime.

Listing 8-19 shows how to implement this trick. Entity Framework Core instantiates the context class as part of creating or deleting a schema migration and calls `OnModelCreating()`. However, at development time this does not happen via the actual starting point of the application (then the application would start) but by hosting the DLL with the context class in the command-line tool `ef.exe`. In `OnModelCreating()`, you therefore check whether the current process has the name `ef`. If so, then the application is not at runtime, and you are in the development environment and want to ignore the database view with `Ignore()`. At runtime of the application, however, the `Ignore()` method will not be executed, and thus using the database view through the entity class is possible.

Listing 8-19. Entity Framework Core Should Ignore the Entity Class for the Database View at Development Time Only

```

if (System.Diagnostics.Process.GetCurrentProcess().ProcessName.ToLower()
== "ef")
{
    modelBuilder.Ignore<DepartureGrouping>();
}

```

Alternative Trick If the query of the process name is too uncertain for you because Microsoft could change this name, you can instead use a switch in the context class in the form of a static attribute (e.g., `IsRuntime`). By default, `IsRuntime` is false and ignores the pseudo-entity class. At runtime, however, `IsRuntime` is set to true before the first instantiation of the context class.

Groupings with Database Views

In Entity Framework Core 1.x and 2.0, you solve the `GroupBy` problem a little differently, by using the database views. Here you define a database view that does the grouping and returns the grouping result.

However, because these versions of Entity Framework Core do not support database views either, the same trick still applies to an entity class that represents the database view result. It is important that you then no longer have the option to create the table in the schema migration because there is already a database view with this name, which would lead to a naming conflict.

You can find details about using database views in Chapter 18 (Mapping of Database Views).

Brief Overview of the LINQ Syntax

This section presents the most important commands of LINQ with meaningful examples as a quick reference for you. All queries are executed on the object model of World Wide Wings version 2, as shown in Figure 8-4. For each of these classes, there is a corresponding table of the same name in the database.

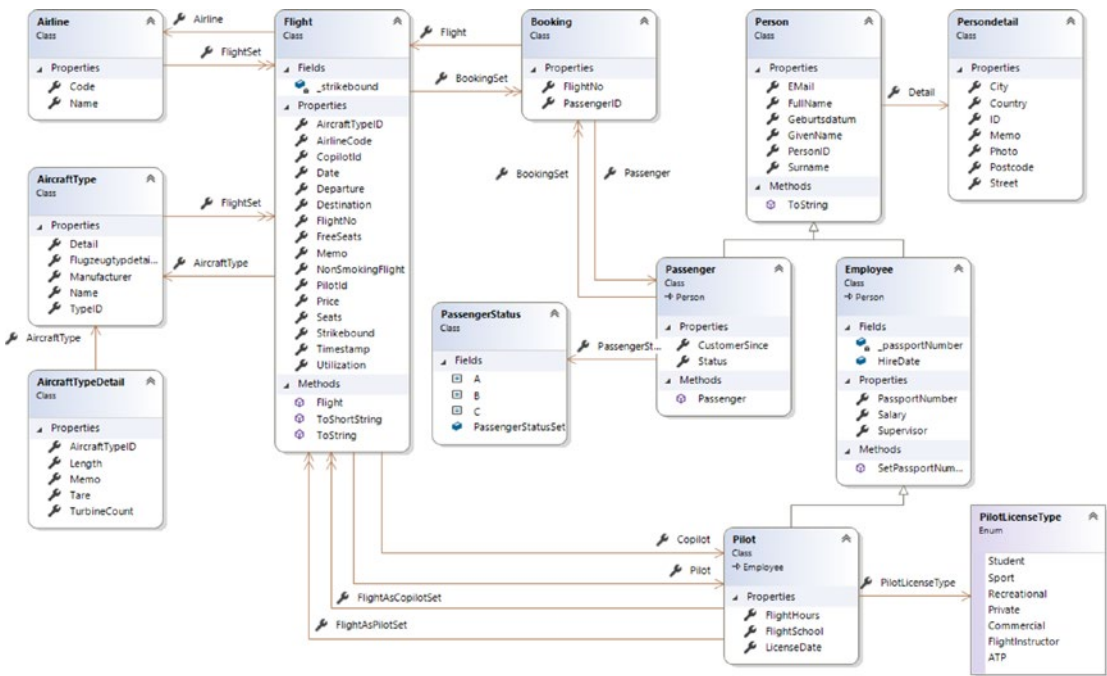

Figure 8-4. Object model for the following LINQ examples

All commands are based on the previous instantiation of the Entity Framework Core context.

```
WWingsContext ctx = new WWingsContext();
```

In addition to the LINQ commands, the alternative lambda notation and the resulting SQL command are displayed. The resulting SQL command is always the same for the LINQ and lambda notation; it is therefore reprinted here only once.

Tip For a more detailed sample collection of basic LINQ commands, see <https://code.msdn.microsoft.com/101-LINQ-Samples-3fb9811b>.

Simple SELECT Commands (All Records)

Entity Framework Core supports `ToArray()`, `ToList()`, `ToDictionary()`, and `ToLookup()` to convert a query to a set of objects.

```
CUI.Headline("All records as Array<T>");
Flight[] flightSet0a = (from f in ctx.FlightSet select f).ToArray();
Flight[] flightSet0b = ctx.FlightSet.ToArray();

CUI.Headline("All records as List<T>");
List<Flight> flightSet1a = (from f in ctx.FlightSet select f).ToList();
List<Flight> flightSet1b = ctx.FlightSet.ToList();

CUI.Headline("All records as Dictionary<T, T>");
Dictionary<int, Flight> flightSet2a = (from f in ctx.FlightSet
select f).ToDictionary(f=>f.FlightNo, f=>f);
Dictionary<int, Flight> flightSet2b = ctx.FlightSet.ToDictionary(f =>
f.FlightNo, f => f);

CUI.Headline("All records as ILookup<T, T>");
ILookup<int, Flight> flightSet2c = (from f in ctx.FlightSet
select f).ToLookup(f => f.FlightNo, f => f);
ILookup<int, Flight> flightSet2d = ctx.FlightSet.ToLookup(f =>
f.FlightNo, f => f);
```

In all eight cases, the following SQL statement is sent to the DBMS:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound],
[f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
```

Conditions (where)

```
List<Flight> flightSet3a = (from f in ctx.FlightSet
    where f.Departure == "Berlin" &&
    (f.Destination.StartsWith("Rome") ||
    f.Destination.Contains("Paris"))
    && f.FreeSeats > 0
    select f)
    .ToList();
```

```
List<Flight> flightSet3b = ctx.FlightSet.Where(f => f.Departure == "Berlin" &&
    (f.Destination.StartsWith("Rome") ||
    f.Destination.Contains("Paris"))
    && f.FreeSeats > 0)
    .ToList();
```

The resulting SQL in both cases is as follows:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound],
[f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
WHERE (([f].[Departure] = N'Berlin') AND (([f].[Destination] LIKE
N'Rome' + N'%' AND (LEFT([f].[Destination], LEN(N'Rome')) = N'Rome')) OR
(CHARINDEX(N'Paris', [f].[Destination]) > 0))) AND ([f].[FreeSeats] > 0)
```

Contains (in)

```

ist<string> Orte = new List<string>() { "Berlin", "Hamburg", "Köln",
"Berlin" };
List<Flight> flightSet4a = (from f in ctx.FlightSet
                           where Orte.Contains(f.Departure)
                           select f)
                           .ToList();
List<Flight> flightSet4b = ctx.FlightSet.Where(f => Orte.Contains
                                             (f.Departure)).ToList();

```

The resulting SQL in both cases is as follows:

```

SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode], [f].[CopilotId],
[f].[FlightDate], [f].[Departure], [f].[Destination], [f].[FreeSeats],
[f].[LastChange], [f].[Memo], [f].[NonSmokingFlight], [f].[PilotId],
[f].[Price], [f].[Seats], [f].[Strikebound], [f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
WHERE [f].[Departure] IN (N'Berlin', N'Hamburg', N'Köln', N'Berlin')

```

Sorts (orderby)

```

CUI.Headline("Sorting");
List<Flight> flightSet5a = (from f in ctx.FlightSet
                           where f.Departure == "Berlin"
                           orderby f.Date, f.Destination, f.FreeSeats
                           descending
                           select f).ToList();
List<Flight> flightSet5b = ctx.FlightSet.Where(f => f.Departure == "Berlin")
                                   .OrderBy(f => f.Date)
                                   .ThenBy(f => f.Destination)
                                   .ThenByDescending(f => f.FreeSeats)
                                   .ToList();

```

The resulting SQL in both cases is as follows:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound],
[f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
WHERE [f].[Departure] = N'Berlin'
ORDER BY [f].[FlightDate], [f].[Destination], [f].[FreeSeats] DESC
```

Paging (Skip() and Take())

```
CUI.Headline("Paging");
List<Flight> flightSet6a = (from f in ctx.FlightSet
    where f.Departure == "Berlin"
    orderby f.Date
    select f).Skip(100).Take(10).ToList();
List<Flight> flightSet6b = ctx.FlightSet.Where(f => f.Departure == "Berlin")
    .OrderBy(f => f.Date)
    .Skip(100).Take(10).ToList();
```

Entity Framework is aware of the database engine in use and will implement paging in the most efficient manner possible. For newer versions, support exists for row-limiting clauses. For older databases, more complex queries and Common Table Express (CTE) style syntax with the `rownumber()` function will be used. This is controlled automatically by Entity Framework Core.

```
exec sp_executesql N'SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].
[AirlineCode], [f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].
[Destination], [f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].
[NonSmokingFlight], [f].[PilotId], [f].[Price], [f].[Seats], [f].
[Strikebound], [f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
```

```

WHERE [f].[Departure] = N'Berlin'
ORDER BY [f].[FlightDate]

    where f.Departure == "Berlin"
    orderby f.Date
    select new Flight()
    {
        FlightNo = f.FlightNo,
        Date = f.Date,
        Departure = f.Departure,
        Destination = f.Destination,
        FreeSeats = f.FreeSeats,
        Timestamp = f.Timestamp
    }).ToList();

```

```

List<Flight> flightSet7b = ctx.FlightSet
    .Where(f => f.Departure == "Berlin")
    .OrderBy(f => f.Date)
    .Select(f => new Flight()
    {
        FlightNo = f.FlightNo,
        Date = f.Date,
        Departure = f.Departure,
        Destination = f.Destination,
        FreeSeats = f.FreeSeats,
        Timestamp = f.Timestamp
    }).ToList();

```

The resulting SQL in both cases is as follows:

```
SELECT [f].[FlightNo], [f].[FlightDate] AS [Date], [f].[Departure],
[f].[Destination], [f].[FreeSeats], [f].[Timestamp]
FROM [Flight] AS [f]
WHERE [f].[Departure] = N'Berlin'
ORDER BY [Date]
```

Aggregate Functions (Count(), Min(), Max(), Average(), Sum())

```
int agg1a = (from f in ctx.FlightSet select f).Count();
int? agg2a = (from f in ctx.FlightSet select f).Sum(f => f.FreeSeats);
int? agg3a = (from f in ctx.FlightSet select f).Min(f => f.FreeSeats);
int? agg4a = (from f in ctx.FlightSet select f).Max(f => f.FreeSeats);
double? agg5a = (from f in ctx.FlightSet select f).Average(f => f.FreeSeats);

int agg1b = ctx.FlightSet.Count();
int? agg2b = ctx.FlightSet.Sum(f => f.FreeSeats);
int? agg3b = ctx.FlightSet.Min(f => f.FreeSeats);
int? agg4b = ctx.FlightSet.Max(f => f.FreeSeats);
double? agg5b = ctx.FlightSet.Average(f => f.FreeSeats);
```

The resulting SQL is as follows:

```
SELECT COUNT (*)
FROM [Flight] AS [f]

SELECT SUM([f].[FreeSeats])
FROM [Flight] AS [f]

SELECT MIN([f].[FreeSeats])
FROM [Flight] AS [f]
```

```
SELECT MAX([f].[FreeSeats])
FROM [Flight] AS [f]
```

```
SELECT AVG(CAST([f].[FreeSeats] AS float))

```

Groupings (GroupBy)

```
var group1a = (from f in ctx.FlightSet
               group f by f.Departure into g
               select new { City = g.Key, Count = g.Count(),
                           Sum = g.Sum(f => f.FreeSeats), Avg = g.Average(f =>
                           f.FreeSeats) })
               .ToList();

var group1b = ctx.FlightSet
               .GroupBy(f => f.Departure)
               .Select(g => new
               {
                   City = g.Key,
                   Count = g.Count(),
                   Sum = g.Sum(f => f.FreeSeats),
                   Avg = g.Average(f => f.FreeSeats)
               }).ToList();
```

Note LINQ groupings are still running in RAM in version 2.0 of Entity Framework Core. In the upcoming version 2.1 (see [Appendix C](#)) these should be translated correctly in SQL. Therefore, groupings should be formulated directly in SQL in versions 1.0 to 2.0 (see [Chapter 15](#)).

The database management system currently receives the following command:

```
SELECT [f0].[FlightNo], [f0].[AircraftTypeID], [f0].[AirlineCode],
[f0].[CopilotId], [f0].[FlightDate], [f0].[Departure], [f0].[Destination],
[f0].[FreeSeats], [f0].[LastChange], [f0].[Memo], [f0].[NonSmokingFlight],
[f0].[PilotId], [f0].[Price], [f0].[Seats], [f0].[Strikebound],
[f0].[Timestamp], [f0].[Utilization]
FROM [Flight] AS [f0]
ORDER BY [f0].[Departure]
```

Single Objects (SingleOrDefault(), FirstOrDefault())

```
Flight flight1a = (from f in ctx.FlightSet select f).SingleOrDefault(f
=> f.FlightNo == 101);
```

```
Flight flight1b = ctx.FlightSet.SingleOrDefault(f => f.FlightNo == 101);
```

The resulting SQL in both cases is as follows:

```
SELECT TOP(2) [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound],
[f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
WHERE [f].[FlightNo] = 101
```

```
Flight flight2a = (from f in ctx.FlightSet
    where f.FreeSeats > 0
    orderby f.Date
    select f).FirstOrDefault();
```

```
Flight flight2b = ctx.FlightSet
    .Where(f => f.FreeSeats > 0)
    .OrderBy(f => f.Date)
    .FirstOrDefault();
```

The resulting SQL in both cases is as follows:

```
SELECT TOP(1) [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound],
[f].[Timestamp], [f].[Utilization]
FROM [Flight] AS [f]
WHERE [f].[FreeSeats] > 0
ORDER BY [f].[FlightDate]
```

Related Objects (Include())

```
List<Flight> flightDetailsSet1a = (from f in ctx.FlightSet
    .Include(f => f.Pilot)
    .Include(f => f.BookingSet).ThenInclude
    (b => b.Passenger)
    where f.Departure == "Berlin"
    orderby f.Date
    select f)
    .ToList();
```

```
List<Flight> flightDetailsSet1b = ctx.FlightSet
    .Include(f => f.Pilot)
    .Include(f => f.BookingSet).ThenInclude
    (b => b.Passenger)
    .Where(f => f.Departure == "Berlin")
    .OrderBy(f => f.Date)
    .ToList();
```

Note Entity Framework Core executes two SQL statements directly after each other to avoid joins.

The resulting SQL in both cases is as follows:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],

Inner Join

Explicit join operations are not necessary if there are navigation relationships (see “Related Objects (Include())”). In the following example, to construct a case without a navigation relationship, all flights that have the same ID as a pilot are searched:

```
var flightDetailsSet2a = (from f in ctx.FlightSet
    join p in ctx.PilotSet
    on f.FlightNo equals p.PersonID
    select new { Nr = f.FlightNo, flight = f,
        Pilot = p })
    .ToList();

var flightDetailsSet2b = ctx.FlightSet
    .Join(ctx.PilotSet, f => f.FlightNo, p =>
        p.PersonID,
    (f, p) => new { Nr = f.FlightNo, flight = f,
        Pilot = p })
    .ToList();
```

The resulting SQL in both cases is as follows:

```
SELECT [f].[FlightNo] AS [Nr], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound], [f].[Timestamp],
[f].[Utilization], [p].[PersonID], [p].[Birthday], [p].[DetailID],
[p].[Discriminator], [p].[EMail], [p].[GivenName], [p].[PassportNumber],
[p].[Salary], [p].[SupervisorPersonID], [p].[Surname], [p].[FlightHours],
[p].[FlightSchool], [p].[LicenseDate], [p].[PilotLicenseType]
FROM [Flight] AS [f]
INNER JOIN [Employee] AS [p] ON [f].[FlightNo] = [p].[PersonID]
WHERE [p].[Discriminator] = N'Pilot'
```

Cross Join (Cartesian Product)

```
var flightDetailsSet3a = (from f in ctx.FlightSet
                        from b in ctx.BookingSet
                        from p in ctx.PassengerSet
                        where f.FlightNo == b.FlightNo && b.PassengerID
                               == p.PersonID && f.Departure == "Rome"
                        select new { flight = f, passengers = p })
                        .ToList();
```

```
var flightDetailsSet3b = ctx.FlightSet
    .SelectMany(f => ctx.BookingSet, (f, b) => new { f = f, b = b})
    .SelectMany(z => ctx.PassengerSet, (x, p) => new {x = x, p = p})
    .Where(y => ((y.x.f.FlightNo == y.x.b.FlightNo) &&
                (y.x.b.PassengerID == y.p.PersonID)) &&
            y.x.f.Departure == "Rome")
    .Select(z => new {flight = z.x.f, passengers = z.p } )
```

The resulting SQL in both cases is as follows:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],

CROSS JOIN [Booking] AS [b]
CROSS JOIN [Passenger] AS [p]
WHERE (([f].[FlightNo] = [b].[FlightNo]) AND ([b].[PassengerID] = [p].
[PersonID])) AND ([f].[Departure] = N'Rome')
```

```

var flightDetailsSet4a = (from b in ctx.BookingSet
    join f in ctx.FlightSet on b.FlightNo equals
    f.FlightNo
    join p in ctx.PassengerSet on b.PassengerID
    equals p.PersonID
    where f.Departure == "Berlin"
    group b by b.Flight into g
    select new { flight = g.Key, passengers =
    g.Select(x => x.Passenger) })
    .ToList();

var flightDetailsSet4b = ctx.BookingSet
    .Join(ctx.FlightSet, b => b.FlightNo, f =>
    f.FlightNo, (b, f) => new { b = b, f = f })
    .Join(ctx.PassengerSet, x => x.b.PassengerID,
    p => p.PersonID, (x, p) => new { x = x, p = p })

Subqueries (Subselects)

Note Both Entity Framework and Entity Framework Core subqueries are sent individually for each result data record of the main database management system query. This can lead to significant performance problems!

```
List<Flight> flightDetailsSet5a = (from f in ctx.FlightSet
    where f.FlightNo == 101

CHAPTER 9

Object Relationships and Loading Strategies

An object model describes the relationships between instances of different classes (for example, between `Flight` and `Pilot`) or other instances of the same class (see, for example, the `Supervisor` property in the `Employees` class). The question of when and how relational objects are loaded is crucial not only to the software developer but also to the performance of the application.

Overview of Loading Strategies

The classic Entity Framework supports four connected object loading strategies: lazy loading automatically, explicit loading, eager loading, and preloading versus relationship fixup (see Figure 9-1). In Entity Framework Core 1.0, there was only eager loading and preloading. Entity Framework Core 1.1 introduced explicit loading. Lazy loading does not yet exist in Entity Framework Core 2.0, but it will be introduced in version 2.1 (see Appendix C).

Figure 9-1. Loading strategies in the Entity Framework 1.0 to 6.x. Entity Framework Core currently supports only three strategies; lazy loading is missing.

Seeing the Default Behavior

By default, Entity Framework Core limits itself to loading the actual requested objects in a query and does not automatically load linked objects. The following LINQ query loads only flight objects. Objects of type Pilot, Booking, Airline, and AircraftType that are associated with the flights are not automatically loaded.

```
List<Flight> list = (from x in ctx.FlightSet
                    where x.Departure == "Berlin" &&
                          x.FreeSeats > 0
                    orderby x.Date, x.Departure
                    select x).ToList();
```

Loading linked records (called *eager loading*) is not a good idea for the default setting because in this case data would be loaded that is not needed later. In addition, the associated records have relationships; for example, bookings are related to passengers. Passengers also have bookings on other flights. If you recursively loaded all these related records, then in the example of the object model in Figure 9-2, you would almost certainly load almost all records into RAM because many passengers are connected to other passengers via shared flights. So Eager Loading would not be good as a default setting.

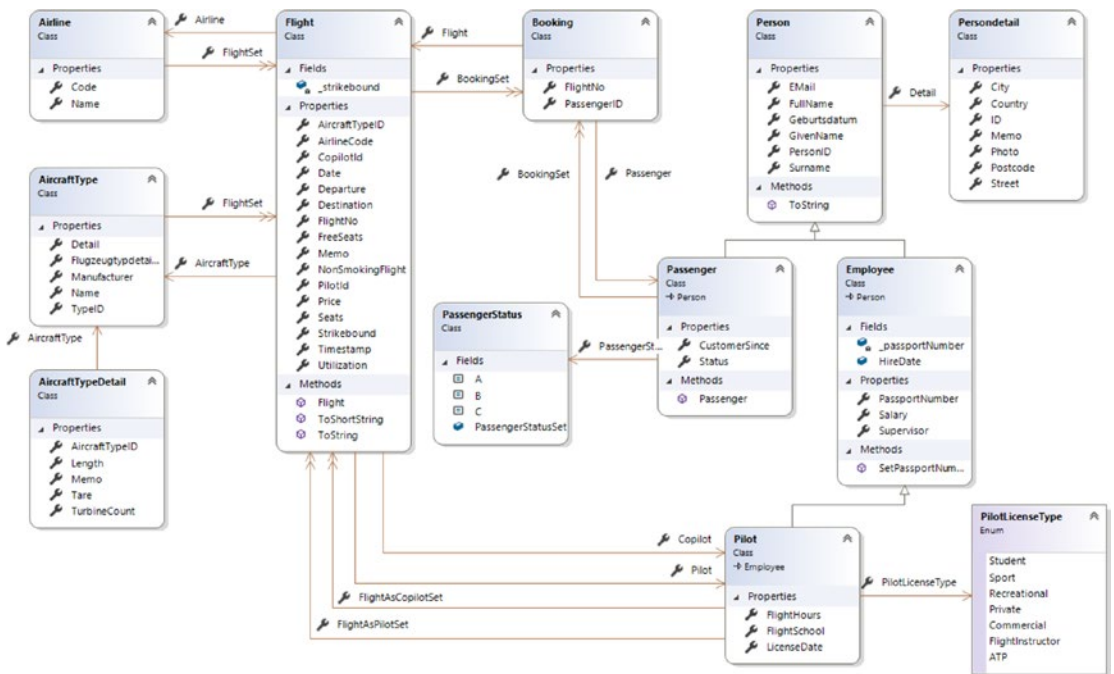

Figure 9-2. Object model for the management of flights and related objects

Even if you load a single object using `Find()`, no linked records are loaded (see Listing 9-1). Figure 9-3 shows the output.

Listing 9-1. Unsuccessful Attempt to Access Connected Objects in Entity Framework Core

```
public static void Demo_LazyLoading()
{
    CUI.MainHeadline(nameof(Demo_LazyLoading));

    using (var ctx = new WWingsContext())
    {
        // Load only the flight
        var f = ctx.FlightSet.SingleOrDefault(x => x.FlightNo == 101);

        Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
        {f.Destination} has {f.FreeSeats} free seats!");
        if (f.Pilot != null) Console.WriteLine($"Pilot: {f.Pilot.Surname} has
        {f.Pilot.FlightAsPilotSet.Count} flights as pilot!");
    }
}
```

```

else Console.WriteLine("No pilot assigned!");
if (f.Copilot != null) Console.WriteLine($"Copilot: {f.Copilot.Surname}
has {f.Copilot.FlightAsCopilotSet.Count} flights as copilot!");
else Console.WriteLine("No copilot assigned!");

if (f.BookingSet is null) CUI.PrintError("No bookings :-(");
else
{
    Console.WriteLine("Number of passengers on this flight: " +
    f.BookingSet.Count);

    Console.WriteLine("Passengers on this flight:");
    foreach (var b in f.BookingSet)
    {
        Console.WriteLine("- Passenger #{0}: {1} {2}", b.Passenger.PersonID,
        b.Passenger.GivenName, b.Passenger.Surname);
    }
}
}
}
}

```

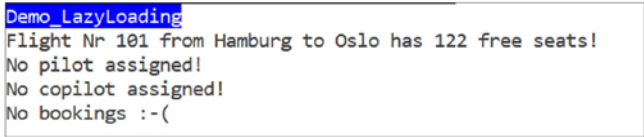

Figure 9-3. Output of Listing 9-1

No Lazy Loading Yet

The previous example would load only the explicitly requested flight in the classic Entity Framework in the first step, but then in the following program code lines the pilot and copilot information (with their other flights) as well as the bookings with the passenger data would be loaded via lazy loading. Entity Framework would send a large number of SELECT commands to the database one after the other. How many commands are used depends on the number of passengers on this flight.

In the case of Entity Framework Core, however, Listing 9-1 does not load the pilot, copilot, or passengers. Microsoft has not yet implemented lazy loading for Entity Framework Core.

Preview Basic support for lazy loading is planned for Entity Framework Core version 2.1; see Appendix C.

Lazy loading involves a special implementation challenge because the OR mapper must catch any access to any object reference in order to reload the connected objects as needed. This interception is done by using specific classes for individual references and sets of classes.

In the classic Entity Framework, you can realize lazy loading by using certain lazy loading-capable classes and mostly invisible runtime proxy objects. Both will be available in Entity Framework Core 2.1.

When you do not need to preload linked records in Entity Framework Core, it would be great to have lazy loading. A typical example is a master-detail view on the screen. If there are many master records, it would waste time to load the detail records for each master record in advance. Rather, you will request the detail records for the master record that the user has just clicked. In the classic Entity Framework Core you could realize the master-detail display via lazy loading without further program code when clicking the master data record. In Entity Framework Core 1.x and 2.0, unfortunately you have to intercept the click and explicitly load the detail data records.

Explicit Loading

In Entity Framework Core version 1.1, which was released in 2016, Microsoft retrofitted the explicit reloading feature. You use the methods `Reference()` (for single objects), `Collection()` (for sets), and then `Load()` to specify that related objects should be loaded.

However, these methods are not available on the entity object itself but are part of the class `EntityEntry<T>`, which is obtained by the method `Entry()` in the class `DbContext` (see Listing 9-2). With `IsLoaded()` you can check whether the object has already been loaded. `IsLoaded()` returns true even if there was no matching object in the database. It therefore does not indicate whether a navigation relationship has a

counter object; it indicates whether in the current context instance a suitable object has ever been loaded for the instance. So if in Listing 9-2 Flight 101 already has an assigned pilot (Mrs. Merkel) but no copilot, this leads to the output in Figure 9-4.

Important It is important to understand that every execution of `Load()` will result in an explicit submission of a SQL command to the database management system.

Listing 9-2. With Explicit Reloading, Entity Framework Core Sends a Lot of Individual SQL Commands to the Database

```
public static void Demo_ExplizitLoading_v11()
{
    CUI.MainHeadline(nameof(Demo_ExplizitLoading_v11));

    using (var ctx = new WWWingsContext())
    {
        // Load only the flight
        var f = ctx.FlightSet
            .SingleOrDefault(x => x.FlightNo == 101);

        Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
            {f.Destination} has {f.FreeSeats} free seats!");

        // Now load the pilot and copilot
        if (!ctx.Entry(f).Reference(x => x.Pilot).IsLoaded)
            ctx.Entry(f).Reference(x => x.Pilot).Load();
        if (!ctx.Entry(f).Reference(x => x.Copilot).IsLoaded)

Eager Loading

Like the classic Entity Framework, Entity Framework Core supports eager loading. However, the syntax has changed a little bit.

In the classic Entity Framework versions 1.0 and 4.0 (there were never versions 2.0 and 3.0), you could specify a string with `Include()` only with the name of a navigation property; the string was not checked by the compiler. From the third version on (version number 4.1), it was then possible to specify a robust lambda expression for the navigation properties instead of the character string. For multilevel loading paths, you had to nest the lambda expressions and also use the `Select()` method.

In Entity Framework Core, there are still strings and lambda expressions, but the syntax for the lambda expressions has been slightly modified. Instead of using `Select()`, the new extension method `ThenInclude()` can be for nested relations, like `ThenOrderBy()` does for sorting across multiple columns. Listing 9-3 shows the eager loading of a flight with the following linked data:

- The bookings and passenger information for every booking: `Include(b => b.Bookings).ThenInclude(p => p.Passenger)`
- The pilot and the pilot's other flights as a pilot: `Include(b => b.Pilot).ThenInclude(p => p.FlightAsPilotSet)`
- The copilot and the copilot's other flights as copilot: `Include(b => b.Co-Pilot).ThenInclude(p => p.FlightAsCopilotSet)`

Listing 9-3. With Eager Loading You Can Use the Connected Objects in Entity Framework Core

```
public static void Demo_EagerLoading()
{
    CUI.MainHeadline(nameof(Demo_EagerLoading));

    using (var ctx = new WWWingsContext())
    {
        var flightNo = 101;

        // Load the flight and some connected objects via Eager Loading
        var f = ctx.FlightSet
            .Include(b => b.BookingSet).ThenInclude(p => p.Passenger)
            .Include(b => b.Pilot).ThenInclude(p => p.FlightAsPilotSet)
            .Include(b => b.Copilot).ThenInclude(p => p.FlightAsCopilotSet)
            .SingleOrDefault(x => x.FlightNo == flightNo);

        Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
            {f.Destination} has {f.FreeSeats} free seats!");
        if (f.Pilot != null) Console.WriteLine($"Pilot: {f.Pilot.Surname} has
            {f.Pilot.FlightAsPilotSet.Count} flights as a pilot!");
        else Console.WriteLine("No pilot assigned!");
    }
}
```

```

if (f.Copilot != null) Console.WriteLine($"Copilot: {f.Copilot.Surname}
has {f.Copilot.FlightAsCopilotSet.Count} flights as a Copilot!");
else Console.WriteLine("No Copilot assigned!");

Console.WriteLine("Number of passengers on this flight: " +
f.BookingSet.Count);
Console.WriteLine("Passengers on this flight:");
foreach (var b in f.BookingSet)
{
    Console.WriteLine("- Passenger #{0}: {1} {2}", b.Passenger.PersonID,
    b.Passenger.GivenName, b.Passenger.Surname);
}
}
}

```

Figure 9-5 shows the output. Both the Pilot and Copilot information and the list of booked passengers are available.

Attention The compiler checks with `Include()` and `ThenInclude()` only if the class has an appropriate property or field. It does not check whether this is also a navigation property to another entity class. If it is not a navigation property, the following error will not occur until runtime: “The property `xy` is not a navigation property of entity type `'ab'`. The `'Include(string)'` method can only be used with a `'.'` separated list of navigation property names.”

Figure 9-5. Output of Listing 9-3

However, there is another crucial difference to the classic Entity Framework. While Entity Framework versions 1.0 to 6.x sent only a single, large SELECT command to the database management system, Entity Framework Core decides to split the query into four steps (see Figure 9-6), as shown here:

1. First, the flight is loaded with join on the employee table, which also contains the pilot information (a table via hierarchy mapping).
2. In the second step, Entity Framework Core loads the other flights of the copilot.
3. In the third step, Entity Framework Core loads the other flights of the pilot.
4. In the last step, Entity Framework Core loads the passenger details.

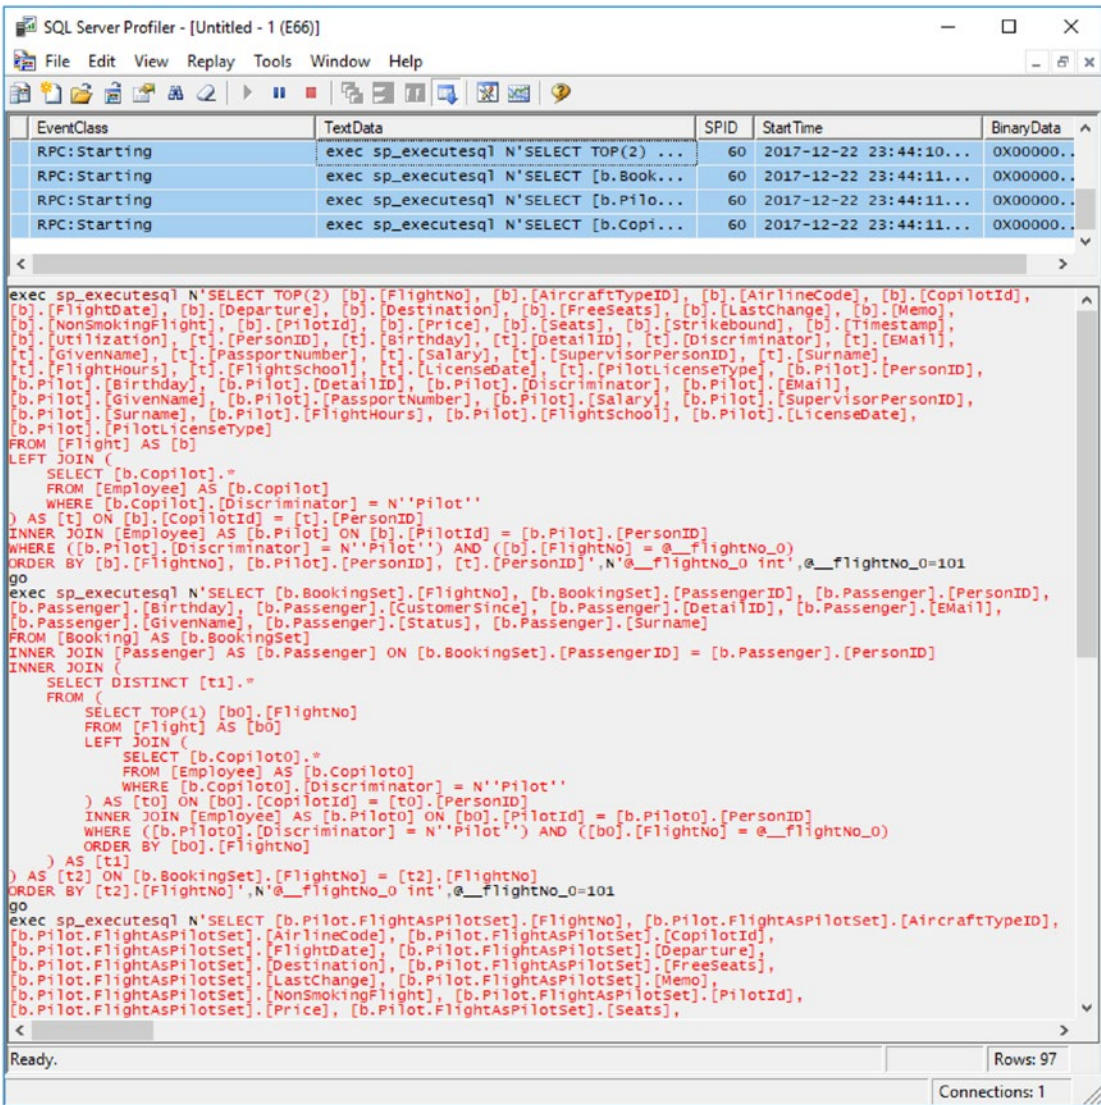

Figure 9-6. SQL Server Profiler shows the four SQL commands that the eager loading example triggers in Entity Framework Core

This strategy can be faster than executing a large SELECT command that returns a large set of results that duplicate records and that the OR mapper must then disassemble and clean up the duplicates. The strategy of separate SELECT commands from Entity Framework Core can also be slower because each round-trip of the database management system takes time. In the classic Entity Framework, you had

the choice of how large you wanted to cut an eager loading instruction and where you wanted to load it. In Entity Framework Core, you lose control over the number of round-trips to the database management system.

Relationship Fixup

Relationship fixup is a mechanism of Entity Framework Core that already existed in the classic Entity Framework. The relationship fixup does the following between two objects in RAM:

- *Case 1:* When two objects from the database that are related through a foreign key in the database are loaded independently, Entity Framework Core establishes the relationship between the two objects through their defined navigation properties.
- *Case 2:* When an object is created in RAM or modified to be related to another object in RAM by foreign key, Entity Framework Core establishes the relationship between the two through their defined navigation properties.
- *Case 3a:* When an object in RAM is connected to another object in RAM by navigation and there is also a bidirectional relationship with navigation in the other direction, Entity Framework Core also updates the other navigation property.
- *Case 3b:* When an object in RAM is connected to another object in RAM using a foreign key property, Entity Framework Core updates the other navigation properties on the two objects.

Note In cases 3a and 3b, the relationship fixup will not be executed until `ctx.ChangeTracker.DetectChanges()` is called. Unlike the classic Entity Framework, Entity Framework Core no longer automatically calls the `DetectChanges()` call on almost all API functions, which was a performance problem. Entity Framework Core runs `DetectChanges()` only on `ctx.SaveChanges()`, `ctx.Entry()`, and `ctx.Entries()` as well as the method `DbSet<T>().Add()`.

Example for Case 1

In Listing 9-4, a flight is first loaded into the `flight` variable. Then for the flight, the `PilotId` value of the `Pilot` object is printed. However, the `Pilot` object is not yet available at this point because it was not loaded with the flight, and Entity Framework Core does not currently support lazy loading.

Then the `Pilot` object for the `Flight` object is individually loaded into the variable `pilot` using the ID. The `Pilot` object and the `Flight` object would normally now be detached from each other. However, the output of `flight.Pilot` shows now that Entity Framework Core has established the relationship via relationship fixup. Likewise, the backward relationship has been recorded; `pilot.FlightAsPilotSet` shows the previously loaded flight.

Note Further flights of this pilot, which may be included in the database, do not appear here because they were not loaded.

Listing 9-4. Relationship Fixup in Case 1

```
public static void RelationshipFixUp_Case1()
{
    CUI.MainHeadline(nameof(RelationshipFixUp_Case1));

    using (var ctx = new WWingsContext())
    {
        int flightNr = 101;

        // 1. Just load the flight
        var flight = ctx.FlightSet.Find(flightNr);

        // 2. Output of the pilot of the Flight
        Console.WriteLine(flight.PilotId + ": " + (flight.Pilot != null ?
            flight.Pilot.ToString() : "Pilot not loaded!"));

        // 3. Load the pilot separately
        var pilot = ctx.PilotSet.Find(flight.PilotId);
```

```
// 4. Output of the Pilot of the Flight: Pilot now available
Console.WriteLine(flight.PilotId + ": " + (flight.Pilot != null ?
flight.Pilot.ToString() : "Pilot not loaded!"));

// 5. Output the list of flights of this pilot
foreach (var f in pilot.FlightAsPilotSet)
{
    Console.WriteLine(f);
}
}
}
```

As with the classic Entity Framework, Entity Framework Core also assigns an instance of a collection type to the navigation property as part of the relationship fixup if the navigation property is null.

This automation exists regardless of whether you used an interface or a class as the type when declaring the navigation property. If a collection class is used, Entity Framework Core instantiates the collection class. In the case of the declaration of the navigation property with an interface type, Entity Framework Core chooses an appropriate collection class. With `ICollection<T>`, the class `HashSet<T>` is selected. With `IList<T>`, the class `List<T>` is selected.

Example for Case 2

In Listing 9-5 for case 2, a pilot is loaded. At first, there are no flights from the pilot in RAM. Then a new flight is created, and this flight is assigned the `PilotID` of the loaded Pilot. When calling `ctx.FlightSet.Add()`, Entity Framework Core performs a relationship fixup so that the navigation property called `FlightAsPilotSet` of the Pilot object and the navigation property called `flying.Pilot` are filled.

Listing 9-5. Relationship Fixup in Case 2

```
public static void RelationshipFixUp_Case2()
{
    CUI.MainHeadline(nameof(RelationshipFixUp_Case2));
    void PrintPilot(Pilot pilot)
    {
```

```

CUI.PrintSuccess(pilot.ToString());
if (pilot.FlightAsPilotSet != null)
{
    Console.WriteLine("Flights of this pilot:");
    foreach (var f in pilot.FlightAsPilotSet)
    {
        Console.WriteLine(f);
    }
}
else
{
    CUI.PrintWarning("No flights!");
}
}

using (var ctx = new WWingsContext())
{
    // Load a Pilot
    var pilot = ctx.PilotSet.FirstOrDefault();

    // Print pilot and his flights
    PrintPilot(pilot);
    // Create a new flight for this pilot
    var flight = new Flight();
    flight.Departure = "Berlin";
    flight.Destination = "Berlin";
    flight.Date = DateTime.Now.AddDays(10);
    flight.FlightNo = ctx.FlightSet.Max(x => x.FlightNo) + 1;
    flight.PilotId = pilot.PersonID;
    ctx.FlightSet.Add(flight);

    // Print pilot and his flights
    PrintPilot(pilot);
    // Print pilot of the new flight
    Console.WriteLine(flight.Pilot);
}
}

```

Example for Case 3

Table 9-1 optionally includes cases 3a and 3b. 'In the example, a flight is loaded first. Then any pilot is loaded and assigned to the loaded flight by PilotID (case 3a) or a navigation property (case 3b). However, Entity Framework Core does not automatically run a relationship fixup operation here. In case 3a, `flight.Pilot` and `pilot.FlightsAsPilotSet` are empty. This changes only with the call `ctx.ChangeTracker.DetectChanges()`. In case 3b, `Flight.Pilot` is filled manually, and `Pilot.FlightsAsPilotSet` becomes filled after `ctx.ChangeTracker.DetectChanges()` is called. Listing 9-6 shows the relationship fixup.

Table 9-1. Comparing the Behavior of Cases 3a and 3b

	Case 3a	Case 3b

using (var ctx = new WWingsContext())
{
    int flightNr = 101;

    CUI.Headline("Load flight");

    var flight = ctx.FlightSet.Find(flightNr);
    Console.WriteLine(flight);

    flight.Pilot = pilot; // Case 3a
    //flight.PilotId = pilot.PersonID; // Case 3b

    // Determine which relationships exist
    PrintflightPilot(flight, pilot);

    // Here you have to trigger the Relationship fixup yourself
    CUI.Headline("DetectChanges...");
    ctx.ChangeTracker.DetectChanges();
}

```

```
// Determine which relationships exist
PrintflightPilot(flight, pilot);
}
}
```

Preloading with Relationship Fixup

Like the classic Entity Framework, Entity Framework Core supports another loading strategy: preloading in conjunction with a relationship fixup operation in RAM. You explicitly send out several LINQ commands for the connected objects, and the OR mapper puts the newly added objects together after their materialization with those objects that are already in RAM. After the following statements, Flight 101 as well the Pilot and Copilot objects of Flight 101 can be found in RAM when accessing `flight.Pilot` and `flight.Copilot`:

```
var Flight = ctx.FlightSet.SingleOrDefault(x => x.FlightNo == 101);
ctx.PilotSet.Where(p => p.FlightAsPilotSet.Any(x => x.FlightNo == 101) ||
p.FlightAsCopilotSet.Any(x => x.FlightNo == 101)).ToList();
```

When loading the two pilots Entity Framework Core recognizes that there is already a Flight object in RAM, that needs these two pilots as Pilot or Copilot. It then compiles the Flight object with the two Pilot objects in RAM (via relationship fixup, as covered earlier).

While the Pilot and Copilot objects for Flight 101 were specifically loaded in the previous two lines, you can also use the relationship fixup for caching optimization. Listing 9-7 shows that all pilots and some flights are loaded. For each loaded flight, the Pilot and Copilot objects are available. Of course, as with caching, you will need a bit more RAM here because you will also load Pilot objects that are never needed. In addition, you must be aware that you can have a timeliness problem because the dependent data is on the same level as the main data. But that's always the way caching behaves. However, you can save a round-trip of the database management system and improve its speed.

Listing 9-7 also shows that when loading the information for the two pilots you can avoid the join operator in Entity Framework Core by using the navigation properties and the `Any()` method. `Any()` checks whether there is at least one record that meets or does not meet a condition. In the previous case, it is enough that the Pilot object was assigned once as a Pilot or Copilot for the Flight you are looking for. In other cases, you can use the LINQ `All()` method if you want to address a set of records that all meet or fail a condition.

Note It is noteworthy that neither the previous loading of the two pilots nor the loading of all pilots in the next example assigns the result of the LINQ query to a variable. In fact, this is not necessary because Entity Framework Core (like the classic Entity Framework) contains in its first-level cache a reference in RAM to all objects that have ever been loaded into a specific instance of the context class. The relationship fixup works therefore also without storage in a variable. The assignment to a variable (`List<Pilot> allPilot = ctx.PilotSet.ToList()`) is of course not harmful but can be useful if you need a list of all pilots in the program flow. It should also be noted that relationship fixup does not work across all instances of the context. A second-level cache required for this purpose is not yet available in Entity Framework Core but is available as an additional component (see Chapters 17 and 20).

Listing 9-7. Caching of All Pilots

```
public static void Demo_PreLoadingPilotenCaching()
{
    CUI.MainHeadline(nameof(Demo_PreLoadingPilotenCaching));

    using (var ctx = new WWingsContext())
    {
        // 1. Load ALL pilots
        ctx.PilotSet.ToList();

        // 2. Load only several flights. The Pilot and Copilot object will then
        // be available for every flight!
        var FlightNrListe = new List<int>() { 101, 117, 119, 118 };
        foreach (var FlightNr in FlightNrListe)
        {
            var f = ctx.FlightSet
                .SingleOrDefault(x => x.FlightNo == FlightNr);

            Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
                {f.Destination} has {f.FreeSeats} free seats!");
        }
    }
}
```

```

if (f.Pilot != null) Console.WriteLine($"Pilot: {f.Pilot.Surname} has
{f.Pilot.FlightAsPilotSet.Count} flights as pilot!");
else Console.WriteLine("No pilot assigned!");
if (f.Copilot != null)
    Console.WriteLine($"Copilot: {f.Copilot.Surname} has {f.Copilot.
    FlightAsCopilotSet.Count} flights as copilot!");
else Console.WriteLine("No copilot assigned!");
}
}
}

```

Listing 9-8 shows the redesign of the original task of loading all pilot and passenger data into one flight, this time with preloading and relationship fixup instead of eager loading. Here flights, pilots, pilots' other flights, bookings, and passengers are loaded individually. So, the code sends five SELECT commands to the database management system (as opposed to the four SELECT commands that the solution sends with eager loading) but avoids some joins. Figure 9-7 shows the output.

Figure 9-7. SQL Server Profiler shows the five SQL commands in Listing 9-8

The relationship fixup trick has a positive effect if one or more of the following conditions are true:

- The result set of the main data is large, and the amount of dependent data is small.
- There are several different dependent data sets that can be preloaded.
- The preloaded objects are rarely variable (parent) data.
- You run multiple queries in a single context instance that have the same dependent data.

In the speed comparison, even in the scenario discussed here of loading a flight with pilots and passengers, it already shows a speed advantage for the preloading. The measurement shown in Figure 9-8 was taken to avoid 51-cycle measurement deviations, with the first pass (a cold start for the Entity Framework Core context and possibly also the database) not taken into account. In addition, all screen editions were expanded.

Of course, you can mix eager loading and preloading as you want. In practice, however, you have to find the optimum ratio for each individual case.

CHAPTER 10

Inserting, Deleting, and Modifying Records

In many places, the API and approach to inserting, deleting, and modifying records in Entity Framework Core have remained the same compared to the classic Entity Framework. But there are a few changes in the details, especially when merging multiple changes into a batch round-trip to the database management system.

You can write to the entity objects loaded from the database at any time. You do not have to “announce” them before the write operation or “sign them up” afterward. The context class of Entity Framework Core (more precisely, the Change Tracker built into it) tracks all changes to the objects in the standard system (called *change tracking*). However, the change tracking does not take place if the objects were loaded in the no-tracking mode (e.g. with `AsNoTracking()`), which is specially to be set, or the context instance was destroyed.

Saving with `SaveChanges()`

Listing 10-1 shows how to load a `Flight` object with `SingleOrDefault()`. In this `Flight` object, the number of free seats is reduced by two places. In addition, some text is written to the `memo` attribute of the `Flight` object.

The `SaveChanges()` method is used to store changes in the database. It is implemented in the base class `DbContext` and is inherited from there to the context class that you generate during reverse engineering, or it creates itself during forward engineering.

The `SaveChanges()` method saves all changes (new records, changed records, and deleted records) since loading or the last `SaveChanges()` method on all objects loaded in the current context instance. `SaveChanges()` sends an `INSERT`, `UPDATE`, or `DELETE` command for each saved change to the database.

Note Even in Entity Framework Core, it is unfortunately not possible to save only individual changes when several changes exist.

Of course, `SaveChanges()` saves only the changed objects and only the changed attributes for the changed objects. This is proven by the SQL output shown in Figure 10-1. In the SET part of the UPDATE command, only `FreeSeats` and `Memo` show up. You can also see that the UPDATE command returns the number of changed records. The caller receives this number from `SaveChanges()` as the return value.

The UPDATE command contains only the `FlightNo` value in the WHERE condition. In other words, there is no check here to check whether the object has been changed by another user or background process. The standard for Entity Framework Core is the principle that “the last one wins.” However, you can change this default behavior (see Chapter 17). The caller gets a runtime error of type `DbConcurrencyException` only if the data record to be changed in the database has been deleted. Then, the UPDATE command returns from the database management system that zero records were affected by the change, which Entity Framework Core takes as an indication of a change conflict.

Listing 10-1 prints some information about the `Flight` object three times (before the change, after the change, and after saving). In addition to `FlightNo` (the primary key) and the `Flight` route (the departure and destination), the number of `FreeSeats` and the current state of the object are printed. The state cannot be determined by the entity object itself, but only by the `Entry()` method of the context class with `ctx.Entry(obj).State`.

Listing 10-1. One changed Property of Flights is Saved

```
public static void ChangeFlightOneProperty()
{
    CUI.MainHeadline(nameof(ChangeFlightOneProperty));

    int FlightNr = 101;
    using (WWWingsContext ctx = new WWWingsContext())
    {
        // Load flight
        var f = ctx.FlightSet.Find(FlightNr);

        Console.WriteLine($"Before changes: Flight #{f.FlightNo}:
        {f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State of
        the flight object: " + ctx.Entry(f).State);
```

```

// Change object in RAM
f.FreeSeats -= 2;

Console.WriteLine($"After changes: Flight #{f.FlightNo}:
{f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State
of the flight object: " + ctx.Entry(f).State);

// Persist changes
try
{
    var count = ctx.SaveChanges();
    if (count == 0)
    {
        Console.WriteLine("Problem: No changes saved!");
    }
    else
    {
        Console.WriteLine("Number of saved changes: " + count);
        Console.WriteLine($"After saving: Flight #{f.FlightNo}:
{f.Departure}->{f.Destination} has {f.FreeSeats} free seats!
State of the flight object: " + ctx.Entry(f).State);
    }
}
catch (Exception ex)
{
    Console.WriteLine("Error: " + ex.ToString());
}
}
}

```

Figure 10-1 shows how the state of the object changes from the perspective of Entity Framework Core. After loading, it is Unchanged. After the change is set to Modified, Entity Framework Core knows that the object has changed. After saving with `SaveChanges()`, it is again Unchanged. In other words, the state in RAM again corresponds to the state in the database.

When executing the `SaveChanges()` method, errors are likely (for example, `dbConcurrencyException`). Therefore, in Listing 10-1, there is the explicit try-catch to `SaveChanges()`. Another typical runtime error on `SaveChanges()` is when the .NET Framework allows unauthorized values to be written from the perspective of the database. This would take place, for example, with the `Memo` attribute if this column had a length limit in the database. Since the strings in .NET are basically unlimited in length, it would be possible to assign the `Memo` attribute a string that is too long from the point of view of the database.

Note Unlike the classic Entity Framework, Entity Framework Core does not yet do any validation before saving with `SaveChanges()`. In other words, invalid values are first noticed by the database management system. In this case, you get the following runtime error: “Microsoft.EntityFrameworkCore.DbUpdateException: An error occurred while updating the entries. See the inner exception for details.” The inner exception object then provides the actual source of error: “System.Data.SqlClient.SqlException: String or binary data would be truncated.”

```

After saving: Flight #101: Berlin->Seattle has 114 free seats! Zustand des Flug-Objekts: Unchanged
```

Figure 10-1. Output of Listing 10-1

The following is the SQL command sent by Entity Framework Core on `SaveChanges()` in Listing 10-1:

```
exec sp_executesql N'SET NOCOUNT ON;
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1;
SELECT @@ROWCOUNT;
',N'@p1 int,@p0 smallint',@p1=101,@p0=114'
```

Tracking Changes for Subobjects

Change tracking works in Entity Framework Core (as in its predecessor) for changed subobjects. Listing 10-2 loads the Flight object with its Pilot object. Changes in the Flight object, as well as in the connected Pilot object, are made (the Flight hours of the Pilot are increased). The state of the Pilot object changes analogously to the Flight object from Unchanged to Modified and after the execution of `SaveChanges()` again to Unchanged.

Listing 10-2. Changes in Subobjects

```
public static void ChangeFlightAndPilot()
{
    CUI.MainHeadline(nameof(ChangeFlightAndPilot));

    int flightNo = 101;
    using (WWingsContext ctx = new WWingsContext())
    {
        var f = ctx.FlightSet.Include(x => x.Pilot).SingleOrDefault(x =>
            x.FlightNo == flightNo);

        Console.WriteLine($"After loading: Flight #{f.FlightNo}:
            {f.Departure}->{f.Destination} has {f.FreeSeats} free seats!\nState
            of the flight object: " + ctx.Entry(f).State + " / State of the
            Pilot object: " + ctx.Entry(f.Pilot).State);
        f.FreeSeats -= 2;
        f.Pilot.FlightHours = (f.Pilot.FlightHours ?? 0) + 10;
        f.Memo = $"Changed by User {System.Environment.UserName} on {DateTime.
            Now}.";

        Console.WriteLine($"After changes: Flight #{f.FlightNo}:
            {f.Departure}->{f.Destination} has {f.FreeSeats} free seats!\nState
            of the flight object: " + ctx.Entry(f).State + " / State of the Pilot
            object: " + ctx.Entry(f.Pilot).State);

        try
        {
            var count = ctx.SaveChanges();
```

```

    if (count == 0) Console.WriteLine("Problem: No changes saved!");
    else Console.WriteLine("Number of saved changes: " + count);
    Console.WriteLine($"After saving: Flight #{f.FlightNo}:

}
catch (Exception ex)

Combining Commands (Batching)

In contrast to the classic Entity Framework, Entity Framework Core does not send every INSERT, UPDATE, or DELETE command in its own round-trip to the database management system; instead, it combines the commands into larger round-trips. This feature is called *batching*.

Entity Framework Core decides on the size of the summary of commands for a round-trip. In a test for the mass insertion of Flight data sets, 300 data sets were used for two round-trips; 1,000 were used for six round-trips; 2,000 were used for 11; and 5,000 were used for 27 round-trips of the database management system.

In addition to the `Add()` method, there is an `AddRange()` method on both the context class and the `DbSet<EntityClass>` class, to which you can pass a list of objects to attach. In the classic Entity Framework, `AddRange()` was much faster than `Add()` because it eliminated the need for repeated reviews of the Entity Framework Change Tracker. Entity Framework Core no longer has a performance difference between calling `Add()` in a loop 1,000 times or calling `AddRange()` once with a set of 1,000 objects as parameters. A clearly visible performance advantage in Figure 10-3 is created by batching. But if you always call `SaveChanges()` directly after `Add()`, no batching is possible (see the third bar in Figure 10-3).

Figure 10-3. Power measurement during mass insertion of 1,000 records

Dealing with foreach Loop Considerations

With Entity Framework, it is not necessary to explicitly materialize a query before an iteration with a conversion operator such as `ToList()`. A `foreach` loop over an object with an `IQueryable` interface is enough to trigger the database query. In this case, however, the database connection remains open while the loop is running, and the

records are fetched individually by the iterator of the `IQueryable` interface. This causes a call to `SaveChanges()` within a data-fetching `foreach` loop to result in a runtime error, as shown in Listing 10-3 and Figure 10-4.

There are three solutions, listed here:

- The best solution is to completely materialize the query with `ToList()` before starting the loop and to place `SaveChanges()` after the loop. This leads to the transmission of all changes in one or a few round-trips. But there is a transaction over all changes!
- If changes in multiple transactions are requested, then at least `ToList()` should be executed before the loop.
- Alternatively, you can use `SaveChangesAsync()` instead of `SaveChanges()`; see Chapter 13 for more information.

Tip Use explicit materialization with `ToList()`.

Listing 10-3. `SaveChanges()` Does Not Work Within a `foreach` Loop Unless You Have Previously Materialized the Records

```
public static void Demo_ForeachProblem()
{
    CUI.Headline(nameof(Demo_ForeachProblem));
    WWWingsContext ctx = new WWWingsContext();
    // Define query
    var query = (from f in ctx.FlightSet.Include(p => p.BookingSet).
    ThenInclude(b => b.Passenger) where f.Departure == "Rome" &&
    f.FreeSeats > 0 select f).Take(1);
    // Query is performed implicitly by foreach
    foreach (var Flight in query)
    {
        // Print results
        CUI.Print("Flight: " + Flight.FlightNo + " from " + Flight.Departure
        + " to " + Flight.Destination + " has " + Flight.FreeSeats + " free
        seats");
    }
}
```

```

foreach (var p in Flight.BookingSet)
{
    CUI.Print(" Passenger " + p.Passenger.GivenName + " " + p.Passenger.
        Surname);
}

// Save change to every flight object within the loop
CUI.Print(" Start saving");
Flight.FreeSeats--;
ctx.SaveChangesAsync(); // SaveChanges() will produce ERROR!!!
CUI.Print(" End saving");
}
}

```

Adding New Objects

To add a new record (in SQL, using INSERT), you perform the following steps with Entity Framework Core:

1. Instantiate the object with the new operator (as usual in .NET). A `Create()` factory method, as in the classic Entity Framework, does not exist in Entity Framework Core.
2. Fill the object, in particular all mandatory properties, from the point of view of the database schema.
3. Append the object to the context either through the `Add()` method in the context class or in the appropriate `DbSet<EntityClass>` in the context class.
4. Call `SaveChanges()`.

Listing 10-4 shows how to create a `Flight` object. Compulsory requirements are the flight number (the primary key is not an auto-increment value here and therefore must be set manually), airline, departure, destination, and date as well as the relationship with a `Pilot` object. The copilot is optional. Even if the airline is a mandatory field, the program code would work without explicitly assigning an enumeration value because Entity Framework Core would use the default value 0 here, which is a valid value for the database.

As an alternative to previously loading the `Pilot` object and then assigning it to the `Flight` object, you could implement the task more efficiently by using the foreign key property `PilotId` in the `Flight` object and directly assigning the primary key of the `Pilot` object there: `f.PilotId = 234`. Here you will see the advantages of an explicit foreign key property, which results in saving a round-trip of the database.

Listing 10-4. Creating a New Flight

```
public static void AddFlight()
{
    CUI.MainHeadline(nameof(AddFlight));

    using (WWWingsContext ctx = new WWWingsContext())
    {
        // Create flight in RAM
        var f = new Flight();
        f.FlightNo = 123456;
        f.Departure = "Essen";
        f.Destination = "Sydney";
        f.AirlineCode = "WWW";
        f.PilotId = ctx.PilotSet.FirstOrDefault().PersonID;
        f.Seats = 100;
        f.FreeSeats = 100;

        Console.WriteLine($"Before adding: Flight #{f.FlightNo}:
        {f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State
        of the Flight object: " + ctx.Entry(f).State);

        // Add flight to context
        ctx.FlightSet.Add(f);
        // or: ctx.Add(f);
    }
}
```

```

Console.WriteLine($"After adding: Flight #{f.FlightNo}:
{f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State
of the Flight object: " + ctx.Entry(f).State);

try
{
    var count = ctx.SaveChanges();
    if (count == 0) Console.WriteLine("Problem: No changes saved!");
    else Console.WriteLine("Number of saved changes: " + count);
    Console.WriteLine($"After saving: Flight #{f.FlightNo}:
{f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State
of the Flight object: " + ctx.Entry(f).State);
}
catch (Exception ex)
{
    Console.WriteLine("Error: " + ex.ToString());
}
}
}

```

The sequence of object states is as follows (see Figure 10-5): Detached (before executing `Add()`, the Entity Framework core context does not know about the new instance of the `Flight` and therefore considers it a transient object), Added (after the `add()`), and then after saving `Unchanged`. Incidentally, Entity Framework Core does not consider the multiple calls of `Add()` to be an error, but `Add()` does not need to be called more than once.

Note You can add an object with a primary key value that does not yet exist only in the current context instance. If you want to delete an object and then create a new object under the same primary key value, you have to execute `SaveChanges()` after `Remove()` and before `Add()`; otherwise, Entity Framework Core complains with the following error message: “System.InvalidOperationException: The instance of entity type 'Flight' can not be tracked because another instance with the same key value for {'FlightNo'} is already being tracked.”

```

AddFlight
Before adding: Flight #123456: Essen->Sydney has 100 free seats! State of the Flight object: Detached
After adding: Flight #123456: Essen->Sydney has 100 free seats! State of the Flight object: Added
Number of saved changes: 1
After saving: Flight #123456: Essen->Sydney has 100 free seats! State of the Flight object: Unchanged

```

Figure 10-5. Output from Listing 10-4 (creating a Flight object)

Creating Related Objects

The `Add()` method not only considers the object passed as a parameter but also considers objects associated with that object. If there are objects under the object passed as a parameter in the state `Detached`, they are automatically added to the context and are then in the state `Added`.

The manipulation of relationship in a 1:N situation is done on the 1 side by manipulating the list with the list-specific methods for adding and deleting, mostly with the methods `Add()` and `Remove()`. For bidirectional relationships, the changes can be made either on the 1 side or on the N side. In the specific case of the bidirectional relationship between `Flight` and `Pilot`, there are three equivalent ways to establish the relationship, listed here:

- Using the navigation property of the 1 side, so `Pilot` in `Flight`:
- `flight.Pilot = Pilot;`
- Using the foreign key property `PersonID` in `Flight`:
- `flight.PersonID = 123;`
- Using the navigation property of the N side, in other words, `FlightAsPilotSet` on the `Pilot` page:
- `pilot.FlightAsPilotSet.Add(flight);`

Listing 10-5 shows how to create a new `Flight` with a new `Pilot` object, a new `AircraftType` object, and a new `AircraftTypeDetail` object. It is sufficient to execute `Add()` for the `Flight` object. Entity Framework Core then sends `SaveChanges()` five `INSERT` commands to the database, one for each of the tables: `AircraftType`, `AircraftTypeDetail`, `Employees` (a common table for instances of the `Employee` and `Pilot` classes), `Persondetail`, and `Flight`.

Listing 10-5. Creation of a New Pilot's Flight with Persondetail, New AircraftType, and AircraftTypeDetail

{
    CUI.MainHeadline(nameof(Demo_CreateRelatedObjects));
    using (var ctx = new WWingsContext())
    {
        ctx.Database.ExecuteSqlCommand("Delete from Booking where
            FlightNo = 456789");
        ctx.Database.ExecuteSqlCommand("Delete from Flight where
            FlightNo = 456789");

        var p = new Pilot();
        p.GivenName = "Holger";
        p.Surname = "Schwichtenberg";
        p.HireDate = DateTime.Now;
        p.LicenseDate = DateTime.Now;
        var pd = new Persondetail();
        pd.City = "Essen";
        pd.Country = "DE";
        p.Detail = pd;

        var act = new AircraftType();
        act.TypeID = (byte)(ctx.AircraftTypeSet.Max(x=>x.TypeID)+1);
        act.Manufacturer = "Airbus";
        act.Name = "A380-800";
        ctx.AircraftTypeSet.Add(act);
        ctx.SaveChanges();

        var actd = new AircraftTypeDetail();
        actd.TurbineCount = 4;
        actd.Length = 72.30f;
    }
}

```

```
actd.Tare = 275;
act.Detail = actd;

var f = new Flight();
f.FlightNo = 456789;
f.Pilot = p;
f.Copilot = null;
f.Seats = 850;
f.FreeSeats = 850;
f.AircraftType = act;

// One Add() is enough for all related objects!
ctx.FlightSet.Add(f);
ctx.SaveChanges();

CUI.Print("Total number of flights: " + ctx.FlightSet.Count());
CUI.Print("Total number of pilots: " + ctx.PilotSet.Count());

Changing Linked Objects

Entity Framework Core also detects relationship changes between entity objects and automatically saves them in `SaveChanges()`. As with the initial creation of a `Flight` object with `Pilot`, there are three options for a relationship change in the ideal case (bidirectional relationships with foreign key properties):

- Using the navigation property `Pilot` in `Flight: Flight`.
`Pilot = Pilot;`
- Using the foreign key property `PilotId` in `Flight: Flight`.
`PersonID = 123;`
- Using the navigation property `FlightAsPilotSet` on the `Pilot` page:
`Pilot.FlightAsPilotSet.Add (Flight);`

In all three cases, Entity Framework Core sends `SaveChanges()` to the database. By executing `SaveChanges()`, Entity Framework Core correctly does not make any changes to the database in the `Pilot` table but in the `Flight` table, because the `Flight` table has the foreign key that establishes the relationship between `Pilot` and `Flight`.

```
exec sp_executesql N'SET NOCOUNT ON;
UPDATE [Flight] SET [PilotId] = @p0
WHERE [FlightNo] = @p1;
SELECT @@ ROWCOUNT;
', N' @p1 int, @p0 int ', @p1 = 101, @p0 = 123
```

Tip To remove a relationship, you can simply assign zero or nothing.

Listing 10-6 shows the assignment of a new `Pilot` to a `Flight`. However, this assignment does not take place via `Flight101.Pilot = newPilot` (the 1 side) but on the `Pilot` side (the N side) via `newPilot.FlightAsPilotSet.Add(flight101)`. The output of this listing is exciting; see Figure 10-7. You can see that at the beginning, one pilot has 31 flights, and the other has 10 flights. After the assignment, the new `Pilot` has 11 flights, and the old `Pilot` still has 31 flights, which is wrong. In addition, `flight101.Pilot` still refers to the old `Pilot`, which is also wrong.

However, after running `SaveChanges()`, the object relations have been corrected. Now the old `Pilot` has 30 flights only. In addition, `flight101.Pilot` refers to the new `Pilot`. This feature of Entity Framework Core is called *relationship fixup*. As part of a relationship fixup operation, Entity Framework Core checks all relations between the objects that are currently in RAM and also changes them on the opposite side if changes have occurred in this side. Entity Framework Core runs the relationship fixup operation when saving with `SaveChanges()`.

You can force the relationship fixup operation at any time with the execution of the method `ctx.ChangeTracker.DetectChanges()`. If many objects have been loaded into a context instance, `DetectChanges()` can take many milliseconds. Therefore, in Entity Framework Core, Microsoft does not automatically call `DetectChanges()` in many places, leaving it up to you to decide when you need a consistent state of the object relationships and to use `DetectChanges()`. Figure 10-7 shows the output.

Dealing with Contradictory Relationships

If, as explained earlier, there are up to three ways to establish a relationship between objects, what happens when multiple options are used in parallel with contradictory data?

Listing 10-7, in connection with the output in Figure 10-8 and Figure 10-9, shows that the priority is as follows:

- The highest priority is the value of the object set on the 1 side, so in the case of the relation Pilot<->Flight (1:N), the value from Pilot.FlightAsPilotSet is first.
- The second highest priority is the value from the single object on the N side. In other words, in the case of Pilot<->Flight (1:N), it's the value from Flight.Pilot.
- Only then is the foreign key property taken into account on the N side. In other words, in the case of Pilot: Flight (1:N), it's the value from Flight.PersonID.

Deleting Objects

This section covers different ways of deleting objects and the corresponding rows in the database.

Deleting Objects with Remove()

To delete an object, you must call the `Remove()` method, which, like `Add()`, exists either directly on the context class (inherited from `DbContext`) or on the `DbSet<EntityClass>` property in the context class (see Listing 10-8). Calling `Remove()` causes the loaded `Flight` object to change from the `Unchanged` state to the `Delete` state (see Figure 10-10). However, it has not yet been deleted in the database. Only by calling the `SaveChanges()` method is a `DELETE` command sent to the database management system.

Listing 10-8. Deleting a Flight Record

```

public static void RemoveFlight()
{
    CUI.MainHeadline(nameof(RemoveFlight));

    using (WWWingsContext ctx = new WWWingsContext())
    {
        var f = ctx.FlightSet.SingleOrDefault(x => x.FlightNo == 123456);
        if (f == null) return;

        Console.WriteLine($"After loading: Flight #{f.FlightNo}:
        {f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State of
        the flight object: " + ctx.Entry(f).State);

        // Remove flight
        ctx.FlightSet.Remove(f);
        // or: ctx.Remove(f);

```

Deleting Objects with a Dummy Object

In the previous code, it is inefficient to load the `Flight` object completely; you send only a delete command. Listing 10-9 shows a solution that avoids this round-trip to the database management system by creating a `Flight` object in RAM where only the primary key is set to the object to be deleted. You then attach this dummy object to the context with `Attach()`. This causes the object to change state from `Detached` to `Unchanged`. Finally, you execute `Remove()` and `SaveChanges()`. The trick works because Entity Framework needs to know only the primary key for deletion.

Note the following about this trick:

- The method `Attach()`, not `Add()`, is called here; otherwise, Entity Framework Core would consider the dummy object as a new object.
- The trick works only if no conflict checks have been configured in Entity Framework Core. If, however, the model is set to compare the values of other columns when saving, these must be filled with the current values in the dummy object. Otherwise, the object cannot be deleted, and a `DbConcurrencyException` occurs.

Listing 10-9. Deleting a Flight Record More Efficiently with a Dummy Object

```
public static void RemoveFlightWithKey()
{
    Console.WriteLine(nameof(RemoveFlightWithKey));

    using (WWWingsContext ctx = new WWWingsContext())
    {
        // Create a dummy object
        var f = new Flight();
        f.FlightNo = 123456;

        Console.WriteLine($"After creation: Flight #{f.FlightNo}:
        {f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State of
        the flight object: " + ctx.Entry(f).State);

        // Append dummy object to context
        ctx.Attach(f);

        Console.WriteLine($"After attach: Flight #{f.FlightNo}:
        {f.Departure}->{f.Destination} has {f.FreeSeats} free seats! State of

    }
}

{
    var count = ctx.SaveChanges();
    if (count == 0) Console.WriteLine("Problem: No changes saved!");
    else Console.WriteLine("Number of saved changes: " + count);

{
    Console.WriteLine("Error: " + ex.ToString());
}
}
}
}

```

Bulk Deleting

The `Remove()` method is not suitable for a mass deletion as defined in `Delete from Flight where FlightNo > 10000` because Entity Framework Core will generate a `DELETE` command per object in each case. Entity Framework Core does not recognize that many `DELETE` commands can be combined into one command. In this case, you should always rely on classic techniques (SQL or stored procedures) since using `Remove()` would be many times slower here. Another option is the extension `EFPlus` (see Chapter 20).

Performing Database Transactions

Note these important points about database transactions:

- When you run `SaveChanges()`, Entity Framework Core always automatically makes a transaction, meaning that all changes made in the context are persisted or none of them.
- If you need a transaction across multiple calls to the `SaveChanges()` method, you must do so with `ctx.Database.BeginTransaction()`, `Commit()`, and `Rollback()`.

- `System.Transactions.Transactions.TransactionScope` is not supported yet in Entity Framework Core. It will be supported in version 2.1 of Entity Framework Core; see [Appendix C](#).

Tip The best transaction is a transaction that you avoid. Transactions always negatively impact the performance, scalability, and robustness of an application.

Example 1

The following example shows a transaction with two changes to a `Flight` object that are each persisted independently with `SaveChanges()`:

```
public static void ExplicitTransactionTwoSaveChanges()
{
    Console.WriteLine(nameof(ExplicitTransactionTwoSaveChanges));
    using (var ctx = new WWingsContext())
    {
        // Start transaction. Default is System.Data.IsolationLevel.
        ReadCommitted
        using (var t = ctx.Database.BeginTransaction(System.Data.
            IsolationLevel.ReadCommitted))
        {
            // Print isolation level
            RelationalTransaction rt = t as RelationalTransaction;
            DbTransaction dbt = rt.GetDbTransaction();
            Console.WriteLine("Transaction with Level: " + dbt.IsolationLevel);

            // Read data
            int FlightNr = ctx.FlightSet.OrderBy(x => x.FlightNo).
                FirstOrDefault().FlightNo;
            var f = ctx.FlightSet.Where(x => x.FlightNo == FlightNr).
                SingleOrDefault();

            Console.WriteLine("Before: " + f.ToString());
        }
    }
}
```

```

// Change data and save
f.FreeSeats--;
var count1 = ctx.SaveChanges();
Console.WriteLine("Number of saved changes: " + count1);

// Change data again and save
f.Memo = "last changed at " + DateTime.Now.ToString();
var count2 = ctx.SaveChanges();
Console.WriteLine("Number of saved changes: " + count2);

Console.WriteLine("Commit or Rollback? 1 = Commit, other = Rollback");
var input = Console.ReadKey().Key;
if (input == ConsoleKey.D1)
{ t.Commit(); Console.WriteLine("Commit done!"); }
else
{ t.Rollback(); Console.WriteLine("Rollback done!"); }

Console.WriteLine("After in RAM: " + f.ToString());
ctx.Entry(f).Reload();
Console.WriteLine("After in DB: " + f.ToString());
}
}
}

```

Example 2

The following example shows a transaction with a change to the table `Booking` (insert a new booking) and to the table `Flight` (Reduce Number of Free Picks). Here the transaction takes place via two different context instances of a context class. It would also be possible to have a transaction via two different context classes if they refer to the same database.

Note the following:

- The database connection is created and opened separately.
- The transaction is opened on this connection.

- The context instances do not open their own connections but use the open connection. For this purpose, the database connection object is passed into the constructor of the context class, where it is kept in mind. In `OnConfiguring()`, this database connection object must be used with `UseSqlServer()` or similar instead of passing the connection string as a parameter!
- After instantiating the transaction object has to be passed to `ctx.Database.UseTransaction()`.

Note Failure to open the connection in advance and passing it to the context instances involved will result in the following runtime error: “The specified transaction is not associated with the current connection. Only transactions associated with the current connection may be used.”

Figure 10-11 shows the output.

```
public static void ExplicitTransactionTwoContextInstances()
{
    CUI.MainHeadline(nameof(ExplicitTransactionTwoContextInstances));

    using (var connection = new SqlConnection(Program.CONNSTRING))

        ReadCommitted
        using (var t = connection.BeginTransaction(System.Data.IsolationLevel.
            ReadCommitted))
        {
            // Print isolation level
            Console.WriteLine("Transaction with Level: " + t.IsolationLevel);

            using (var ctx = new WWWingsContext(connection))
            {

```

flightNo = flight.FlightNo;
ctx.Database.ExecuteNonQuery("Delete from booking where flightno= "
+ flightNo);
var pasID = ctx.PassengerSet.FirstOrDefault().PersonID;

// Create and persist booking
var b = new BO.Booking();
b.FlightNo = flightNo;
b.PassengerID = pasID;
ctx.BookingSet.Add(b);
var count1 = ctx.SaveChanges();
Console.WriteLine("Numer of bookings saved: " + count1);
}

    ctx.Database.UseTransaction(t);

Using the Change Tracker

The Change Tracker built into Entity Framework Core, which monitors changes to all objects connected to the Entity Framework Core context, can be queried at any time by program code.

Getting the State of an Object

Because Entity Framework Core works with plain old CLR objects (POCOs), which have entity objects and not a base class and which implement an interface, entity objects have no knowledge of their context class or state.

To query the object state, you do not ask the entity object itself but the `ChangeTracker` object of the context class. The `ChangeTracker` object has an `Entry()` method that returns an associated `EntryObject<EntityType>` for a given Entity object. This object owns the following:

- The `ChangeTracker` object has a `State` property of type `EntityState`, which is an enumeration type with the values `Added`, `Deleted`, `Detached`, `Modified`, and `Unchanged`.
- In `Properties` you find a list of all the properties of the entity object in the form of `PropertyEntry` objects. The `PropertyEntry` objects each have an `IsModified` property that indicates whether the property is changed, as well as the old (`OriginalValue`) and new (`CurrentValue`) values.
- Using `EntryObject<EntityType>`, you can also directly get a specific `PropertyEntry` object by specifying a lambda expression using the `Property` method.
- `GetDatabaseValues()` is used to get the current state of the object from the database.

The subroutine in Listing 10-10 loads a `Flight` (the first one) and modifies this `Flight` object. At the beginning of the routine, not only is a variable created for the `Flight` object itself but also an `entryObj` variable is created for `EntryObject<Flight>` and `propObj` is created for a `PropertyEntry` object.

After loading `Flight`, `entryObj` and `propObj` are first filled with objects of the `ChangeTracker` object. The entity object is in the `Unchanged` state, and the `FreeSeats` property returns `IsModified False`. Then the object is changed in the property `FreeSeats`. The entity object is now in the `Modified` state, and `IsModified` for `FreeSeats` returns `True`.

Note It is important that the information from the `ChangeTracker` object of the context is retrieved here; the instances of `EntryObject<Flight>` and `PropertyEntry` do not automatically update with the entity object change but reflect the current state at the time of the retrieval.

Therefore, you must also request these objects for the third time after the `SaveChanges()` method from the `ChangeTracker` object. After `SaveChanges()`, the state of the entity object is again `Unchanged`, and the property `FreeSeats` returns `IsModified False`.

The routine also loops over the `Properties` property of `EntryObject<Flight>` to return all the modified properties of the entity object with old and new values and the current value of the database. This value can be determined using the `GetDatabaseValues()` method in `EntryObject<Flight>`. Then `GetDatabaseValues()` raises a query of the database and populates a `PropertyValues` list with all the current values in the database. These values in the database may be different from the values that Entity Framework Core knows and that are visible in the `OriginalValue` properties, another process (or another Entity Framework Core context in the same process) meanwhile persisted a change to the record. In this case a data conflict occurred. Figure 10-12 shows the output.

Listing All Changed Objects

The `ChangeTracker` object can provide not only information about a single object but also a list of all entity objects monitored by it using its `Entries()` method. You can then filter entity objects for the desired state.

The routine in Listing 10-11 modifies three flights and then creates a flight with the value 123456 if it does not already exist. If the `Flight` object already exists, it will be deleted. Thereafter, the routine separately asks the `ChangeTracker` object for the new, changed, and deleted objects (Listing 10-12). All three sets are provided by `Entries()`. The set is filtered from LINQ to Objects using the `Where()` operator. In all three cases, the `PrintChangedProperties()` helper routine is called. But only in the case of the changed objects does it deliver some output. If the object has been added or deleted, the individual properties are considered unchanged.

Figure 10-13 and Figure 10-14 show the output.

CHAPTER 11

Preventing Conflicts (Concurrency)

In many production scenarios, it's possible for multiple people or automatic background tasks to access the same records at the same time. This can lead to conflicts in which contradictory data changes take place. This chapter shows how to detect and resolve such conflicts in Entity Framework Core.

A Look at the History of Concurrency

Like its predecessor Entity Framework and the underlying basic technology ADO.NET, Entity Framework Core does not support the blocking of data records for read access by other processes. This was a deliberate decision by Microsoft in .NET 1.0 (2002) because locks cause a lot of performance issues. In the alpha version of .NET 2.0 (2005), there was a prototype of such a lock function in the then-new class `SqlResultSet`, but this class was never released in an RTM version of .NET.

Therefore, in .NET and the frameworks based on it, such as Entity Framework and Entity Framework Core, there is only so-called optimistic locking. *Optimistic locking* is a euphemism because actually nothing is blocked in the database management system and in RAM. It is only ensured that change conflicts will be noticed later. The first process that wants to write a change wins. All other processes cannot write and will get an error message. To accomplish this, the UPDATE and DELETE commands in the WHERE condition include single or multiple values from the source record.

A DataSet in conjunction with a DataAdapter and a SqlCommandBuilder object not only queries the primary key column or columns in the WHERE clause of an UPDATE or DELETE command but also queries all columns with their old values from the point of view of the current process values that the process received while reading the record (see Listing 11-1). In the meantime, if another process has changed any individual columns, the UPDATE or DELETE command does not cause a runtime error in the database management system; instead, it results in zero records being affected. This allows the DataAdapter to detect that there was a change conflict.

Listing 11-1. Update Command, As Created by a SqlCommandBuilder for the Flight Table with the Primary Key FlightNo

```
UPDATE [dbo].[Flight]
SET [FlightNo] = @p1, [Departure] = @p2, [Strikebound] = @p3,
[CopilotId]= @p4, [FlightDate] = @p5, [Flightgesellschaft] = @p6,
[AircraftTypeID] = @p7, [FreeSeats] = @p8, [LastChange] = @p9,
[Memo] = @p10, [NonSmokingFlight] = @p11, [PilotId] = @p12, [Seats] = @p13,
[Price] = @p14, [Timestamp] = @p15, [destination] = @p16
WHERE (([FlightNo] = @p17) AND ((@p18 = 1 AND [Departure] IS NULL) OR
([Departure] = @p19)) AND ((@p20 = 1 AND [Expires] IS NULL) OR
([Strikebound] = @p21)) AND ((@p22 = 1 AND [CopilotId] IS NULL) OR
([CopilotId] = @p23)) AND ([FlightDate] = @p24) AND ([Airline] = @p25)
AND ((@p26 = 1 AND [aircraftID_ID] IS NULL) OR ([aircraft_type_ID] =
@p27)) AND ((@p28 = 1 AND [FreeSeats] IS NULL) OR ([FreeSeats] = @p29))
AND ([Lastchange] = @p30) AND ((@p31 = 1 AND [NonSmokingFlight] IS NULL)
OR ([NonSmokingFlight] = @p32)) AND ([PilotId] = @p33) AND ([Seats] = @p34)
AND ((@p35 = 1 AND [price] IS NULL) OR ([price] = @p36)) AND ((@p37 = 1 AND
[destination] IS NULL) OR ([destination] = @p38)))
```

No Conflict Detection by Default

Entity Framework Core, like Entity Framework, does not lock at all by default, not even with optimistic locking. The standard is simply “the last who writes wins.”

Listing 11-2 shows how to change a Flight object in RAM and persist the change with

SaveChanges() via Entity Framework Core. This program code sends the following SQL command to the database management system:

```
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1;
SELECT @@ ROWCOUNT;
```

As you can see, only the primary key FlightNo appears in the WHERE condition; the old value of the column FreeSeats or other columns does not appear. Thus, the value is persisted, even if other processes have changed the value in the meantime. As a result, an airline may experience the overbooking of flights. For example, if there are only two free seats left and two processes load this information (almost) simultaneously, each of the two processes can subtract two places from this remaining contingent. The state in the column FreeSeats is then zero in the database. In fact, four passengers were placed in the two seats. That will be a tight fit on the plane!

Although SaveChanges() opens a transaction, it applies only to the one store operation and therefore does not protect against data change conflicts. However, ignoring conflicts is often not viable or acceptable to users. Luckily, you can reconfigure Entity Framework Core, much as you did with Code First in its predecessor Entity Framework.

The only change conflict that Entity Framework Core would notice would be to delete the record with another process because, in this case, the UPDATE command would return the fact that zero records were changed, and then Entity Framework Core would raise a DbUpdateConcurrencyException error.

Detecting Conflicts with Optimistic Locking

Entity Framework Core sends the following SQL command to the database management system:

```
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1 AND [FreeSeats] = @p2;
SELECT @@ROWCOUNT;
```

Here, in addition to the query of the primary key, `FlightNo` takes a query of the old value (the original value when reading) of the column `FreeSeats`. To implement this conflict detection, it is not the program code that needs to be changed but the Entity Framework Core model.

There are two ways to configure the model.

- Via the data annotation `[ConcurrencyCheck]`
- Via `IsConcurrencyToken()` in the Fluent API

Listing 11-3 shows a section from the entity class `Flight`. Here, `FreeSeats` was annotated with `[ConcurrencyCheck]`, whereby Entity Framework Core automatically queries the old value in the `WHERE` condition for all `UPDATE` and `DELETE` commands. This is achieved by calling `IsConcurrencyToken()` on the corresponding `PropertyBuilder` object in `OnModelCreating()` in the Entity Framework Core context class (see Listing 11-4).

Listing 11-3. Use of Data Annotation `[ConcurrencyCheck]`

```
public class Flight
{
    [Key]
    public int FlightNo {get; set; }

    [ConcurrencyCheck]
    public short? FreeSeats {get; set;}

    [ConcurrencyCheck]
    public decimal? Price {get; set; }
    public short? Seats { get; set; }

    ...
}
```

Listing 11-4. Using `IsConcurrencyToken()` in the Fluent API

```
public class WWingsContext: DbContext
{
    public DbSet<Flight> FlightSet { get; set; }
    ...
    protected override void OnModelCreating (ModelBuilder builder)
    {
        Builder %Entity<Flight>().Property (f => f.FreeSeats).IsConcurrencyToken();
    }
    ...
}
```

Now it may be useful to run the conflict check over several columns. For example, the conflict check can also be performed via the `Price` column of the `Flight` object. In terms of content, this would mean that if the price of the `Flight` has changed, you cannot change the number of seats because this booking would then have been displayed to the user at the old price. You can then annotate the `Price` property with `[ConcurrencyCheck]` or add it to the Fluent API.

```
builder.Entity<Flight>().Property(x => x.FreeSeats).ConcurrencyToken();
```

The following SQL command with three parts in the `WHERE` condition arises from the listing:

```
SET NOCOUNT ON;
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1 AND [FreeSeats] = @p2 AND [Price] = @p3;
SELECT @@ ROWCOUNT;
```

Detecting Conflicts for All Properties

It can be tedious to do this configuration via a data annotation or the Fluent API for all entity classes and all persistent properties. Fortunately, Entity Framework Core lets you do a mass configuration. Listing 11-5 shows how to use `Model` in `OnModelCreating()` from the `ModelBuilder` object. `GetEntityTypes()` gets a list of all entity classes and therefore all properties in each entity class via `GetProperties()` so that `IsConcurrencyToken = true` is set there.

Listing 11-5. Mass Configuration of the ConcurrencyToken for All Properties in All Entity Classes

```

public class WWWingsContext: DbContext
{
    public DbSet<Flight> FlightSet { get; set; }
    ...
    protected override void OnModelCreating (ModelBuilder builder)
    {
        foreach (IMutableEntityType entity in modelBuilder.Model.
            GetEntityTypes())
        {
            // get all properties
            foreach (var prop in entity.GetProperties())
            {
                prop.IsConcurrencyToken = true;
            }
        }
    }
    ...
}

```

The listing then creates a SQL command that includes all the columns in the WHERE condition, shown here:

```

SET NOCOUNT ON;
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1 AND [Departure] = @p2 AND [Destination] = @p3
AND [CopilotId] = @p4 AND [FlightDate] = @p5 AND [Airline] = @p6 AND
[AircraftTypeID] IS NULL AND [FreeSeats] = @p7 AND [LastChange] = @p8
AND [Memo] = @p9 AND [NonSmokingFlight] IS NULL AND [PilotId] = @p10 AND
[Seats] = @p11 AND [Price] = @p12 AND [Strikebound] = @p13;
SELECT @@ ROWCOUNT;

```

Settling Conflicts by Convention

If you want to exclude individual columns, that's also possible. In this case, it makes sense to define a separate annotation, called `[ConcurrencyNoCheckAttribute]` (see Listing 11-6), which then annotates all persistent properties of the entity class for which Entity Framework Core should not perform a conflict check. Listing 11-7 shows the extension of the example that considers the annotation `[ConcurrencyNoCheck]`. What is important here is the zero-propagation operator `?.` after `PropertyInfo`; it's important because you can define so-called shadow properties in Entity Framework Core, which exist only in the Entity Framework Core model and not in the entity class. These shadow properties will not have a `PropertyInfo` object, so in the case of a shadow property without the null-propagating operator, the popular `Null Reference` runtime error would occur. With `ConcurrencyNoCheckAttribute`, you can elegantly exclude individual properties from conflict checking as needed.

    protected override void OnModelCreating (ModelBuilder builder)
    {
        // Get all entity classes
        foreach (IMutableEntityType entity in modelBuilder.Model.GetEntityTypes())
        {
            // get all properties
            foreach (var prop in entity.GetProperties())
            {
                // Look for annotation [ConcurrencyNoCheck]
                var annotation = prop.PropertyInfo?.GetCustomAttribute<ConcurrencyNoCheckAttribute>();
                if (annotation == null)
                {
                    prop.IsConcurrencyToken = true;
                }
                else
                {
                    Console.WriteLine("No Concurrency Check for" + prop.Name);
                }
                if (prop.Name == "Timestamp")
                {
                    prop.ValueGenerated = ValueGenerated.OnAddOrUpdate;
                    prop.IsConcurrencyToken = true;
                }
            }
        }
    }
}
```

```

    {
        Console.WriteLine(prop.Name + ":" + a.Name + "=" + a.Value);
    }
}
}
}
...
}
}

```

Setting Up Conflict Checks Individually

Sometimes, in practice, there is a desire to activate or deactivate the conflict check on a case-by-case basis for individual changes for individual properties. Unfortunately, this cannot be fulfilled because the data annotations are compiled, and `OnModelCreating()` is also called only once per process. Unfortunately, you cannot change the Entity Framework Core model after the end of `OnModelCreating()`. Although the `DbContext` class, like the `ModelBuilder` class, provides a property model, in `ModelBuilder` the property model has the `IMutableModel` type (which is a variable, as the name implies). `DbContext` gets only the `IModel` type, and `IsConcurrencyToken` is read-only like many other properties. So, if you want to change optimistic locking columns on a case-by-case basis, you need to send UPDATE and DELETE commands to the database management system yourself (via Entity Framework Core or another means).

Adding Timestamps

Instead of the original value comparison at the level of individual data columns, it is possible to introduce an additional timestamp column. You can find one such column in Microsoft SQL Server with the type `rowversion` (<https://docs.microsoft.com/en-us/sql/t-sql/data-types/rowversion-transact-sql>), called `timestamp` (see Figure 11-1 and Figure 11-2). It is automatically increased by the database management system for each individual data record change. Consequently, in the case of an UPDATE or DELETE command, it is only necessary to check whether the value is still at the previous value

that existed during loading. If so, the entire record is unchanged. If not, another process has changed at least part of the record. However, with a timestamp column, you cannot differentiate between columns where changes are relevant and those where changes are not relevant. The database management system adjusts the timestamp each time a column is changed; exceptions are not possible.

Note While currently SQL Server Management Studio (SSMS) still displays the old name `timestamp`, SQL Server Data Tools in Visual Studio 2016 shows the current name of `rowversion`.

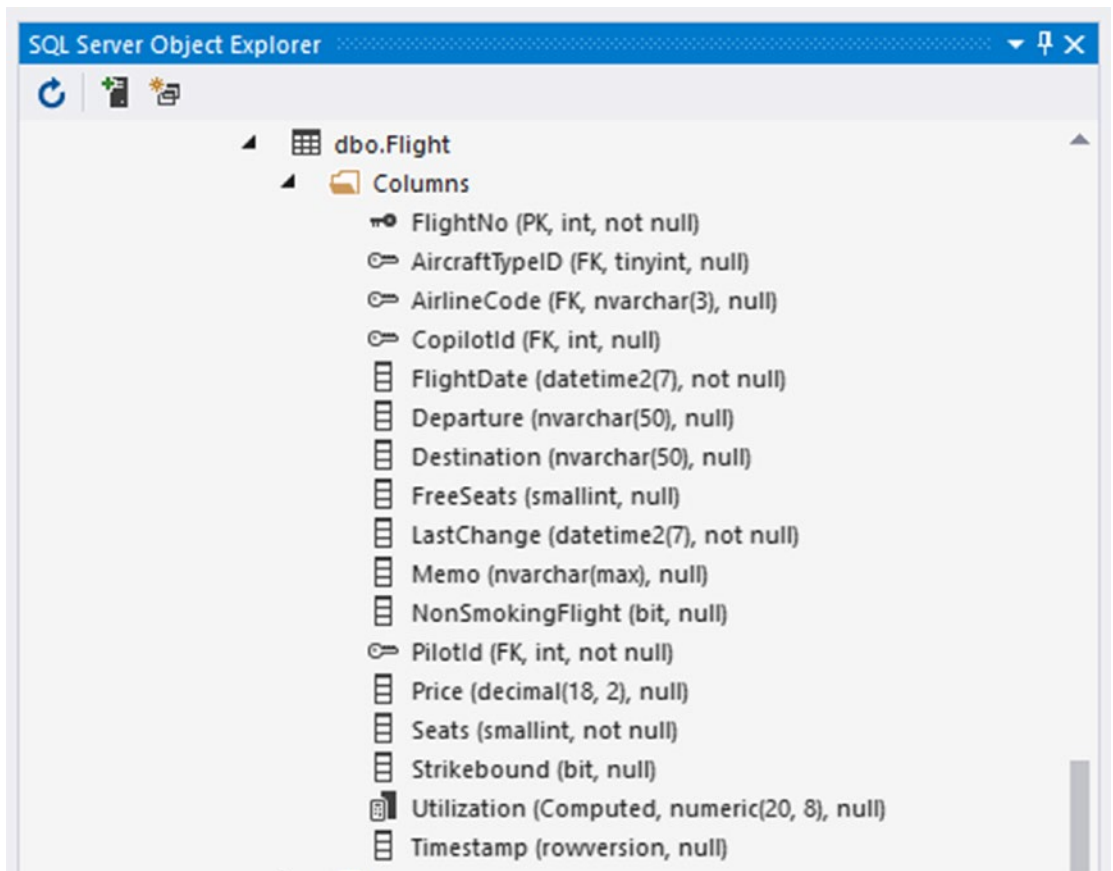

Figure 11-1. A timestamp column for a record in Microsoft SQL Server 2017 as shown in Visual Studio 2017

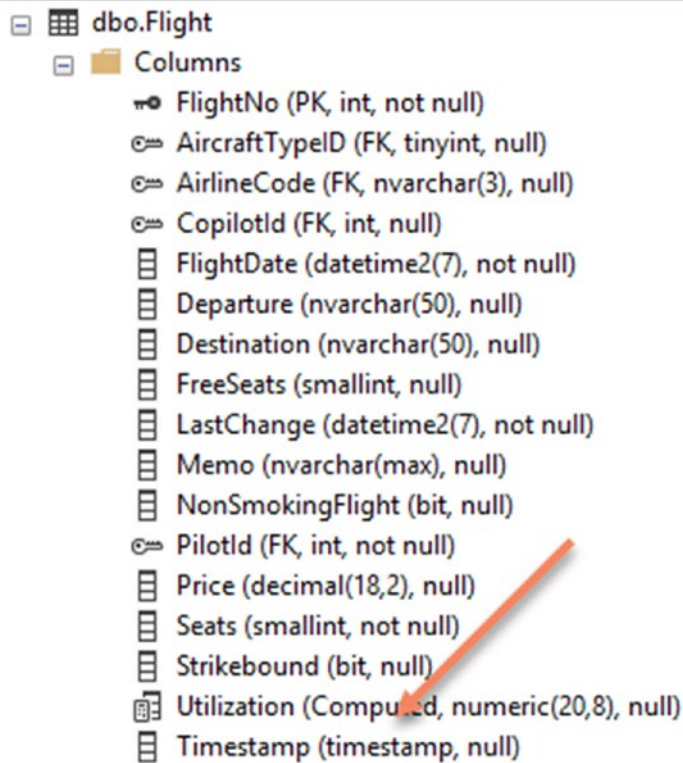

Figure 11-2. A timestamp column for a record in Microsoft SQL Server 2017 as shown in SQL Server Management Studio 17.1

To use timestamps for change conflict detection, you add a byte-array column (`byte[]`) to the entity class and annotate it with `[timestamp]`. The name of the column, however, does not matter to Entity Framework Core.

```
[Timestamp]
public byte[] Timestamp { get; set; }
```

Alternatively, you can set this again by using the Fluent API, but this happens in the program code, as shown here:

```
builder.Entity<Flight>()
    .Property(p => p.Timestamp)
    .ValueGeneratedOnAddOrUpdate()
    .IsConcurrencyToken();
```

Since version 1.1 of Entity Framework Core, you can also use `IsRowVersion()` as an alternative, as shown here:

```
modelBuilder.Entity<Flight>().Property(x => x.Timestamp).IsRowVersion();
```

Note There can be only one timestamp/rowversion column per table. Unfortunately, the error message “A table can only have one timestamp column.” occurs only when you call `Update-Database`, not with `Add-Migration`.

You do not have to implement anything else for the timestamp support. If there is such a property in the object model and the corresponding column in the database table, Entity Framework Core always refers to the previous timestamp value for all `DELETE` and `UPDATE` commands in the `WHERE` condition.

```
SET NOCOUNT ON;
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1 AND [Timestamp] IS NULL;
SELECT [Timestamp]
FROM [Flight]
WHERE @@ ROWCOUNT = 1 AND [FlightNo] = @p1;
```

As you can see, Entity Framework Core also uses `SELECT [Timestamp]` to reload the timestamp that is changed by the database management system after an `UPDATE` to update the object in RAM accordingly. If that did not happen, then a second update of an object would not be possible because then the timestamp in RAM would be out of date and Entity Framework Core would always report a change conflict, even if there was none (because the first change was the one that changed the timestamp in the database table).

The timestamp configuration can also be automated by convention. The mass configuration shown in Listing 11-8 automatically makes all properties bearing the name `timestamp` timestamps for conflict detection.

Listing 11-8. Automatically Turning Any Properties Called Timestamp into Timestamps for Conflict Detection

```

public class WWingsContext: DbContext
{
    public DbSet<Flight> FlightSet {get; set; }
    ...
    protected override void OnModelCreating (ModelBuilder builder)
    {
        // Get all entity classes
        foreach (IMutableEntityType entity in modelBuilder.Model.
        GetEntityTypes())
        {
            // Get all properties
            foreach (var prop in entity.GetProperties())
            {
                if (prop.Name == "Timestamp")
                {
                    prop.ValueGenerated = ValueGenerated.OnAddOrUpdate;
                    prop.IsConcurrencyToken = true;
                }
            }
        }
    }
    ...
}

```

Resolving Conflicts

This section shows how to validate the conflict detection. Figure 11-3 shows some typical output of the program when it is started twice. First the process with the ID 10596 starts, and then the process 18120 starts. Both read the flight with the number 101, in which there are currently 143 seats left. The process 10596 then reduces the number of places by 5 and persists 138 in the FreeSeats column. Now process 18120 makes a booking for two people, so in RAM the value changes to 141 FreeSeats. However,

process 18120 cannot persist because Entity Framework Core throws an error of type `DbUpdateConcurrencyException` because of conflict detection for the `FreeSeats` column or based on a timestamp column. The user in process 18120 is given the choice of either accepting or overwriting the other user's changes or offsetting the two changes, which may make sense in some cases.

Figure 11-3. Conflict detection and conflict resolution

Listing 11-9 shows the implementation. `SaveChanges()` catches the `DbUpdateConcurrencyException`. In the error handler, the `PrintChangedProperties()` helper function is used to specify which properties of the flight were changed in this process and what the current database state is. You get the current state of the database through the method `GetDatabaseValues()`, which sends a corresponding SQL query to the database management system. After that, the user has to decide. If the user chooses to apply the changes to the other process, the `Reload()` method is called in the Entity Framework Core API, which discards the changed object in RAM and reloads it from the database. If the user chooses to override the changes to the other process, the program code is a little more complicated and indirect. The command chain loads the current state from the database and sets it in the Entity Framework Core Change

Tracker to the original values of the object: `ctx.Entry(Flight).OriginalValues.SetValues(ctx.Entry(Flight).GetDatabaseValues())`. After that, `SaveChanges()` is called again, which now works because the original values used in the `WHERE` condition or the timestamp used there correspond to the current state of the data record in the database. Theoretically, however, a conflict can occur again if in the short time between `GetDatabaseValues()` and `SaveChanges()` another process changes the record in the database table. You should therefore encapsulate `SaveChanges()` and the associated error handling, but this did not happen here for didactic reasons to better illustrate the example.

In Figure 11-3, the user has opted for the third option, clearing the two changes. In addition to its original value and its current value, process 18120 requires the current database value of the column `FreeSeats`. The result is then correctly 136. However, the calculation assumes that both processes have started from the same original value. Without interprocess communication, process 18120 may not know the seed value of process 10596. The billing works only in special cases.

Of course, it is also possible to let the user solve the conflict in a (graphical) user interface by not deciding on one or the other side but by entering values. In terms of implementation, the clearing just like the input of another value then corresponds to the second case, in other words, overwriting the changes of the other process. Before calling `SaveChanges()`, simply set the values in the object that you want to have in the database afterward (see the case `ConsoleKey.D3` in Listing 11-9 and Listing 11-10).

Pessimistic Locking on Entity Framework Core

Although Microsoft has deliberately not implemented a class in .NET and .NET Core that can be used to block records for read access by others, I am constantly meeting clients who nevertheless desperately want to avoid conflicts in the first place. With a LINQ command, a read lock is not feasible, even with the activation of a transaction. You need a transaction and additionally a database management system-specific SQL

command. In Microsoft SQL Server, this is the query hint `SELECT ... WITH (UPDLOCK)` associated with a transaction. This query hint ensures that a read record is locked until the transaction is completed. It works only within a transaction, so you will find a `ctx.Database.BeginTransaction()` method in Listing 11-11 and later the call to `commit()`. The listing also shows the use of the `FromSql()` method provided by Entity Framework Core, which allows you to send your own SQL command to the database management system and materialize the result into entity objects.

Listing 11-11. A Lock Is Already Set Up When Reading the Data Record

```
public static void UpdateWithReadLock()
{
    CUI.MainHeadline(nameof(UpdateWithReadLock));
    Console.WriteLine("--- Change flight");
    int flightNo = 101;
    using (WWingsContext ctx = new WWingsContext())
    {
        try
        {
            ctx.Database.SetCommandTimeout(10); // 10 seconds
            // Start transaction
            IDbContextTransaction t = ctx.Database.BeginTransaction(IsolationLevel.
                ReadUncommitted); // default is System.Data.IsolationLevel.ReadCommitted
            Console.WriteLine("Transaction with Level: " + t.GetDbTransaction().
                IsolationLevel);

            // Load flight with read lock using WITH (UPDLOCK)
            Console.WriteLine("Load flight using SQL...");

Figure 11-4 provides evidence that in fact a second process cannot read FlightNo 101 as long as the first process has not yet completed its transaction. In this sample code, processing waits for user input in the middle of the transaction. User input in a transaction is of course a “worst practice” and should never occur in productive code. Here in the example code, however, it is a useful tool to simulate a transaction’s runtime over several seconds until the other process times out.

Figure 11-4. If the program code runs twice in parallel, in the second run the process will time out because the first process has a read lock on the record

Note I must reiterate that such a data record lock in the database management system is not a good practice. Locks, especially read locks, slow down applications and also quickly lead to deadlocks, where processes wait for each other so that processing can no longer take place. Such practices harm the performance, scalability, and stability of software. Why did I even show it in this chapter? Because I know some developers who still want it.

Incidentally, a better alternative to record locks in the database management system is to use locks at the application level, where the application manages the locks, possibly also using a self-defined lock table in RAM. This has the advantage that the application can accurately present to the user, who is currently working on a record. For example, user Müller can say, “This record is still available for 4 minutes and 29 seconds for exclusive editing by you.” And Mrs. Meier says, “This data set is currently being processed by Mr. Müller. He still has 4 minutes and 29 seconds to save the record. During this time, you cannot make any changes to this record.” This offers many more possibilities. For example, you can have the button say “I am a star, and now I want to kick out Mr. Müller immediately from the record.” However, there is no predefined mechanism for application-level locking in Entity Framework Core. Here your own creativity is in demand!

CHAPTER 12

Logging

In the classic Entity Framework, there are two easy ways to get the SQL commands that the OR mapper sends to the database.

- You can call `ToString()` on a query object (`IQueryable<T>`).
- You can use the `Log` attribute (since Entity Framework version 6.0), as in `ctx.Database.Log = Console.WriteLine;`

Unfortunately, neither of these options is available in Entity Framework Core. The following command

```
var query = ctx.FlightSet.Where(x => x.FlightNo > 300).OrderBy(x =>
x.- Date).Skip(10).Take(5);
Console.WriteLine (query.ToString());
```

only delivers the following output: `Microsoft.EntityFrameworkCore.Query.Internal.EntityQueryable`1 [B0.Flight]`.

The `ctx.Database` object has no `log` attribute in Entity Framework Core.

Using the Extension Method `Log()`

Logging in Entity Framework Core is possible, but it's much more complicated than in its predecessor. Therefore, I created an extension to the `Database` object in the form of the `Log()` extension method for the `DbContext` class. It is a method, not an attribute, because in .NET unfortunately there are only extension methods and no extension attributes.

Note The `Log()` method is used in a few listings in this book.

You can use the method `Log()` like this:

```
using (var ctx1 = new WWWingsContext())
{
    var query1 = ctx1.FlightSet.Where(x => x.FlightNo > 100).OrderBy(x =>
    x.Date).Skip(10).Take(5);
    ctx1.Log(Console.WriteLine);
    var flightSet1 = query1.ToList();
    flightSet1.ElementAt(0).FreeSeats--;
    ctx1.SaveChanges();
}
```

Similar to the `Log` attribute in Entity Framework, `Log()` is a method with no return value; it expects a string as the only parameter. Unlike the classic Entity Framework, you can omit the parameter in `Log()`. Then the output will be printed automatically to `Console.WriteLine()` in the color cyan (see Figure 12-1).

```
using (var ctx2 = new WWWingsContext())
{
    var query2 = ctx2.FlightSet.Where(x => x.FlightNo < 3000).OrderBy(x =>
    x.Date).Skip(10).Take(5);
    ctx2.Log();
    var flightSet2 = query2.ToList();
    flightSet2.ElementAt(0).FreeSeats--;
    ctx2.SaveChanges();
}
```

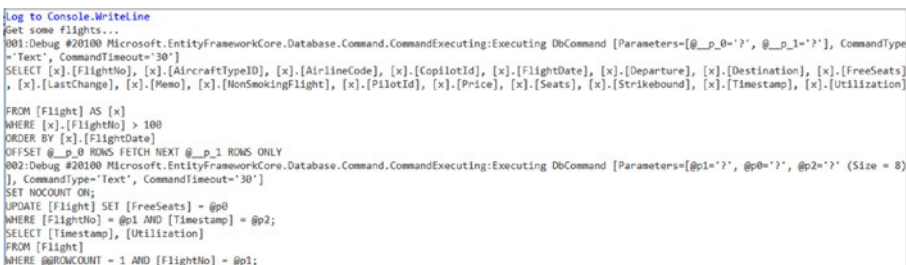

Figure 12-1. Default logging for the `Log()` method

If you want to log to a file, you can do that by writing a method with a string parameter and no return value and by passing it to `Log()`.

```
using (var ctx3 = new WWWingsContext())
{
    Console.WriteLine("Get some flights...");
    var query3 = ctx3.FlightSet.Where(x => x.FlightNo > 100).OrderBy(x =>
    x.Date).Skip(10).Take(5);
    ctx3.Log(LogToFile);
    var flightSet3 = query3.ToList();
    flightSet3.ElementAt(0).FreeSeats--;
    ctx3.SaveChanges();
}
}

public static void LogToFile(string s)
{
    Console.WriteLine(s);
    var sw = new StreamWriter(@"c:\temp\log.txt");
    sw.WriteLine(DateTime.Now + ": " + s);
    sw.Close();
}
```

By default, the `Log()` method logs only those commands sent to the DBMS. Two other parameters of the `Log()` method affect the amount of logging, shown here:

- Parameter 2 is a list of logging categories (strings).
- Parameter 3 is a list of event numbers (numbers).

The next command will print all the log output from Entity Framework Core (which produces a lot of screen output for each command):

```
ctx1.Log(Console.WriteLine, new List<string>(), new List<int>());
```

The next command will print only certain logging categories and event numbers:

```
ctx1.Log(Console.WriteLine, new List<string>() { "Microsoft.
EntityFrameworkCore.Database.Command" }, new List<int>() { 20100, 20101});
```

Event 20100 is Executing, and 20101 is Executed.

Note Because Entity Framework Core assigns the internally used Logger Factory classes not to one context instance but to all context instances, an established logging method on a particular instance also applies to other instances of the same context class.

Implementing the Log() Extension Method

Listing 12-1 shows the implementation of the extension method Log().

- The Log() extension method adds an instance of a logger provider to the ILoggerFactory service.
- A logger provider is a class that implements ILoggerProvider. In this class, Entity Framework Core calls CreateLogger() once for each logging category.
- CreateLogger() must then supply a logger instance for each logging category.
- A logger is a class that implements ILogger.
- Listing 12-1 has a FlexLogger class that sends a string to the method specified by Log(). If no method is specified, Console.WriteLineColor() is called.
- A second logger class is NullLogger, which discards the log output for all log categories that have nothing to do with the SQL output.

Logging Categories

Unfortunately, Microsoft changed the names of the logging categories between Entity Framework Core versions 1.x and 2.0.

The following are the logging categories in Entity Framework Core 1.x:

- Microsoft.EntityFrameworkCore.Storage.Internal.
SQLServerConnection
- Microsoft.EntityFrameworkCore.Storage.IExecutionStrategy
- Microsoft.EntityFrameworkCore.Internal.
RelationalModelValidator
- Microsoft.EntityFrameworkCore.Query.Internal.
SqlServerQueryCompilationContextFactory
- Microsoft.EntityFrameworkCore.Query.Translators expression.
Internal.SqlServerCompositeMethodCallTranslator
- Microsoft.EntityFrameworkCore.Storage.
IRelationalCommandBuilderFactory
- Microsoft.EntityFrameworkCore.Query.Internal.QueryCompiler
- Microsoft.EntityFrameworkCore.DbContext

The following are the logging categories in Entity Framework Core 2.0:

- Microsoft.EntityFrameworkCore.Infrastructure
- Microsoft.EntityFrameworkCore.Update
- Microsoft.EntityFrameworkCore.Database.Transaction

- `Microsoft.EntityFrameworkCore.Database.Connection`
- `Microsoft.EntityFrameworkCore.Model.Validation`
- `Microsoft.EntityFrameworkCore.Query`
- `Microsoft.EntityFrameworkCore.Database.Command`

The implementation of the `Log()` extension method takes this change into account; it also considers the category `Microsoft.EntityFrameworkCore.Query`, which has two events: `Executing` (event ID 20100) and `Executed` (event ID 20101). `Log()` outputs only the event ID 20100 in the standard system. However, categories and event IDs are controllable through the parameters of `Log()`.

CHAPTER 13

Asynchronous Programming

.NET has supported simplified asynchronous, task-based programming with `async` and `await` since .NET Framework 4.5. The classic ADO.NET Entity Framework has supported related asynchronous operations since version 6.0. In Entity Framework Core, you have been able to use asynchronous operations since version 1.0.

Asynchronous Extension Methods

Entity Framework Core allows both the reading and writing of data with the asynchronous design pattern. For this Microsoft extended the result set delivering LINQ conversion and aggregate operators in the `Microsoft.EntityFrameworkCore`. `EntityFrameworkQueryableExtensions` class with asynchronous variants. Now you can find here for example, the `EntityFrameworkQueryableExtensions` class includes the extension methods `ToListAsync()` and `ToArrayAsync()`; the methods `SingleAsync()`, `FirstAsync()`, `SingleOrDefaultAsync()`, and `FirstOrDefaultAsync()`; and aggregate functions such as `CountAsync()`, `AllAsync()`, `AnyAsync()`, `AverageAsync()`, `MinAsync()`, `MaxAsync()`, and `SumAsync()`. The `SaveChangesAsync()` method is used for saving. Putting a `using Microsoft.EntityFrameworkCore` line in your code is a prerequisite to using these extension methods.

ToListAsync()

Listing 13-1 shows how to use ToListAsync(). The only differences from a synchronous call with the same result set are in these two lines:

- The subprocedure ReadDataAsync() is declared as async.
- Instead of query.ToList(), now await query.ToListAsync() is called.

Figure 13-1 shows that database queries and object materialization by Entity Framework Core are actually asynchronous with these marginal changes. This shows that the main program is already waiting for an input before the first Flight is issued. The output Start Database Query is still in thread 10. Then it returns to the main program, while the database query and the remainder of the procedure ReadDataAsync() continue in thread 13.

```

SaveChangesAsync()

There is also an asynchronous operation for saving. Listing 13-2 shows how the threads switch to `ToList()` and `SaveChangesAsync()`, and Figure 13-2 shows the output.

ForEachAsync()

With Entity Framework, it is not necessary to explicitly materialize a query before an iteration with a conversion operator such as `ToList()`. A `foreach` loop over an object with an `IQueryable` interface is enough to trigger the database query. In this case, however, the database connection remains open while the loop is running, and the records are fetched individually by the iterator of the `IQueryable` interface.

You can also execute this construct asynchronously using the method `ForEachAsync()`, which retrieves a result set step-by-step and executes the method body of a method (an anonymous method in the form of a lambda expression in Listing 13-3) over all elements of the set.

As mentioned in Chapter 10, you have to use `SaveChangesAsync()` instead of `SaveChanges()` to avoid a transaction problem between the still-running read operation and the write operation.

Note If you want to use the result of `SaveChangesAsync()`: `var count = await ctx.SaveChangesAsync()`, you'll get the following runtime error: "New transaction is not allowed because there are other threads running in the session." The best solution is to not use `ForEachAsync()` and to use `ToListAsync()` instead!

Listing 13-3. Using `ForEachAsync()`

```
public static async void AsyncForeach()
{
    CUI.MainHeadline("Start " + nameof(AsyncForeach));
    WWingsContext ctx = new WWingsContext();
    // Define query
    var query = (from f in ctx.FlightSet.Include(p => p.BookingSet).
    ThenInclude(b => b.Passenger) where f.Departure == "Rome" && f.FreeSeats
    > 0 select f).Take(1);
    // Executing and iterate query with ForEachAsync
    CUI.PrintWithThreadID("Print objects");
    await query.ForEachAsync(async flight =>
    {
        // Print results
        CUI.PrintWithThreadID("Flight: " + flight.FlightNo + " from " + flight.
        Departure + " to " + flight.Destination + " has " + flight.FreeSeats + "
        free Seats");

        foreach (var p in flight.BookingSet)
        {
            CUI.PrintWithThreadID(" Passenger: " + p.Passenger.GivenName + " " +
            p.Passenger.Surname);
        }

        // Save changes to each flight object within the loop
        CUI.PrintWithThreadID(" Start saving");
        flight.FreeSeats--;
        await ctx.SaveChangesAsync();
    });
}
```

```
//not possible: var count = await ctx.SaveChangesAsync(); --> "New  
transaction is not allowed because there are other threads running in  
the session."  
  
CUI.PrintWithThreadID("  Changes saved!");  
});  
  
CUI.Headline("End " + nameof(AsyncForeach));  
}
```

CHAPTER 14

Dynamic LINQ Queries

One of the benefits of Language Integrated Query (LINQ) is that compilers can validate the instructions at design time. However, there are some real-world cases in which the executing command is not completely established at design time, for example, because the user selects from a number of drop-down filters on a screen. This chapter shows ways to make LINQ commands dynamic partially or fully in conjunction with Entity Framework Core.

Creating LINQ Queries Step-by-Step

LINQ queries are not executed until you execute a conversion operator (called *deferred execution*). Previously, you can extend a LINQ query with more conditions, but also with sorting and paging. Listing 14-1 shows how occasionally a condition for a departure or a destination, occasionally a filtering for flights with free seats and occasionally a sorting is to be added. The cases are controlled by the variables at the beginning, which represents a user input here.

Tip As long as you do not apply a conversion operator to a query, such as `ToList()`, `To Dictionary()`, `ToArray()`, or `First()/Single()`, or access on the enumerator or a single element (e.g., with `ElementAt()`), the query lingers in RAM and can still be modified.

Listing 14-1. Composing LINQ Commands

```

public static void LINQComposition()
{
    CUI.MainHeadline(nameof(LINQComposition));
    using (WWWingsContext ctx = new WWWingsContext())
    {
        ctx.Log();
        string departure = "Paris";
        string destination = "";
        bool onlyWithFreeSeats = true;
        bool sortieren = true;

        // Base query
        IQueryable<Flight> flightQuery = (from f in ctx.FlightSet select f);

        // Adding optional condition
        if (!String.IsNullOrEmpty(departure)) flightQuery = from f in
            flightQuery where f.Departure == departure select f;
        if (!String.IsNullOrEmpty(destination)) flightQuery = from f in
            flightQuery where f.Destination == destination select f;
        // Adding optional condition using a method
        if (onlyWithFreeSeats) flightQuery = FreeSeatsMustBeGreaterZero(flight
            Query);
        // Optional sorting
        if (sortieren) flightQuery = flightQuery.OrderBy(f => f.Date);

        // Send to the database now!
        List<Flight> flightSet = flightQuery.ToList();

        // Print the result set
        Console.WriteLine("Flights found:");
        foreach (var f in flightSet)

```

```

    {
        Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
        {f.Destination}: {f.FreeSeats} free seats! Pilot: {f.PilotId} ");
    }
}
}

static public IQueryable<Flight> FreeSeatsMustBeGreaterZero(IQueryable
<Flight> query)
{
    return query.Where(f => f.FreeSeats > 0);
}

```

The following SQL command is generated from this program code, in this case with a filter about Departure and FreeSeats and the sorting by flight date:

```

SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode], [f].
[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination], [f].
[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight], [f].
[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound], [f].[Timestamp],
[f].[Utilization]
FROM [Flight] AS [f]
WHERE ([f].[Departure] = @__departure_0) AND ([f].[FreeSeats] > 0)
ORDER BY [f].[FlightDate]

```

Expression Trees

Expression trees (.NET namespace `System.Linq.Expressions`) are the basis for all LINQ queries. Entity Framework Core converts every LINQ query into an expression tree. You can also work with expression trees directly, but it is usually very time-consuming.

The C# program code in Listing 14-2 first defines a LINQ query with a condition. Then, depending on the values of two local variables, the query is extended by two additional conditions. This program code also takes advantage of the fact that LINQ commands are not executed until the result set is actually needed (again, called *deferred execution*).

Listing 14-2. Extending LINQ Commands with Expression Trees

```

public static void ExpressionTreeTwoConditions()
{
    CUI.MainHeadline(nameof(ExpressionTreeTwoConditions));

    string destination = "Rome";
    short? minNumberOfFreeSeats = 10;

    using (WWWingsContext ctx = new WWWingsContext())
    {
        // Base query
        IQueryable<BO.Flight> query = from flight in ctx.FlightSet where
            flight.FlightNo < 300 select flight;

        // Optional conditions
        if (!String.IsNullOrEmpty(destination) && minNumberOfFreeSeats > 0)
        {
            // Define query variable
            ParameterExpression f = Expression.Parameter(typeof(BO.Flight), "f");

            // Add first condition
            Expression left = Expression.Property(f, "Destination");
            Expression right = Expression.Constant(destination);
            Expression condition1 = Expression.Equal(left, right);

            // Add second condition
            left = Expression.Property(f, "FreeSeats");
            right = Expression.Constant((short?)minNumberOfFreeSeats,
                typeof(short?));
            Expression condition2 = Expression.GreaterThan(left, right);

            // Connect conditions with AND operator
            Expression predicateBody = Expression.And(condition1, condition2);

            // Build expression tree
            MethodCallExpression whereCallExpression = Expression.Call(
                typeof(Queryable),

```

```

    "Where",
    new Type[] { query.ElementType },
    query.Expression,
    Expression.Lambda<Func<BO.Flight, bool>>(predicateBody, new
    ParameterExpression[] { f }));

// Create query from expression tree
query = query.Provider.CreateQuery<BO.Flight>(whereCallExpression);
}

ctx.Log();
// Print the result set
Console.WriteLine("Flights found:");
foreach (BO.Flight f in query.ToList())
{
    Console.WriteLine($"Flight No {f.FlightNo} from {f.Departure} to
    {f.Destination}: {f.FreeSeats} free seats! Pilot: {f.PilotId} ");
}
}
}
}

```

The listing generates the following SQL command:

```

SELECT [flight].[FlightNo], [flight].[AircraftTypeID], [flight].
[AirlineCode], [flight].[CopilotId], [flight].[FlightDate], [flight].
[Departure], [flight].[Destination], [flight].[FreeSeats], [flight].
[LastChange], [flight].[Memo], [flight].[NonSmokingFlight], [flight].
[PilotId], [flight].[Price], [flight].[Seats], [flight].[Strikebound],
[flight].[Timestamp], [flight].[Utilization]
FROM [Flight] AS [flight]
WHERE ([flight].[FlightNo] < 300) AND ((CASE
    WHEN [flight].[Destination] = N'Rome'
    THEN CAST(1 AS BIT) ELSE CAST(0 AS BIT)
END & CASE
    WHEN [flight].[FreeSeats] > 10
    THEN CAST(1 AS BIT) ELSE CAST(0 AS BIT)
END) = 1)

```

Of course, this also works with any number of conditions that are not fixed at runtime, as Listing 14-3 shows, in which the conditions are passed as SortedDictionary.

Listing 14-3. Extending LINQ Commands with Expression Trees

```
public static void ExpressionTreeNumerousConditions()
{
    CUI.MainHeadline(nameof(ExpressionTreeNumerousConditions));

    // Input data
    var filters = new SortedDictionary<string, object>() { { "Departure",
    "Berlin" }, { "Destination", "Rome" }, { "PilotID", 57 } };

    using (WWWingsContext ctx = new WWWingsContext())
    {
        ctx.Log();
        // Base query
        var baseQuery = from flight in ctx.FlightSet where flight.FlightNo <
        1000 select flight;

        ParameterExpression param = Expression.Parameter(typeof(BO.Flight), "f");

        Expression completeCondition = null;
        foreach (var filter in filters)
        {
            // Define condition
            Expression left = Expression.Property(param, filter.Key);
            Expression right = Expression.Constant(filter.Value);
            Expression condition = Expression.Equal(left, right);
            // Add to existing conditions using AND operator
            if (completeCondition == null) completeCondition = condition;
            else completeCondition = Expression.And(completeCondition, condition);
        }

        // Create query from expression tree
        MethodCallExpression whereCallExpression = Expression.Call(
            typeof(Queryable),
            "Where",
```

```

    new Type[] { baseQuery.ElementType },
    baseQuery.Expression,
    Expression.Lambda<Func<BO.Flight, bool>>(completeCondition, new
    ParameterExpression[] { param }));

// Create query from expression tree
var Q_Endgueltig = baseQuery.Provider.CreateQuery<BO.
Flight>(whereCallExpression);

// Print the result set
Console.WriteLine("Flights found:");
foreach (var f in Q_Endgueltig)
{
    Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
    {f.Destination}: {f.FreeSeats} free seats! Pilot: {f.PilotId} ");
}
}
}
}

```

Listing 14-3 results in the following SQL command:

```

SELECT [flight].[FlightNo], [flight].[AircraftTypeID], [flight].
[AirlineCode], [flight].[CopilotId], [flight].[FlightDate], [flight].
[Departure], [flight].[Destination], [flight].[FreeSeats], [flight].
[LastChange], [flight].[Memo], [flight].[NonSmokingFlight], [flight].
[PilotId], [flight].[Price], [flight].[Seats], [flight].[Strikebound],
[flight].[Timestamp], [flight].[Utilization]
FROM [Flight] AS [flight]
WHERE ([flight].[FlightNo] < 1000) AND (((CASE
    WHEN [flight].[Departure] = N'Berlin'
    THEN CAST(1 AS BIT) ELSE CAST(0 AS BIT)
END & CASE
    WHEN [flight].[Destination] = N'Rome'
    THEN CAST(1 AS BIT) ELSE CAST(0 AS BIT)
END) & CASE
    WHEN [flight].[PilotId] = 57
    THEN CAST(1 AS BIT) ELSE CAST(0 AS BIT)
END) = 1)

```

Using Dynamic LINQ

If creating LINQ queries step-by-step is not sufficient, you do not necessarily have to use expression trees. An alternative is to use the library Dynamic LINQ. Dynamic LINQ is not part of the .NET Framework and is not an official add-on. Dynamic LINQ is just an example that Microsoft used in a sample collection (see <http://weblogs.asp.net/scottgu/archive/2008/01/07/dynamic-linq-part-1-using-the-linq-dynamic-query-library.aspx>). However, this example was “ennobled” by a blog post by Scott Guthrie (<http://weblogs.asp.net/scottgu/archive/2008/01/07/dynamic-linq-part-1-using-the-linq-dynamic-query-library.aspx>) and has been widely used ever since. The original example had `System.Linq.Dynamic` in the root namespace `System`, which was unusual and suggested that Microsoft might integrate this into the .NET Framework in the future. This has not happened yet and does not seem to be on the agenda anymore. Dynamic LINQ consists of several classes with around 2,000 lines of code. The most important class is `DynamicQueryable`. This class provides many extension methods for the `IQueryable` interface, such as `Where()`, `OrderBy()`, `GroupBy()`, and `Select()`, all of which accept strings.

Listing 14-4 shows a solution with Dynamic LINQ that is more elegant than the expression tree solution.

Note Unfortunately, there are no dynamic joins in Dynamic LINQ., but you can find a solution on the Internet (<http://stackoverflow.com/questions/389094/how-to-create-a-dynamic-linq-join-extension-method>).

Listing 14-4. Use of Dynamic LINQ

```
public static void DynamicLINQNumerousCondition()
{
    CUI.MainHeadline(nameof(DynamicLINQNumerousCondition));
    // input data
    var filters = new SortedDictionary<string, object>() { { "Departure",
    "Berlin" }, { "Destination", "Rome" }, { "PilotID", 57 } };
    string sorting = "FreeSeats desc";
```

```

using (WWWingsContext ctx = new WWWingsContext())
{
    ctx.Log();
    // base query
    IQueryable<BO.Flight> query = from flight in ctx.FlightSet where
    flight.FlightNo < 1000 select flight;

    // Add conditions
    foreach (var filter in filters)
    {
        Console.WriteLine(filter.Value.GetType().Name);
        switch (filter.Value.GetType().Name)
        {
            case "String":
                query = query.Where(filter.Key + " = \"" + filter.Value + "\""); break;

            default:
                query = query.Where(filter.Key + " = " + filter.Value); break;
        }
    }

    // optional sorting
    if (!String.IsNullOrEmpty(sorting)) query = query.OrderBy(sorting);

    // Print the result set
    Console.WriteLine("Flights found:");
    foreach (var f in query)
    {
        Console.WriteLine($"Flight Nr {f.FlightNo} from {f.Departure} to
        {f.Destination}: {f.FreeSeats} free seats!");
    }
}
}

```

The following SQL command results from this program code:

```
SELECT [flight].[FlightNo], [flight].[AircraftTypeID], [flight].  
[AirlineCode], [flight].[CopilotId], [flight].[FlightDate], [flight].  
[Departure], [flight].[Destination], [flight].[FreeSeats], [flight].  
[LastChange], [flight].[Memo], [flight].[NonSmokingFlight], [flight].  
[PilotId], [flight].[Price], [flight].[Seats], [flight].[Strikebound],  
[flight].[Timestamp], [flight].[Utilization]  
FROM [Flight] AS [flight]  
WHERE ((([flight].[FlightNo] < 1000) AND ([flight].[Departure] = N'Berlin'))  
AND ([flight].[Destination] = N'Rome')) AND ([flight].[PilotId] = 57)  
ORDER BY [flight].[FreeSeats] DESC
```

CHAPTER 15

Reading and Modifying Data with SQL, Stored Procedures, and Table-Valued Functions

If LINQ and the Entity Framework Core API are not sufficient in terms of functionality or performance, you can send any SQL commands directly to the database, including invoking stored procedures and using table-value functions (TVFs).

LINQ and the Entity Framework Core API (`Add()`, `Remove()`, `SaveChanges()`, and so on) are abstractions of SQL. Entity Framework Core (or the respective database provider) converts LINQ and API calls to SQL. The abstraction that Entity Framework Core offers here is, in many cases, well-suited to sending efficient, robust database management system-neutral commands to the database. But LINQ and the API cannot do everything that SQL can do, and not everything that Entity Framework Core sends to the database is always powerful enough.

Even in the classic Entity Framework, you were able to send SQL commands to the database instead of using LINQ. In Entity Framework Core, you have some of these same abilities, but they take a different form. In some cases there are more options, but in other situations there are fewer options than in the classic Entity Framework.

Writing Queries with FromSql()

For SQL queries that return an entity type known to the Entity Framework Core context, the `FromSql()` and `FromSql<EntityType>()` methods are available in the `DbSet<EntityType>` class. The result is an `IQueryable<EntityType>` (see Listing 15-1).

Note You should not compose the SQL commands as a string because this carries the risk of a SQL injection attack.

Listing 15-1. SQL Query in Entity Framework Core, Risking a SQL Injection Attack

```
public static void Demo_SQLDirect1()
{
    CUI.MainHeadline(nameof(Demo_SQLDirect1));
    string departure = "Berlin";
    using (var ctx = new WWingsContext())
    {
        ctx.Log();
        IQueryable<Flight> flightSet = ctx.FlightSet.FromSql("Select * from
        Flight where Departure='" + departure + "'");
        Console.WriteLine(flightSet.Count());
        foreach (var flight in flightSet)
        {
            Console.WriteLine(flight);
        }
        Console.WriteLine(flightSet.Count());
    }
}
```

It is better to use the .NET placeholders `{0}`, `{1}`, `{2}`, and so on (see Listing 15-2). These placeholders are handled by Entity Framework Core as parameterized SQL commands so that a SQL injection attack is not possible.

Listing 15-2. SQL Query in Entity Framework Core Without the Risk of SQL Injection Attack

```

public static void Demo_SQLDirect2()
{
    CUI.MainHeadline(nameof(Demo_SQLDirect2));
    string departure = "Berlin";
    using (var ctx = new WWWingsContext())
    {
        ctx.Log();
        IQueryable<Flight> flightSet = ctx.FlightSet.FromSql("Select * from
Flight where Departure={0}", departure);
        Console.WriteLine(flightSet.Count());
        foreach (var flight in flightSet)
        {
            Console.WriteLine(flight);
        }
        Console.WriteLine(flightSet.Count());
    }
}

```

Since Entity Framework Core 2.0, it is even possible to use string interpolation, which has existed since C# 6.0 (see Listing 15-3).

Listing 15-3. Third Variant of SQL Query in Entity Framework

```

public static void Demo_SQLDirect3()
{
    CUI.MainHeadline(nameof(Demo_SQLDirect3));
    string departure = "Berlin";
    string destination = "Rome";
    using (var ctx = new WWWingsContext())
    {
        ctx.Log();
        IQueryable<Flight> flightSet = ctx.FlightSet.FromSql($"Select * from
Flight where Departure={departure} and Destination={destination}");
        Console.WriteLine(flightSet.Count());
    }
}

```

```

foreach (var flight in flightSet)
{
    Console.WriteLine(flight);
}
Console.WriteLine(flightSet.Count());
}
}

```

In Listing 15-2 and Listing 15-3 you do not have to put the placeholders in single quotes. Strictly speaking, you should not use single quotes here because Entity Framework Core converts the query into a parameterized query (the parameters become an instance of the class `dbParameter`). In both listings, the database receives a SQL command with a parameter, as shown here:

```
Select * from Flight where departure = @p0
```

or with two parameters, as shown here:

```
Select * from Flight where departure= @p0 and destination = @p1
```

You are therefore protected against SQL injection attacks; you should never compose the SQL command as a string to avoid such vulnerabilities!

As with the classic Entity Framework, the SQL command must supply all columns to completely populate the entity object. A partial filling (projection) is not supported yet. Any attempt at partial filling fails because Entity Framework Core complains at runtime with the following error message: “The required column xy was not present in the results of a FromSql.” This happens until all the properties of the entity object have counterparts in the result set.

Using LINQ and SQL Together

The implementation in the classic Entity Framework was called `DbSet<EntityClass>.SqlQuery()` and did not return an `IQueryable<EntityClass>` as the return object; instead it returned an instance of `DbRawSqlQuery<EntityType>`. Returning `IQueryable<EntityClass>` has the advantage that you can now mix SQL and LINQ in one query.

Here's an example:

```
IQueryable<Flight> Flightlist = ctx.FlightSet.FromSql("Select * from Flight
where departure = {0}", location);
Console.WriteLine (Flight list.Count());
foreach(var Flight in Flight list) {...}
```

Here Entity Framework Core will convert `flightSet.Count()` to the following:

```
SELECT COUNT(*)
FROM (
    Select * from Flight where departure = 'Berlin'
) AS [f]
```

The self-written SQL command is thus embedded as a subquery in the query that is generated by the LINQ operation.

In this case, there are three round-trips to the database, two for counting and one for collecting the records. As with LINQ, you should make sure to use a conversion operator such as `ToList()` when using `FromSql()`. In Listing 15-4, the result set will now be fetched directly, and instead of counting three-times, you have only one query of the length of the materialized object set in RAM, which is much faster!

Listing 15-4. `ToList()` Ensures That There Is Only One Round-Trip to the Database

```
public static void Demo_SQLDirect4()
{
    CUI.MainHeadline(nameof(Demo_SQLDirect4));
    string departure = "Berlin";
    using (var ctx = new WWWingsContext())
    {
        ctx.Log();
        List<Flight> flightSet = ctx.FlightSet.FromSql($"Select * from Flight
where Departure={departure}").ToList();
        Console.WriteLine(flightSet.Count());
        foreach (var flight in flightSet)
        {
            Console.WriteLine(flight);
        }
    }
}
```

```

    Console.WriteLine(flightSet.Count());
}
}

```

Even more impressively, Listing 15-5 shows the possibility to combine SQL and LINQ together in Entity Framework Core, where `Include()` even loads linked records. This otherwise Listing is impossible with `FromSql()`.

Listing 15-5. Compiling SQL and LINQ in Entity Framework Core

```

public static void Demo_SQLDirectAndLINQComposition()
{
    CUI.MainHeadline(nameof(Demo_SQLDirectAndLINQComposition));
    string departure = "Berlin";
    using (var ctx = new WWWingsContext())
    {
        ctx.Log();
        var flightSet = ctx.FlightSet.FromSql("Select * from Flight where
        Departure={0}", departure).Include(f => f.Pilot).Where(x => x.FreeSeats >
        10).OrderBy(x => x.FreeSeats).ToList();
        Console.WriteLine(flightSet.Count());
        foreach (var flight in flightSet)
        {
            Console.WriteLine(flight);
        }
        Console.WriteLine(flightSet.Count());
    }
}

```

With the program code from Listing 15-5, the database receives the following SQL command:

```

SELECT [x].[FlightNo], [x].[AircraftTypeID], [x].[AirlineCode], [x].
[CopilotId], [x].[FlightDate], [x].[Departure], [x].[Destination], [x].
[FreeSeats], [x].[LastChange], [x].[Memo], [x].[NonSmokingFlight], [x].
[PilotId], [x].[Price], [x].[Seats], [x].[Strikebound], [x].[Timestamp],
[x].[Utilization], [x.Pilot].[PersonID], [x.Pilot].[Birthday], [x.Pilot].

```

```

[DetailID], [x.Pilot].[Discriminator], [x.Pilot].[EMail], [x.Pilot].
[GivenName], [x.Pilot].[PassportNumber], [x.Pilot].[Salary], [x.Pilot].
[SupervisorPersonID], [x.Pilot].[Surname], [x.Pilot].[FlightHours],
[x.Pilot].[FlightSchool], [x.Pilot].[LicenseDate], [x.Pilot].
[PilotLicenseType]
FROM (
    Select * from Flight where Departure=@p0
) AS [x]
INNER JOIN [Employee] AS [x.Pilot] ON [x].[PilotId] = [x.Pilot].[PersonID]
WHERE ([x.Pilot].[Discriminator] = N'Pilot') AND ([x].[FreeSeats] > 10)
ORDER BY [x].[FreeSeats]

```

Using Stored Procedures and Table-Valued Functions

With `FromSql()` you can also call stored procedures, which provide a result set, and you can call table-valued functions elegantly (Listing 15-6). It should be noted, however, that the composability works only with table-valued functions.

Listing 15-6. Using a Stored Procedure That Delivers Flight Records

```

/// <summary>
/// Use of a stored procedure that delivers Flight records
/// </summary>

public static void Demo_SP()
{
    CUI.MainHeadline(nameof(Demo_SP));

    using (var ctx = new WWWingsContext())
    {
        ctx.Log();
        var flightSet = ctx.FlightSet.FromSql("EXEC GetFlightsFromSP {0}",
            "Berlin").Where(x => x.FreeSeats > 0).ToList();
        Console.WriteLine(flightSet.Count());
        foreach (var flight in flightSet)

```

```

{
    Console.WriteLine(flight);
}
Console.WriteLine(flightSet.Count());
}
}

```

This listing runs the following statement in the database:

```
EXEC GetFlightsFromSP @p0
```

The supplementary conditions (here, `FreeSeats`) are executed in RAM.

In Listing 15-7, however, the additional condition is executed in the database management system because a table-valued function is called here.

Listing 15-7. Using a Table-Valued Function That Delivers Flight Records

```

public static void Demo_TVF()
{
    CUI.MainHeadline(nameof(Demo_TVF));
    using (var ctx = new WWWingsContext())
    {
        ctx.Log();
        var flightSet = ctx.FlightSet.FromSql("Select * from
        GetFlightsFromTVF({0})", "Berlin").Where(x => x.FreeSeats > 10).ToList();
        Console.WriteLine(flightSet.Count());
        foreach (var flight in flightSet)
        {
            Console.WriteLine(flight);
        }
        Console.WriteLine(flightSet.Count());
    }
}

```

Listing 15-7 runs the following in the database:

```

SELECT [x].[FlightNo], [x].[AircraftTypeID], [x].[AirlineCode], [x].
[CopilotId], [x].[FlightDate], [x].[Departure], [x].[Destination], [x].
[FreeSeats], [x].[LastChange], [x].[Memo], [x].[NonSmokingFlight], [x].

```

```
[PilotId], [x].[Price], [x].[Seats], [x].[Strikebound], [x].[Timestamp],
[x].[Utilization]
FROM (
    Select * from GetFlightsFromTVF(@p0)
) AS [x]
WHERE [x].[FreeSeats] > 10
```

However, in Entity Framework Core, there is neither a program code generator for wrapper methods for stored procedures and table-valued functions (as is available in Database First in the classic Entity Framework) nor a SQL generator for stored procedures for INSERT, UPDATE, and DELETE (as available with Code First in the classic Entity Framework).

Tip The third-party tool Entity Developer (see Chapter 20) provides a program code generator for wrapper methods for stored procedures and table-valued functions.

Using Nonentity Classes as Result Sets

Unfortunately, there is also (at least so far) a big limitation in Entity Framework Core compared to its predecessor. In the classic Entity Framework, `SqlQuery()` was not only offered on instances of the class `DbSet<EntityType>` but also in the `Database` object in the context class. You could also specify other types that were not entity types, in other words, other self-defined classes or even elementary data types, in which the classic Entity Framework would materialize the query results.

Unfortunately, Entity Framework Core cannot do this yet (<https://github.com/aspnet/EntityFramework/issues/1862>). Any attempt to specify an object type other than `FromSql()` as the entity type does not compile.

```
var flightSet = ctx.FromSql<FlighDTO>("Select FlightNo, Departure,
Destination, Date from Flight");
```

An experiment with the following method `Set <T>()`:

```
flightSet = ctx.Set<FlighDTO>().FromSql("Select FlightNo, Departure,
Destination, Date from Flight");
```

compiles, but Entity Framework Core then says at runtime that this is not supported: “Cannot create a dbSet for 'FlightDTO' because this type is not included in the model for the context.”

Preview Microsoft will introduce mapping to arbitrary types in Entity Framework Core version 2.1; see Appendix C.

Listing 15-8 shows the retrofitting of an `ExecuteSqlQuery()` method in the `Database` object, which returns only one `DbDataReader` object and does not allow materialization. This extension method will then be used in Listing 15-9.

Listing 15-8. Database Extension Method `ExecuteSqlQuery()`

```
public static class RDBFacadeExtensions
{
    public static RelationalDataReader ExecuteSqlQuery(this DatabaseFacade
databaseFacade, string sql, params object[] parameters)
    {
        var concurrencyDetector = databaseFacade.GetService<IConcurrencyDetector>();
        using (concurrencyDetector.EnterCriticalSection())
        {
            var rawSqlCommand = databaseFacade
                .GetService<IRawSqlCommandBuilder>()
                .Build(sql, parameters);

            return rawSqlCommand
                .RelationalCommand
                .ExecuteReader(
                    databaseFacade.GetService<IRelationalConnection>(),
                    parameterValues: rawSqlCommand.ParameterValues);
        }
    }
}
```

Listing 15-9. Using Database.ExecuteSqlCommand()

```

public static void Demo_Datareader()
{
    CUI.MainHeadline(nameof(Demo_Datareader));
    string Ort = "Berlin";
    using (var ctx = new WWingsContext())
    {
        RelationalDataReader rdr = ctx.Database.ExecuteSqlCommand("Select * from
        Flight where Departure={0}", Ort);
        DbDataReader dr = rdr.DbDataReader;
        while (dr.Read())
        {
            Console.WriteLine("{0}\t{1}\t{2}\t{3} \n", dr[0], dr[1], dr[2], dr[3]);
        }
        dr.Dispose();
    }
}

```

Using SQL DML Commands Without Result Sets

SQL Data Manipulation Language (DML) commands that do not return a result set such as INSERT, UPDATE, and DELETE can be executed in Entity Framework Core exactly like in the classic Entity Framework with ExecuteSqlCommand() in the Database object. You will get back the number of affected records (see Listing 15-10).

Listing 15-10. Using Database.ExecuteSqlCommand()

```

public static void Demo_SqlCommand()
{
    CUI.MainHeadline(nameof(Demo_SqlCommand));
    using (var ctx = new WWingsContext())
    {
        var count = ctx.Database.ExecuteSqlCommand("Delete from Flight where
        flightNo > {0}", 10000);
        Console.WriteLine("Number of deleted records: " + count);
    }
}

```

CHAPTER 16

Tips and Tricks for Mapping

This chapter describes additional ways to influence the mapping of entity classes to the database schema. Many of these possibilities are not shown in the example of World Wide Wings because they do not fit into it well.

Shadow Properties

Entity Framework Core can create *shadow properties* (aka *shadow state properties*) for those columns of the database table for which there is no corresponding property or field in the entity class.

Automatic Shadow Properties

A shadow property is created automatically if there is no matching foreign key property in the entity class for a navigation relationship. Because the database schema needs a foreign key column for most relations, this column automatically becomes a shadow property. If the counterpart to a navigation relationship has several primary key columns, then several foreign key columns with one shadow property each are created accordingly.

The foreign key column and the shadow property are formed from the name of the navigation property and the primary key name of the main class. In doing so, Entity Framework Core avoids word duplications (see Table 16-1).

Table 16-1. Automatic Naming for Shadow Properties

Primary Key of the Main Class	Name of the Navigation Property	Name of the Foreign Key Column/Shadow Property
MainClassID	MainClass	MainClassID
ID	MainClass	MainClassID
ID	Anything	AnythingID
MainClassID	Anything	AnythingMainClassID
MainClassID1 and MainClassID2 (composite key)	Anything	AnythingMainClassID1 and AnythingMainClassID2

Defining a Shadow Property

You can also define shadow properties manually using the `Property()` method. Listing 16-1 shows how to add a `DateTime` shadow property named `LastChange`. This name, however, is stored in a variable and thus can be changed.

Note Changing the content of the variable `ShadowPropertyName` must be done before the first instantiation of the context class because `OnModelCreating()` is called only once, the first time the context class is used.

Listing 16-1. Defining a Shadow Property in `OnModelCreating()` of the Context Class

```
public class WWingsContext: DbContext
{
    static public string ShadowPropertyName = "LastChange";
    ...
    protected override void OnModelCreating (ModelBuilder builder)
```

```

{
...
builder.Entity<Flight>().Property<DateTime>(ShadowPropertyName);
}
}

```

Getting the Output of All Shadow Properties of an Entity Class

You can obtain the list of all properties of an entity class (the real properties and the shadow properties) from the Properties object set of the EntityEntry<T> instance, which is obtained via the Entry() method of the context class (Listing 16-2).

Listing 16-2. Printing a List of All Properties of an Entity Class Including the Shadow Properties

```

using (WWWingsContext ctx = new WWWingsContext())
{
    var flight = ctx.FlightSet.SingleOrDefault(x => x.FlightNo == flightNo);

    foreach (var p in ctx.Entry(flight).Properties)
    {
        Console.WriteLine(p.Metadata.Name + ": " + p.Metadata.IsShadowProperty);
    }
}

```

Reading and Changing a Shadow Property

A shadow property cannot be used directly on the entity object since there is no real property for the corresponding database column. The use therefore takes place via an instance of EntityEntry<T>, which is obtained via the method Entry() of the context class. You can then call the method Property("ColumnName") and query the CurrentValue property from the supplied PropertyEntry object.

```
ctx.Entry(flight).Property("LastChange").CurrentValue
```

Incidentally, this way you can access any information from an entity object, including real properties.

```
ctx.Entry(flight).Property("FreeSeats").CurrentValue
```

However, this is usually not done because access through the entity object is easier.

```
flight.FreeSeats
```

Note You can only access real properties and shadow properties via `Property("Name")`. If the database table has additional columns, they are not accessible by Entity Framework. The call `ctx.Entry(Flight).Property("abc").CurrentValue` causes the following runtime error: “The property 'abc' on entity type 'Flight' could not be found. Ensure that the property exists and has been included in the model.”

You can also change the value via `CurrentValue`, as shown here:

```
ctx.Entry(Flight).Property("LastChange").CurrentValue = DateTime.Now;
```

Listing 16-3 shows the use of the `LastChange` shadow property on the `Flight` entity class.

Listing 16-3. Using a Shadow Property

```
public static void ReadAndChangeShadowProperty()
{
    int flightNo = 101;
    CUI.MainHeadline(nameof(ReadAndChangeShadowProperty));

    using (WWWingsContext ctx = new WWWingsContext())
    {
        var flight = ctx.FlightSet.SingleOrDefault(x => x.FlightNo == flightNo);

        CUI.Headline("List of all shadow property of type Flight");
        foreach (var p in ctx.Entry(flight).Properties)
```

```

{
    Console.WriteLine(p.Metadata.Name + ": " + p.Metadata.IsShadowProperty);
}

CUI.Print("Before: " + flight.ToString() + " / " + ctx.Entry(flight).
State, ConsoleColor.Cyan);
Console.WriteLine("Free seats: " + ctx.Entry(flight).
Property("FreeSeats").CurrentValue);
Console.WriteLine("Last change: " + ctx.Entry(flight).
Property("LastChange").CurrentValue);

CUI.PrintWarning("Changing object...");
flight.FreeSeats += 1;
ctx.Entry(flight).Property("LastChange").CurrentValue = DateTime.Now;

CUI.Print("After: " + flight.ToString() + " / " + ctx.Entry(flight).
State, ConsoleColor.Cyan);
Console.WriteLine("Free seats: " + ctx.Entry(flight).
Property("FreeSeats").CurrentValue);
Console.WriteLine("Last change: " + ctx.Entry(flight).
Property("LastChange").CurrentValue);

var count = ctx.SaveChanges();
Console.WriteLine("Number of saved changes: " + count);
}
}

```

Writing LINQ Queries with Shadow Properties

You can also use shadow properties in Language Integrated Query (LINQ). Here you cannot use `Entry()` and `Property()`; you must use the special construct `EF.Property<T>()`. The class `EF` is a static class of Entity Framework Core.

This construct is not only allowed in conditions but also in sorting and projections. Listing 16-4 identifies the last change that occurred in the last two days.

Listing 16-4. LINQ Queries with Shadow Properties

```

CUI.Headline("LINQ query using a Shadow Property");
using (WWingsContext ctx = new WWingsContext())
{
    var date = ctx.FlightSet
        .Where(c => EF.Property<DateTime>(c, WWingsContext.ShadowStateProp) >
            DateTime.Now.AddDays(-2))
        .OrderByDescending(c => EF.Property<DateTime>(c, WWingsContext.
            ShadowStateProp))
        .Select(x => EF.Property<DateTime>(x, WWingsContext.ShadowStateProp))
        .FirstOrDefault();

    Console.WriteLine("Last change: " + date);
}

```

Practical Example: Automatically Updating the Shadow Property Every Time You Save

Shadow properties are especially useful if you want to hide information from the developer. Listing 16-5 shows how to override the `SaveChanges()` method in the context class, which will automatically update the `LastChange` shadow property to the current date and time each time a change to a `Flight` object is saved.

Listing 16-5. Using a Shadow Property in the Overwritten `SaveChanges()` Method

```

public override int SaveChanges()
{
    // Detect changes
    this.ChangeTracker.DetectChanges();

    // Search all new and changed flights
    var entries = this.ChangeTracker.Entries<Flight>()
        .Where(e => e.State == EntityState.Added || e.State == EntityState.
            Modified);
}

```

```

if (!String.IsNullOrEmpty(ShadowStateProp))
{
    // set the Shadow State column "LastChange" for all of them
    foreach (var entry in entries)
    {
        entry.Property(ShadowStateProp).CurrentValue = DateTime.Now;
    }
}

// Save changes (we do not need DetectChanges() to be called again!)
this.ChangeTracker.AutoDetectChangesEnabled = false;
var result = base.SaveChanges(); // Call base class now
this.ChangeTracker.AutoDetectChangesEnabled = true;
return result;
}

```

Computed Columns

Computed columns are, from the point of view of Entity Framework Core, those database columns whose value the database management system assigns. These can be as follows:

- Auto-increment value columns (identity columns) such as `PersonID` in the `Person` class and the classes `Employee`, `Pilot`, and `Passenger` derived from `Person`
- Timestamp columns (see Chapter 11)
- Columns with default values
- Columns with a calculation formula

Automatic SELECT

In all of these cases, Entity Framework Core responds with an automatic `SELECT` after any generated `INSERT` or `UPDATE` to read the new value of the calculated columns from the database management system into RAM. In the case of a default column, however,

this makes sense only after an INSERT. Entity Framework Core therefore knows three strategies with corresponding methods in the Fluent API:

- `ValueGeneratedOnAdd()`: A SELECT is executed only after an INSERT.
- `ValueGeneratedOnAddOrUpdate()`: A SELECT is executed both after an INSERT and after an UPDATE.
- `ValueGeneratedNever()`: No SELECT is executed after INSERT or UPDATE.

`ValueGeneratedNever()` is the default for all columns, except in these three cases:

- Primary key columns that consist of a single integer column of type `Int16` (`short`), `Int32` (`int`), or `Int64` (`long`) are created by default as auto-increment columns with `ValueGeneratedOnAdd()`.
- Default columns automatically get `ValueGeneratedOnAdd()`.
- Byte-array (`byte[]`) columns annotated with `[Timestamp]` are automatically given `ValueGeneratedOnAddOrUpdate()`.

Note While Microsoft SQL Server does allow identity columns of type `tinyint` (i.e., `byte`), Entity Framework Core always sets for the `Byte` data type, that the primary keys do not use auto-increment values.

Practical Example: Creating Columns with a Calculation Formula

In contrast to its predecessor, Entity Framework Core supports the definition of calculation formulas in the program code for forward engineering that are to be executed in the database management system.

You create a property for the calculated column in the entity class. For example, the entity class `Flight` will get a property called `Utilization`, which will be the percentage of booked seats. It also gets `Seats` (total number of seats in the aircraft) and `FreeSeats`. It makes sense to declare the setter of the `Utilization` property for the calculated column as `private` because no user of the object should be able to set the value. You cannot omit the setter completely here because Entity Framework Core needs a way to set the value received from the database management system.

```
public class Flight
{
    public int FlightNo {get; set; }
    ...
    public short Seats {get; set; }
    public short? FreeSeats {get; set; }
    public decimal? Utilization {get; private set; }
}
```

Now define a formula in the Fluent API in `OnModelCreating()` with `HasComputedColumnSql()`. In this case, the percentage utilization for each `Flight` is calculated from the number of free seats and the total seats.

```
modelBuilder.Entity<Flight>().Property(p => p.Utilization)
    .HasComputedColumnSql("100.0-(((FreeSeats]*1.0)/[Seats])*100.0");
```

Note It is not necessary to use `ValueGeneratedOnAddOrUpdate()` because `HasComputedColumnSql()` implies this strategy.

When creating a schema migration, you can see the formula again in the `MigrationBuilder` call.

```
public partial class v2_FlightCostload: Migration
{
    protected override void up (MigrationBuilder migrationBuilder)
    {
        migration builder.AddColumn<int>(
            name: "Utilization",
            table: "Flight",
            type: "decimal",
            nullable: true,
            computedColumnSql: "100.0-(((FreeSeats]*1.0)/
                [Seats])*100.0");
    }
    ...
}
```

You can also see this formula in the database schema (Figure 16-1).

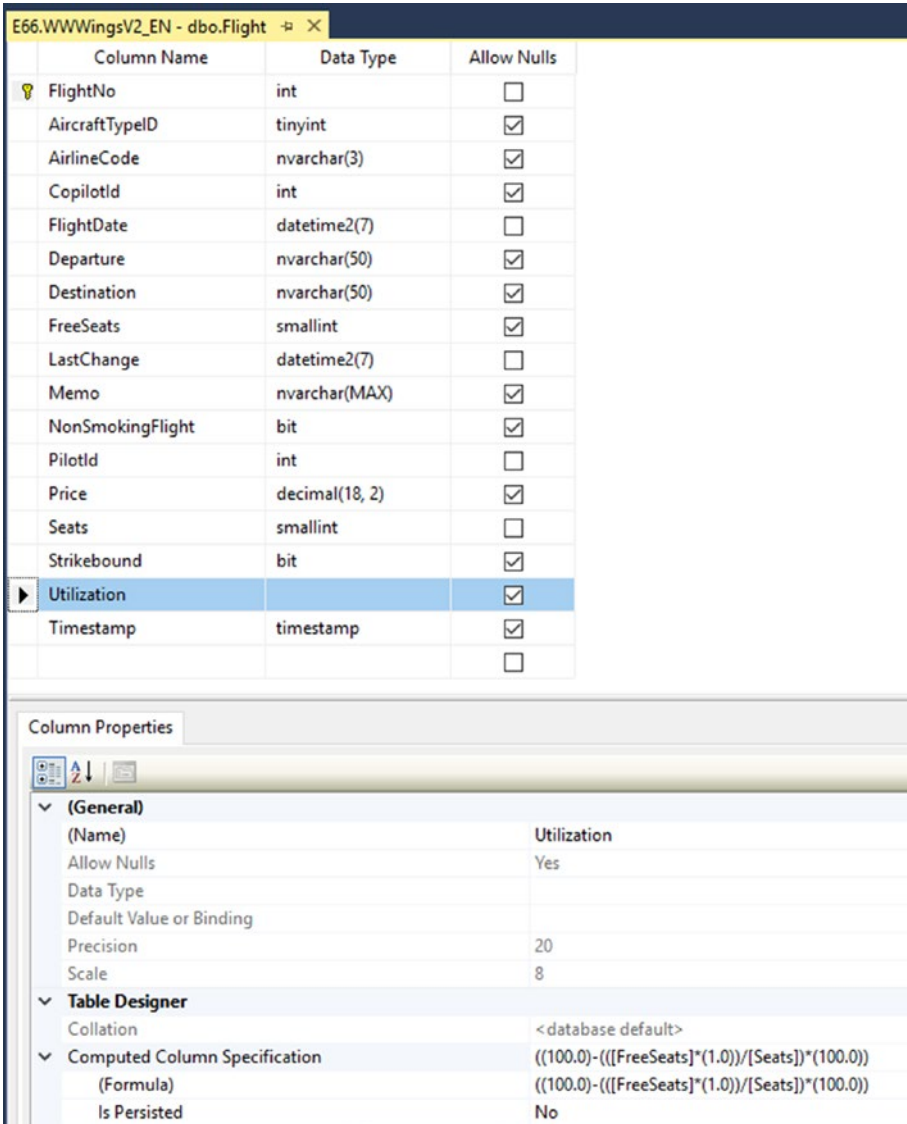

Figure 16-1. Calculation formula column in Microsoft SQL Server Management Studio

Using Columns with a Calculation Formula

The property of a column with a formula can be read like any other, as shown in Listing 16-6.

Note The value of a property of a column with a calculation formula column will not change until you have executed `SaveChanges()`. In Listing 16-6, the utilization initially shows the old value after the number of seats has been reduced. Only after `SaveChanges()` do get the new value.

Listing 16-6. The Utilization Column in the Flight Class Is Based on a Formula

```
public static void ComputedColumnWithFormula()
{
    CUI.MainHeadline(nameof(ComputedColumnWithFormula));

    int flightNo = 101;
    using (WWingsContext ctx = new WWingsContext())
    {
        ctx.Log();
        var flight = ctx.FlightSet.Find(flightNo);
        Console.WriteLine($"BEFORE: {flight}: Utilization={flight.
Utilization:##0.00}%");

        flight.FreeSeats -= 10;
        //not possible: flight.Utilization = 100;

        // The change is not yet visible in the Utilization, since the
        Utilization is calculated in the DBMS
        Console.WriteLine($"After changes: {flight}: Utilization={flight.
Utilization:##0.00}%");

        ctx.SaveChanges();
        // The change in Utilization is now visible
        Console.WriteLine($"After saving: {flight}: Utilization={flight.
Utilization:##0.00}%");
    }
}
```

```

CUI.Headline("Metadata of Flight properties");
foreach (PropertyEntry p in ctx.Entry(flight).Properties)
{
    Console.WriteLine(p.Metadata.Name + ": " + p.Metadata.ValueGenerated);
}
}
}
}

```

Figure 16-2 shows the output of Listing 16-6. Note the following:

- The utilization is updated only after SaveChanges().
- The utilization column has the strategy OnAddOrUpdate (what you get in a PropertyEntry object via Metadata.ValueGenerated).
- Therefore, after SaveChanges(), Entity Framework Core performs a SELECT on that value (and the timestamp).

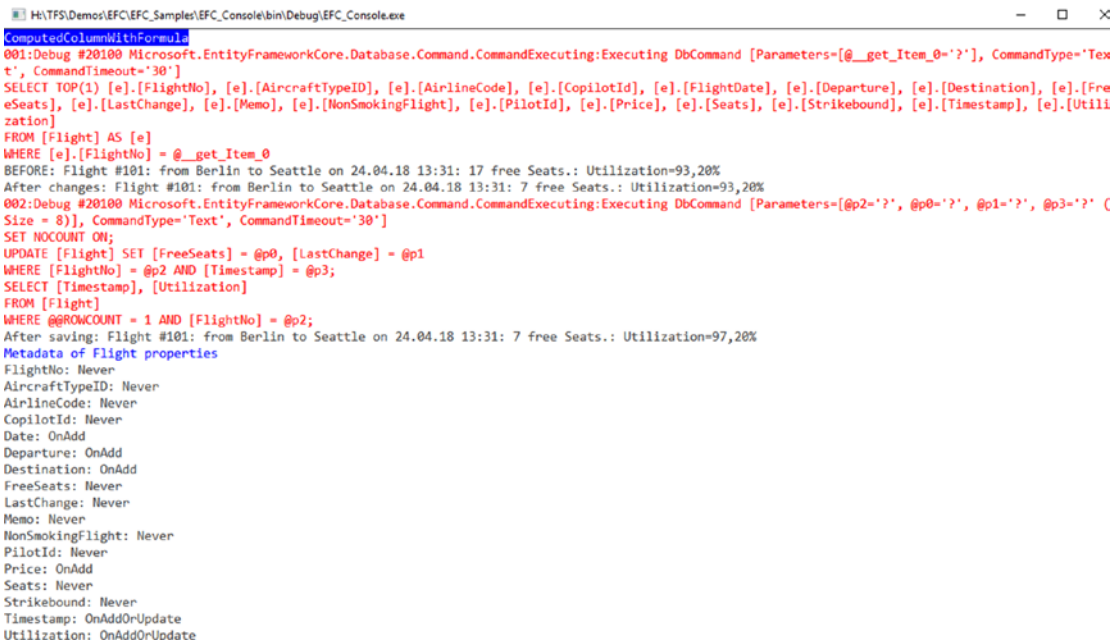

Figure 16-2. Output of Listing 16-6

Using Columns with a Calculation Formula in Reverse Engineering

Entity Framework Core recognizes calculation formulas while reverse engineering with Scaffold-DbContext and creates a property accordingly. However, the property receives a public setter. The formula is stored by the code generator in the Fluent API, but this has no meaning in reverse engineering. It would only become meaningful if you later switched from reverse engineering to forward engineering.

```
public decimal? Utilization {get; set; }
```

The Fluent API contains the following:

```
entity.Property(e => e.Utilization)
    .HasColumnType("numeric(20, 8)")
    .HasComputedColumnSql("((100.0-(([FreeSeats]*1.0)/[Seats])*100.0))")
```

The basis for the reverse engineering was the database schema with the column Utilization, which was previously generated by forward engineering.

Default Values

Entity Framework Core supports default values set by the database management system while creating records for columns for which no value has been passed. This support exists for both forward engineering and reverse engineering.

Defining Default Values for Forward Engineering

Defining column default values to be assigned by the database management system when an explicit value is not supplied is done using the methods `HasDefaultValue()` and `HasDefaultValueSql()` in the Fluent API. The default value can be one of the following:

- A static value (e.g., number or string), using `HasDefaultValue()`
- A SQL expression (e.g., calling a function like `getdate()`), using `HasDefaultValueSql()`

Here are some examples:

```
f.Property(x => x.Price).HasDefaultValue(123.45m);
f.Property(x => x.Departure).HasDefaultValue("(not set)");
```

```
f.Property(x => x.Destination).HasDefaultValue("(not set)");
f.Property(x => x.Date).HasDefaultValueSql("getdate());
```

Entity Framework Core considers these default values when creating the database (see Figure 16-3).

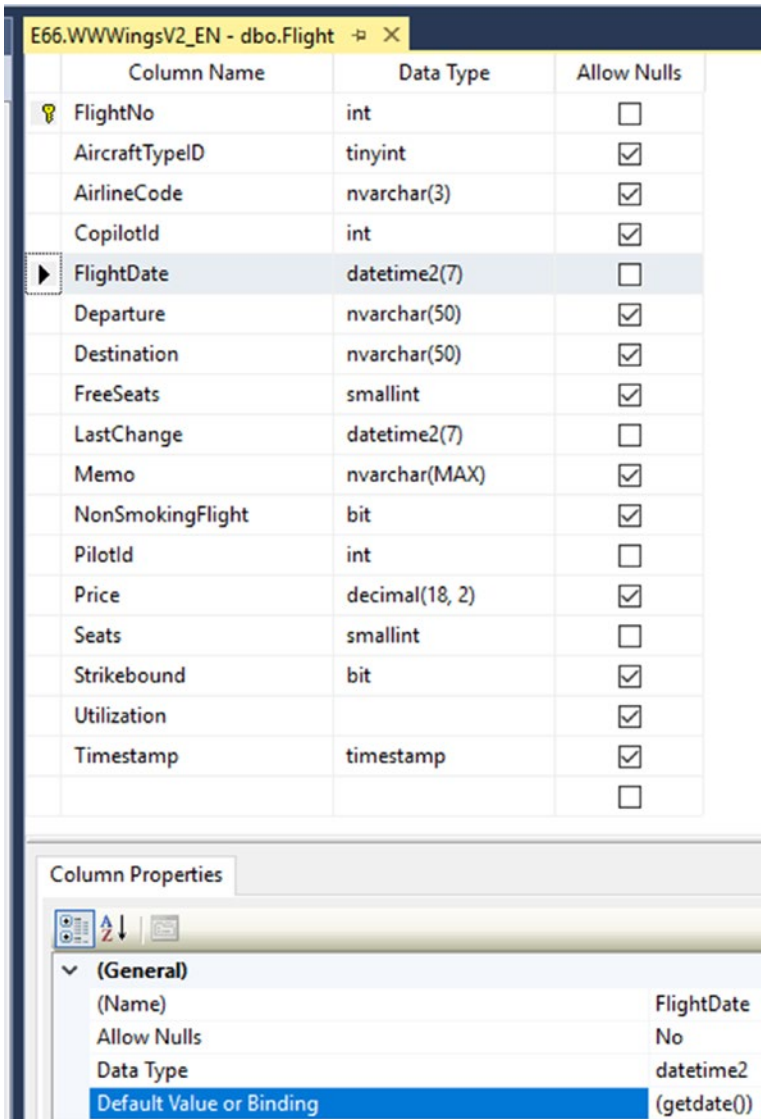

Figure 16-3. Default value for the FlightDate column in Microsoft SQL Server Management Studio

Using Default Values

Defined default values are taken into account by Entity Framework Core. As part of the ValueOnAdd strategy, Entity Framework Core queries the default values after an INSERT, but only if no value has been passed before.

Listing 16-7 shows this very impressively.

- A value for the `Departure` is set in code. Therefore, Entity Framework Core does not ask for the departure location in SELECT.
- `Destination` is null. Entity Framework Core therefore does ask in SELECT for the `Destination` value given by the database management system.
- `FlightDate` and `Price` were not set in the new object. Entity Framework Core therefore queries in SELECT for the `FlightDate` and `Price` values assigned by the database management system.

Listing 16-7. Using Default Values

```
public static void DefaultValues()
{
    CUI.MainHeadline(nameof(DefaultValues));

    using (WWWingsContext ctx = new WWWingsContext())
    {
        var pilot = ctx.PilotSet.FirstOrDefault();
        ctx.Log();
        var f = new Flight();
        f.FlightNo = ctx.FlightSet.Max(x => x.FlightNo) + 1;
        f.Departure = "Berlin";
        f.Destination = null;
        f.Pilot = pilot;
        f.Copilot = null;
        f.FreeSeats = 100;
        f.Seats = 100;
        CUI.Headline("Object has been created in RAM");
        Console.WriteLine($"{f} Price: {f.Price:###0.00} Euro.");
        ctx.FlightSet.Add(f);
    }
}
```

```

CUI.Headline("Object has been connected to the ORM");
Console.WriteLine($"{f} Price: {f.Price:###0.00} Euro.");
ctx.SaveChanges();
CUI.Headline("Object has been saved");
Console.WriteLine($"{f} Price: {f.Price:###0.00} Euro.");

f.FreeSeats--;
CUI.Headline("Object has been changed in RAM");
Console.WriteLine($"{f} Price: {f.Price:###0.00} Euro.");
ctx.SaveChanges();
CUI.Headline("Object has been saved"); ;
Console.WriteLine($"{f} Price: {f.Price:###0.00} Euro.");

//if (f.Destination != "(not set)") Debugger.Break();
//if (f.Price != 123.45m) Debugger.Break();
}
}

```

Figure 16-4 shows that the default values are set only after `SaveChanges()`. After updating with `UPDATE`, Entity Framework Core does not ask for the defaults again (only the column with the `Utilization` calculation formula and the timestamp column assigned by the database management system are part of the `SELECT` after `UPDATE`).

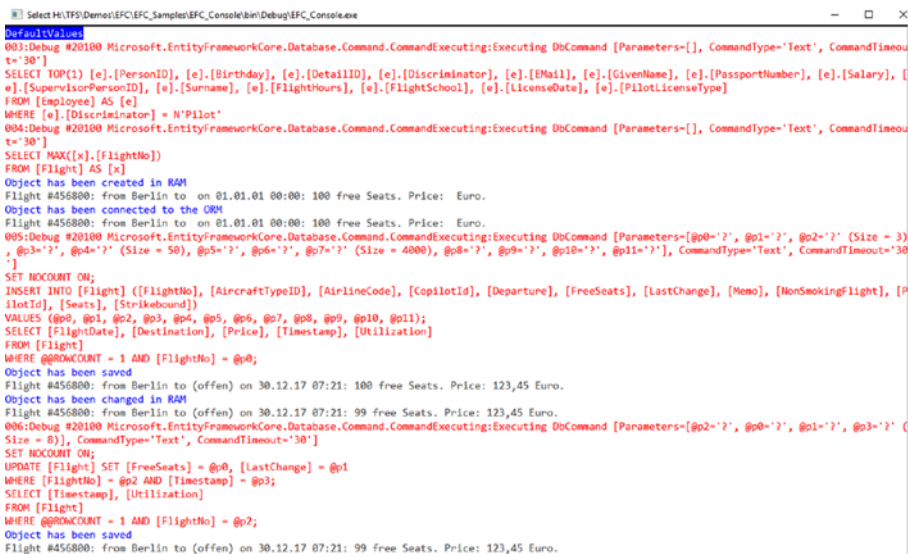

Figure 16-4. Output of Listing 16-7

Practical Example: Defaults Already Assigned When Creating the Object

If you want the defaults values to work in RAM immediately after an object has been created, then you do not have to assign these defaults in the database management system but in the constructor of the class (Listing 16-8).

Listing 16-8. Assigning Default Values in the Constructor

```
public class Flight
{
    /// <summary>
    /// Parameterless constructor
    /// </summary>
    public Flight()
    {
        // Default Values
        this.Departure = "(not set)";
        this.Destination = "(not set)";
        this.Price = 123.45m;
        this.Date = DateTime.Now;
    }
    ...
}
```

Figure 16-5 uses the example of the Date and Price properties to show that the default values apply immediately. However, the Departure and Destination default values set in the Flight constructor do not work because the program code overrides these values.

```

Using Default Values for Reverse Engineering

Entity Framework Core recognizes default values on Scaffold-DbContext and places them in the Fluent API. All that matters here is that Entity Framework Core knows there is a default value. What the actual value is does not matter for reverse engineering. In fact, you could also enter an empty string here later. The generated code always uses `HasDefaultValueSql()`, even for static values.

```

entity.Property(e => e.FlightDate).HasDefaultValueSql("(getdate())")
entity.Property(e => e.Price).HasDefaultValueSql("((123.45))");
entity.Property(e => e.Departure)
    .HasMaxLength(50)
    .HasDefaultValueSql("N'(not set)')");
entity.Property(e => e.Destination)
    .HasMaxLength(50)
    .HasDefaultValueSql("N'(not set)')");
    
```

Table Splitting

Since Entity Framework Core 2.0, the OR mapper allows you to spread a single database table across multiple entity classes. The table splitting is done as follows:

- You create an entity class (Master) and one or more dependent classes for the table.
- The entity class implements 1:1 navigation properties that reference the dependent classes.
- For these navigation properties you call the method `OwnsOne()` in `OnModelCreating()`.

Listing 16-9 shows a Master class with three dependent Split classes.

Sequence Objects (Sequences)

A sequence object (aka a *sequence*) exists in some database management systems (e.g., Oracle, Microsoft SQL Server) for the flexible allocation of auto-increment values. In Microsoft SQL Server, sequences have existed since version 2012.

What Are Sequences?

A sequence returns numbers in ascending or descending order, generated at a defined interval. The sequence can be configured so that it is restarted when a definable end value is reached, in other words, forms a cycle (sequence cycle). While identity columns work only with `tinyint`, `smallint`, `int`, and `bigint`, you can also use sequences to assign values to the decimal and numeric column types.

Sequence objects therefore have the following properties:

- Minimum value
- Maximum value
- Start value (a value between the minimum and maximum values) that represents the first number that will be delivered
- Increment or decrement (value by which the current value is increased for the next value)
- Sequence cycle (yes or no)

Unlike identity columns, sequence objects are independent of a table, so they can be used by multiple tables.

Sequence objects can be seen in Microsoft SQL Server Management Studio (SSMS) in the Programmability/Sequences branch of a database.

Sequences allow you to retrieve the next item without inserting a row in a table. This is done in T-SQL via this statement:

```
select NEXT VALUE FOR schema.NameofSequence
```

Thereafter, the sequence number is considered retrieved. The fetch is not rolled back if it is part of a transaction that is aborted.

Creating Sequences at Forward Engineering

A sequence is defined in the Fluent API via `HasSequence()` and then used with `HasDefaultValueSql()` (e.g., for a primary key). Listing 16-10 shows the definition of a cyclic sequence between 1000 and 1300, with steps of 10 starting at 1100. This sequence is then used in three places (simple primary key, composite primary key, and other column). Figure 16-7 shows the output.

Listing 16-10. Creating and Applying Sequences

```

// cyclic sequence between 1000 and 1300, step 10, starting at 1100
modelBuilder.HasSequence<int>("Setp10IDs", schema: "demo")
    .StartsAt(1100).IncrementsBy(10).HasMin(1000).HasMax(1300).IsCyclic();

// Sequence used for primary key (Data type: short)
modelBuilder.Entity<EntityClass1>()
    .Property(o => o.EntityClass1Id)
    .HasDefaultValueSql("NEXT VALUE FOR demo.Setp10IDs");
// Sequence used for normal column (Data type: decimal)
modelBuilder.Entity<EntityClass2>()
    .Property(o => o.Value)
    .HasDefaultValueSql("NEXT VALUE FOR demo.Setp10IDs");

// Sequence used for part of a composite key (Data type: int)
modelBuilder.Entity<EntityClass3>().HasKey(b => new { b.EntityClass3Id1,
b.EntityClass3Id2 });
modelBuilder.Entity<EntityClass3>()
    .Property(o => o.EntityClass3Id1)
    .HasDefaultValueSql("NEXT VALUE FOR demo.Setp10IDs");

```

Seeing Sequences in Action

Listing 16-11 shows a self-contained example:

1. The context class references three entity classes.
2. The context class creates a sequence.
3. Entity class 1 uses the sequence for the primary key.
4. Entity class 2 uses the sequence for the Value column (type decimal).
5. Entity class 3 uses the sequence for part of the primary key.
6. The program then creates and persists instances of all three classes.

Then for entity class 1, 1290 is used, and for entity class 2, 1300 is assigned. Thus, the end of the value range of the cyclic sequence is reached. The next value is 1000.

Note If it eventually happens that a value for a primary key that is already in use in this table is used in the sequence cycle, the following runtime error occurs: “Violation of PRIMARY KEY constraint 'PK_EntityClass1Set'. Can not insert duplicate key into object 'dbo.EntityClass1Set'. The duplicate key value is (...).”

Alternative Keys

In addition to a primary key (which may consist of one or more columns), a table can have additional keys (which can also consist of one or more columns) that uniquely identify each row in the database table. For this purpose, database management systems have concepts such as unique indexes and unique constraints. Both concepts are similar. This is discussed at [https://technet.microsoft.com/en-us/library/aa224827\(v=sql.80\).aspx](https://technet.microsoft.com/en-us/library/aa224827(v=sql.80).aspx).

Table 16-2. *Unique Index vs. Alternative Key*

Entity Framework Concept	Unique Index	Alternative Key
Database concept	Unique index	Unique constraint
Supported in classic Entity Framework	Yes, from version 6.1	No
Supported in Entity Framework Core	Yes, from version 1.0	Yes, from version 1.0
Use as foreign key in relationships	No	Yes

The classic Entity Framework Core allows the creation of a unique index only. In Entity Framework Core, you can now also create unique constraints. Entity Framework Core calls this an *alternative key*.

Defining Alternative Keys

An alternative key is defined in the Fluent API with `HasAlternateKey()`. Here the class `Detail` receives an alternative key for the column `Guid`.

```
modelBuilder.Entity<Detail>().HasAlternateKey(c => c.Guid);
```

An alternative key, like a primary key, can be composed of multiple columns. To do this, use an anonymous object as a parameter in `HasAlternateKey()`:

```
modelBuilder.Entity<Detail>()
    .HasAlternateKey(c => new { c.Guid, Bereich = c.Area });
```

Entity Framework Core automatically generates an alternate key if, in a relationship definition, you do not create the relationship between foreign key and primary key but use a different column of the parent class instead of the primary key.

```
modelBuilder.Entity<Detail>()
    .HasOne(p => p.Master)
    .WithMany(b => b.DetailSet)
    .HasForeignKey(p => p.MasterGuid)
    .HasPrincipalKey(b => b.Guid);
```

Figure 16-9 shows the created unique constraints in Microsoft SQL Server Management Studio. Entity Framework Core gives unique constraints names that begin with the letters AK (for “alternative key”).

The `MasterSet` table has a unique constraint for the `Guid` column in addition to the primary key. In addition to the primary key and the foreign key leading to the `Guid` column of `MasterSet`, the `DetailSet` table still has two unique constraints: one on the `Guid` column and one on the `Guid` and `Area` columns together as a composite key. This proves that Entity Framework Core allows a column to be part of multiple alternative keys.

Tip If possible, you should always use relationships to form integer columns, and the foreign key should refer to the primary key because this provides the greatest performance and the least memory overhead. The relationship shown in Figure 16-9 via a column of type GUID column is for illustrative purposes only.

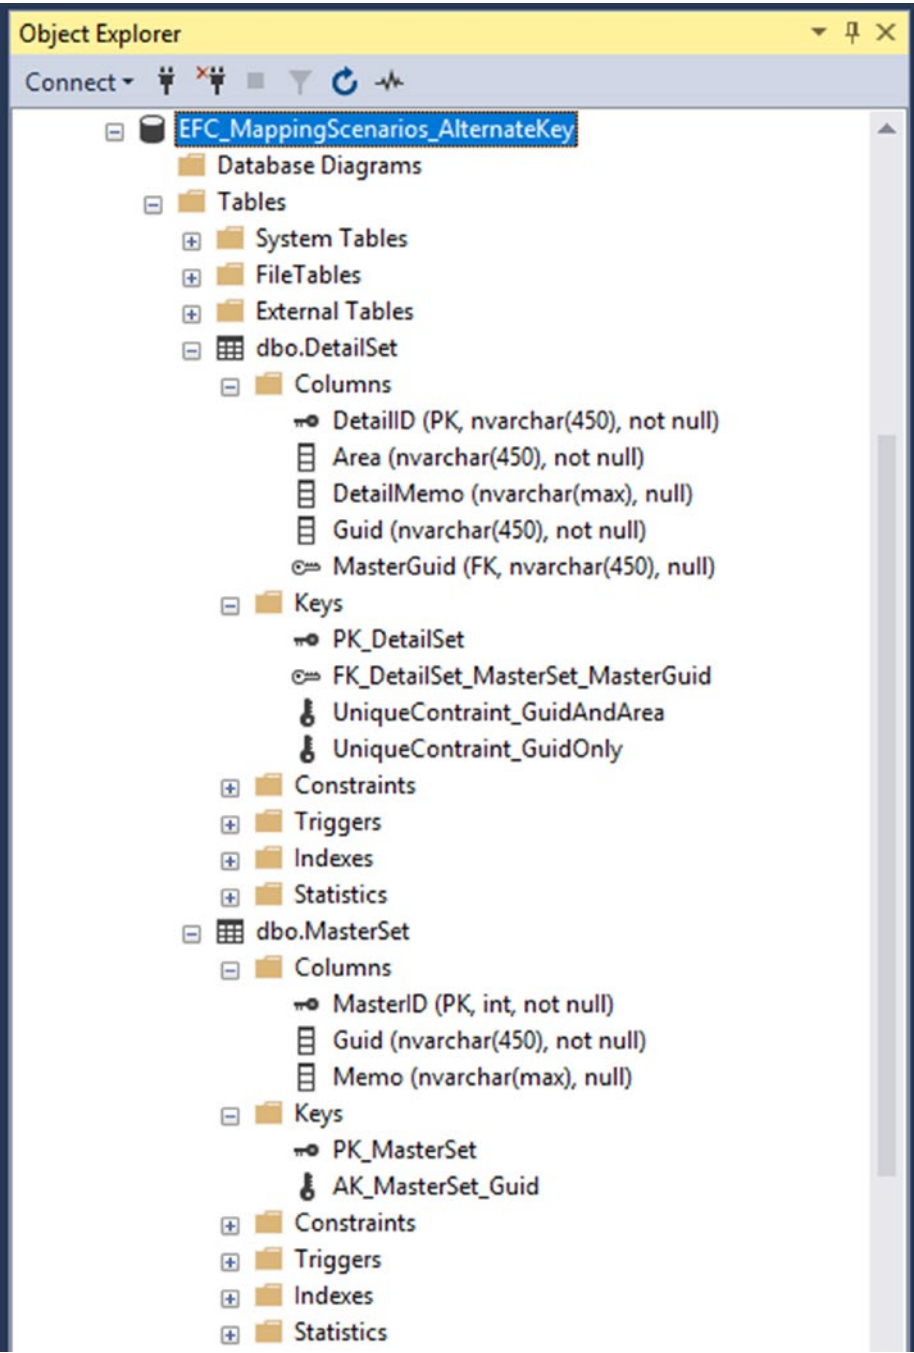

Figure 16-9. Unique constraints in Microsoft SQL Server Management Studio

Tip If you do not like the names of the unique constraints assigned by Entity Framework Core, you can also give your own names in the Fluent API using `HasName()`.

Here is an example:

```
// Alternative key with one column
modelBuilder.Entity<Detail>()
    .HasAlternateKey(c => c.Guid).HasName("UniqueConstraint_GuidOnly"); ;
// Alternative key with two columns
modelBuilder.Entity<Detail>()
    .HasAlternateKey(c => new { c.Guid, Bereich = c.Area
    }).HasName("UniqueConstraint_GuidAndArea");
```

Seeing Alternative Keys in Use

Listing 16-12 shows a self-contained example:

- The context class refers to two entity classes: `Master` and `Detail`.
- The `Master` class has an alternate key for the GUID column in addition to the primary key.
- In addition to the primary key and the foreign key leading to the `Guid` column of `MasterSet`, the `Detail` class has two alternate keys: one on the `Guid` property and one on the `Guid` and `Area` property together.
- The program first outputs the list of properties of both classes and writes on the screen whether it is a key (`IsKey()`) or additionally a primary key (`IsPrimaryKey()`). For each primary key, `IsKey()` also returns `true`.
- The program then creates a `Detail` object and a `Master` object. It connects these objects using the GUID.

Figure 16-10 shows the output.

Note Alternative keys (as primary keys) must not have NULL values. This is acknowledged by Entity Framework Core with the following runtime error, which also states that zero NULL values are allowed in a unique index: “Unable to track an entity of type 'DetailKlasse' because alternate key property 'Guid' is null. If the alternate key is not used in a relationship, then consider using a unique index instead. Unique indexes may contain nulls, while alternate keys must not.”

Cascading Delete

If a master record is deleted in an object relationship (1:1, 1:N), what happens to the one detail data record (1:1) or the many detailed data records (1:N)? *Cascading delete* is the answer.

Delete Options in Entity Framework Core

Entity Framework Core offers a total of four options for the cascading deletion of dependent objects and thus more options than its predecessor ADO.NET Entity Framework.

If no related objects are materialized for the related records, Entity Framework Core will always send (no matter what setting) a single delete command for the master record to the database. What happens to the detailed data sets is up to the database management system.

However, if the related records are materialized for the related records, Entity Framework Core may send (depending on the setting) a DELETE or UPDATE record detail record command to the database management system before deleting the master record. In addition, depending on the setting, the foreign key properties in the RAM are also changed.

Table 16-3. *Cascading Delete Settings and Their Effects*

Entity Framework Core Setting	Default at...	Resulting Setting of the Foreign Key in the Database	Runtime Behavior: Materialized Related Objects	Runtime Behavior: NOT Materialized Related Records
Cascade	Mandatory relations	Cascade	Entity Framework Core sends DELETE for related objects. Foreign key property in RAM is retained.	DBMS deletes related record automatically.
ClientSetNull	Optional relationships (since Entity Framework Core 2.0)	No Action	Entity Framework Core sends UPDATE SET = NULL for related objects. Foreign key property in RAM is set to NULL.	None. Error if records exist in database.
SetNull		SetNull	Entity Framework Core sends UPDATE SET = NULL for related objects. Foreign key property in RAM is set to NULL.	DBMS sets foreign key column to NULL.
Restrict	Optional relationships (in Entity Framework Core 1.x)	No Action	Version 1.x: UPDATE SET = NULL. Version 2.x: Error when objects exist in RAM.	None. Error if records exist in database.

The cascading delete settings for Entity Framework Core are made in the relationship declaration in the Fluent API using the `OnDelete()` method and using the `DeleteBehavior` enumeration.

```
modelBuilder.Entity<Detail1>()
    .HasOne(f => f.Master)
    .WithMany(t => t.Detail1Set)
    .HasForeignKey(x => x.MasterId)
    .OnDelete>DeleteBehavior.Cascade);

modelBuilder.Entity<Detail2>()
    .HasOne(f => f.Master)
    .WithMany(t => t.Detail2Set)
    .HasForeignKey(x => x.MasterId)
    .OnDelete>DeleteBehavior.ClientSetNull);

modelBuilder.Entity<Detail3>()
    .HasOne(f => f.Master)
    .WithMany(t => t.Detail3Set)
    .HasForeignKey(x => x.MasterId)
    .OnDelete>DeleteBehavior.SetNull);

modelBuilder.Entity<Detail4>()
    .HasOne(f => f.Master)
    .WithMany(t => t.Detail4Set)
    .HasForeignKey(x => x.MasterId)
    .OnDelete>DeleteBehavior.Restrict);
```

Looking at an Example

Listing 16-13 sets up a test scenario for the deletion options. There is a `Master` class with four collections of four different `Detail` classes. One of the four cascading deletion options of Entity Framework Core is used for each of the four `Detail` classes.

```

In this situation, assuming that a Master object in RAM is connected to one of each of the first three Detail objects, that these three Details objects are in RAM, and that the main class object has been deleted by calling `Remove()` and then `SaveChanges()`, the following reaction occurs:

- DELETE command for the record in table `Detail1Set` (in cascade mode). However, the foreign key value from `Detail1` to the main class object in RAM is preserved.
- UPDATE command for record in table `Detail2Set` (in `ClientSetNull` mode). The foreign key value is set to NULL. The foreign key value from the `Detail2` object to the Master object in RAM is also set to NULL.
- UPDATE command for the record in table `Detail3Set` (in `SetNull` mode). The foreign key value is set to NULL. The foreign key value from the `Detail3` object to the Master class object in RAM is also set to NULL.
- DELETE command for the main class object.

Figure 16-11. Entity Framework Core has disconnected the three DetailClass objects before deleting the main class object record

If you uncomment the line `m.Detail4Set.Add(d4)`, the code will fail with the following error: “The DELETE statement conflicted with the REFERENCE constraint “FK_Detail4Set_MasterSet_MasterId”.” The conflict occurred in database `EFC_MappingScenarios_CascadingDelete`, table `dbo.Detail4Set`, and column `MasterId` because the relation to `Detail4` is in `Restrict` mode. The same would happen with `Detail2` (in `ClientSetNull` mode) if the object was not in RAM.

If you uncomment the line and also load `Detail4Set` to RAM with `.Include(x => x.Detail4Set)`, that the code will fail with the following error: “The association between entity types 'Master' and 'Detail4' has been severed but the foreign key for this relationship cannot be set to null. If the dependent entity should be deleted, then setup the relationship to use cascade deletes.”

Mapping of Database Views

The mapping of database views is not yet officially supported in Entity Framework Core. In other words, it is not possible to create the reverse engineering program code for existing database views or to create forward engineering database views from the object model or the Fluent API.

However, it is possible to create database views manually in the database and treat them like tables in the program code. However, it is a bit tricky, as this section shows.

Note Microsoft plans to provide better support for database views in version 2.1 of Entity Framework Core; see Appendix C.

Creating a Database View

The database view must be created manually in the database (possibly with the help of a tool such as SQL Server Management Studio) via `CREATE VIEW`. The database view created by `CREATE VIEW` in Listing 16-14 provides the number of flights and the last flight for the `Flight` table per departure (from the World Wide Wings database).

Listing 16-14. Creating a Database View via SQL Command

```
USE WWingsV2_EN
GO
CREATE VIEW dbo.[V_DepartureStatistics]
AS
SELECT departure, COUNT(FlightNo) AS FlightCount
FROM dbo.Flight
GROUP BY departure
GO
```

Creating an Entity Class for the Database View

You must create an entity class for the database view whose attributes correspond to the columns of the database view that are to be mapped. In this example, this class is named `DepartureStatistics` and will receive the data of the database view `V_DepartureStatistics`. The `[Table]` annotation specifies the database view name in the database because the entity class differs by name.

Listing 16-15 deliberately ignores the `LastFlight` value of the view `V_DepartureStatistics`. It is important that the entity class requires a primary key to be specified with `[Key]` or the Fluent API method `HasKey()`.

Listing 16-15. Entity Class with Two Properties for the Two Columns of the Database View to Be Mapped

```
[Table("V_DepartureStatistics")]
public class DepartureStatistics
{
    [Key] // must have a PK
    public string Departure { get; set; }
    public int FlightCount { get; set; }
}
```

Including the Entity Class in the Context Class

The entity class for the database view is now included as an entity class for a table in the context class via `DbSet<T>`, as shown in Listing 16-16.

Listing 16-16. Including the Entity Class for the Database View in the Context Class

```
public class WWWingsContext: DbContext
{
    #region Entities for tables
    public DbSet<Airline> AirlineSet { get; set; }
    public DbSet<Flight> FlightSet { get; set; }
    public DbSet<Pilot> PilotSet { get; set; }
    public DbSet<Passenger> PassengerSet { get; set; }
    public DbSet<Booking> BookingSet { get; set; }
    public DbSet<AircraftType> AircraftTypeSet { get; set; }
    #endregion

    #region Pseudo-entities for views
    public DbSet<DepartureStatistics> DepartureStatisticsSet { get; set; }
    // for view
    #endregion

    ...
}
```

Using the Database View

You can now use the entity class for the database view, such as for a table in LINQ queries or in `FromSql()` for direct SQL queries. If the database view is writable, then you could also use the API of Entity Framework Core via `SaveChanges()` to change, add, or delete records (Listing 16-17).

Listing 16-17. Using the Entity Class for the Database View

```
public static void DatabaseViewWithPseudoEntity()
{
    CUI.MainHeadline(nameof(DatabaseViewWithPseudoEntity));

    using (var ctx = new WWingsContext())
    {
        var query = ctx.DepartureStatisticsSet.Where(x => x.FlightCount > 0);
        var liste = query.ToList();
        foreach (var stat in liste)
        {
            Console.WriteLine($"{stat.FlightCount:000} Flights departing from
                {stat.Departure}.");
        }
    }
}
```

Challenge: Migrations

Although the previous sections showed some manual work, integrating database views did not seem to be all that challenging beyond some typing required. Unfortunately, on closer inspection, this is not the whole story.

If you create a schema migration in the context class after creating the database view, you detect that Entity Framework Core now undesirably wants to create a table for the database view in the database (Listing 16-18).

Listing 16-18. Entity Framework Core Creates a CreateTable() for the Database View in the Schema Migration Class, Which Is Not Desirable

```

using Microsoft.EntityFrameworkCore.Migrations;
using System;
using System.Collections.Generic;

namespace DA.Migrations
{
    public partial class v8 : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "V_DepartureStatistics",
                columns: table => new
                {
                    Departure = table.Column<string>(nullable: false),
                    FlightCount = table.Column<int>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_V_DepartureStatistics", x =>
                        x.Departure);
                });
        }

        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "V_DepartureStatistics");
        }
    }
}

```

This is correct from the point of view of Entity Framework Core, as the code told the OR mapper that `V_DepartureStatistics` would be a table and Entity Framework Core in the current version 2.0 has absolutely no understanding of database views.

Unfortunately, this schema migration could not be executed because there can be only one object named `V_DepartureStatistics` in the database.

There are two possible solutions to this situation, explained here:

- You manually delete `CreateTable()` in the `Up()` method and the corresponding `DropTable()` in `Down()` from the migration class.
- You trick Entity Framework Core so that the OR mapper ignores the entity class `DepartureStatistics` when creating the migration step at development time but not at runtime.

Tip The trick is realized in Listing 16-19. Entity Framework Core instantiates the context class as part of creating or deleting a schema migration and calls `OnModelCreating()`. However, this does not happen at development time via the actual starting point of the application (in which case the application would start). This happens when hosting the DLL with the context class in the command-line tool `ef.exe`. In `OnModelCreating()`, you therefore check whether the current process has the name `ef`. If so, then you are not in the runtime of the application but in the development environment and want to ignore the database view with `Ignore()`. At runtime of the application, however, `Ignore()` will not be executed, and thus using the database view through the entity class is possible.

Listing 16-19. Entity Framework Core Should Only Ignore the Entity Class for the Database View at Development Time

```
// Trick: hide the view or grouping pseudo entities from the EF
migration tool so it does not want to create a new table for it
if (System.Diagnostics.Process.GetCurrentProcess().ProcessName.ToLower()
== "ef")
{
    modelBuilder.Ignore<DepartureStatistics>();
    ...
}
```

Note If the query of the process name is too uncertain because Microsoft could change this name, you can instead use a switch in the context class in the form of a static attribute (e.g., `bool IsRuntime {get; set; } = false`). By default, this `IsRuntime` is false and ignores the entity class for the database view. At runtime, however, the application sets `IsRuntime` to true before the first instantiation of the context class.

Global Query Filters

Global query filters are a nice new feature in Entity Framework Core 2.0. This allows you to define filter conditions centrally in `OnModelCreating()`, which Entity Framework Core then appends to any LINQ query, any direct SQL query, any call to a table-valued function, and any explicit load operation. This feature is well-suited to the following scenarios:

- *Multitenancy*: A column in a record expresses which tenant a record belongs to. The global filter ensures that each tenant only sees their data. Without a global filter, you would have to remember to consider the tenant condition in each query.
- *Soft delete*: Records that are deleted should not really be deleted; they should only be marked. The global filter ensures that the user does not see any “deleted” data. Without a global filter, you would have to remember to include the `deleted = false` condition in each query.

Defining a Filter

You set a global filter in `OnModelCreating()` per an entity class using the method `HasQueryFilter()`.

The following is a global filter where only the flights of an specific airline (i.e., one tenant) and only flights that are not fully booked are returned for all inquiries:

```
modelBuilder.Entity<Flight>().HasQueryFilter(x => x.FreeSeats > 0 &&
x.AirlineCode == "WWW");
```

Note You can only define at most one filter per entity class. If you call `HasQueryFilter()` multiple times, only the conditions of the last filter apply. To link multiple conditions, use the AND operator (in C#, `&&`), as shown earlier.

Using Filters in LINQ

The previous filter forces this LINQ query in the database management system:

```
List<Flight> flightSet = (from f in ctx.FlightSet //
                        where f.Departure == "Berlin"
                        select f).ToList();
```

It executes the following SQL with additional conditions from the global filter:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode], [f].
[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination], [f].
[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight], [f].
[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound], [f].[Timestamp],
[f].[Utilization]
FROM [Flight] AS [f]
WHERE (([f].[FreeSeats] > 0) AND ([f].[AirlineCode] = N'WWW')) AND ([f].
[Departure] = N'Berlin')
```

Entity Framework Core considers the global filters also during eager loading and explicit loading, as shown in Listing 16-20 and Listing 16-21.

Listing 16-20. Explicit Load Example with `Load()`

```
CUI.Headline("Pilots (Eager Loading)");

var pilotWithFlights= ctx.PilotSet.Include(x => x.FlightAsPilotSet).
ToList();

foreach (var p in pilotWithFlights)
{
    Console.WriteLine(p);
    foreach (var f in p.FlightAsPilotSet.ToList())
```

```

{
    Console.WriteLine(" - " + f.ToString());
}
}

```

Listing 16-21. Explicit Load Example with Load()

```

CUI.Headline("Pilots (Explicit Loading)");

var pilotenSet = ctx.PilotSet.ToList();

foreach (var p in pilotenSet)
{
    Console.WriteLine(p);
    ctx.Entry(p).Collection(x => x.FlightAsPilotSet).Load();
    foreach (var f in p.FlightAsPilotSet.ToList())
    {
        Console.WriteLine(" - " + f.ToString());
    }
}

```

Practical Example: Ignoring a Filter

You can decide in each individual query to ignore the global filter. This is done with `IgnoreQueryFilters()`, as shown here:

```

List<Flight> FlightAllSet = (from f in ctx.FlightSet.IgnoreQueryFilters()
                           where f.Departure == "Berlin"
                           select f).ToList();

```

Note However, it is not possible to ignore only individual parts of a filter. Although this is desired by users, an implementation has not yet been provided by Microsoft.

Global Query Filters for SQL Queries

The global query filters (see chapter 14) also work when querying directly via SQL with `FromSql()`. For a global filter that returns only flights from a specific airline and only flights that are not fully booked, this is the SQL query in code:

```
List<Flight> flightSet2 = ctx.FlightSet.FromSql("select * from Flight where
Departure = 'Berlin']").ToList();
```

Entity Framework Core will embed your SQL query in the global filter query and send it to the database management system.

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode], [f].
[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination], [f].
[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight], [f].
[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound], [f].[Timestamp],
[f].[Utilization]
FROM (
    select * from Flight where Departure = 'Berlin'
) AS [f]
WHERE ([f].[FreeSeats] > 0) AND ([f].[AirlineCode] = N'WWW')
```

Global Query Filters for Stored Procedures and Table-Valued Functions

The global query filters also work with `FromSql()` when using table-valued functions (TVFs).

With the previous global filter, where only the flights of an airline and only nonbooked flights are returned, this SQL query

```
List<Flight> flightSet3 = ctx.FlightSet.FromSql("Select * from
GetFlightsFromTVF({0})", "Berlin").Where(f=>f.NonSmokingFlight == true).
ToList();
```

will result in the following:

```
SELECT [f].[FlightNo], [f].[AircraftTypeID], [f].[AirlineCode],
[f].[CopilotId], [f].[FlightDate], [f].[Departure], [f].[Destination],
[f].[FreeSeats], [f].[LastChange], [f].[Memo], [f].[NonSmokingFlight],
```

```
[f].[PilotId], [f].[Price], [f].[Seats], [f].[Strikebound],
[f].[Timestamp], [f].[Utilization]
FROM (
    Select * from GetFlightsFromTVF(@p0)
) AS [f]

```

Warning When a stored procedure is called, the global filters in RAM do not work!

From the following query: `List<Flight> flightSet4 = ctx.FlightSet.FromSql("EXEC GetFlightsFromSP {0}", "Berlin").ToList();`

Entity Framework Core will execute only the following: `EXEC GetFlightsFromSP @p0`

Future Queries

Entity Framework Plus (see Chapter 20) implements an additional feature called *future queries*. This allows you to define a series of queries, by calling the `Future()` extension method, that are not executed immediately. These queries can then be executed individually later, but this would also work with the standard functionality of Entity Framework Core. The special feature of future queries is that all the defined queries are executed together when the data of a query is needed because a conversion or aggregate operator is applied.

Listing 16-22 first defines three future queries and then uses `ToList()` to retrieve the data from two queries (all pilots and flights from Berlin). As Figure 16-12 shows, all three queries are executed the first time the data is accessed. Then two more queries are defined (flights from London and flights from Paris). Then you get access to the data of the third query (flights from Rome) of the first action. There is no round-trip to the database management system since this data has already been loaded. Only then, on a call to `ToList()` on the flights from London, does Entity Framework Core execute the queries of the flights from London and Paris.

CHAPTER 17

Performance Tuning

This chapter provides guidance on accelerating database access with Entity Framework Core.

Process Model for Performance Optimization in Entity Framework Core

Like the classic Entity Framework, the following process model for optimizing the performance of database accesses has proven itself in Entity Framework Core:

- The first step is to implement all data accesses using Entity Framework Core and LINQ, except for UPDATE, DELETE, and INSERT bulk operations. Bulk operations use SQL or a bulk insert directly.
- The application is then tested with realistic data sets. Where the speed is too slow, it is optimized in three stages.
 - In stage 1, tricks within Entity Framework Core are used, such as no tracking, caching, paging, changing the loading strategy (for example, eager loading or preloading instead of explicit loading), and reducing the number of round-trips.
 - Where this is not enough, in stage 2 the LINQ commands are checked and replaced with better-optimized SQL commands or other database constructs such as views, stored procedures, or table-valued functions (TVFs). Access to them continues via Entity Framework Core.
 - Only in stage 3 is Entity Framework Core replaced by `DataReader` and `Command` objects for access to SQL commands, views, stored procedures, and TVFs.

Best Practices for Your Own Performance Tests

If you are performing performance testing to check the speed of different alternatives, consider the following:

- Do not run the performance test in Visual Studio. The debugger and the possibly activated IntelliTrace feature will slow down your program code in different ways, depending on the procedure, and you will not receive either absolutely or proportionally correct results.
- Do not run the performance test in a graphical user interface (GUI) application or do any console output. Write a console application for the performance test, but do print anything to the console and do not include the time of the console output in your measures.
- Repeat each test several times, at least ten times, and calculate the average. There are many factors that can influence the results (for example, .NET garbage collection and the Windows paging file).
- Do not include the first run (cold start) in the average. Additional tasks of Entity Framework Core and the database management system have to be done on the first run (for example, starting up the database, establishing a connection, generating the mapping code, and so on) that falsify your result. Do eleven runs if you want to get ten valid results.
- Test against a remote database management system on a different system (unless your solution really uses a local database).
- Make sure that the test machine does not perform any other significant processes during the test and the network is not significantly active (run the tests when everyone else is at home or set up your own network!).

Performance Comparison of Various Data Access Techniques in .NET

When developing Entity Framework Core, Microsoft's goals were platform independence and increased performance over the classic ADO.NET Entity Framework. This chapter covers one of many performance test scenarios.

Figure 17-1 shows that Entity Framework Core 1.1 on .NET Framework 4.7 in no-tracking mode is almost as fast as a DataReader with manual mapping (in other words, copying from the DataReader to a .NET object: `obj.x = Convert (dr ["x"])`).

Figure 17-1. Performance comparison of various data access techniques in .NET

With .NET Core 2.0, both manual mapping and Entity Framework Core are faster than .NET Framework 4.7. Interestingly, Entity Framework Core's no-tracking mode benefits greatly from .NET Core 2.0 and is equivalent to manual mapping in .NET Core 2.0.

Also in tracking mode, Entity Framework Core is faster than ADO.NET Entity Framework 6.x.

The fastest measurement (22 ms in .NET Framework 4.7 or 21 ms in .NET Core 2.0) comes from a DataReader, but the data sets were not mapped to objects.

Note the following about this measurement scenario:

- The database server is running Microsoft SQL Server 2016 (virtualized) on Windows Server 2016. The performance of the database server would be even better if it were not virtualized or at least could use nonvirtualized hard disk space.
- The client is a Windows 10 machine.
- The two computers are connected via a 1GB Ethernet network.
- The executed command is a simple SELECT without joins or aggregate operators.

- 10,000 records were loaded.
- A result record consists of 13 columns from a single table.
- Data types are int, smallint, nvarchar(30), nvarchar(max), bit, and timestamp.
- The displayed value is the average of 100 repetitions.
- The first access for each technique (cold start) was not included in the average.

Note Of course, this is just one of many possible comparison scenarios. Since the performance depends on the hardware, the operating system, the software versions, and above all the database schema, it makes no sense to document further performance comparisons at this point. You have to measure the performance in your particular scenario anyway.

Optimizing Object Assignment

To assign related objects, Entity Framework Core gives you two options.

- Assignment via an object reference (Listing 17-1)
- Assignment via a foreign key property (Listing 17-2)

Listing 17-1. Assignment via an Object Reference

```
public static void ChangePilotUsingObjectAssignment()
{
    CUI.Headline(nameof(ChangePilotUsingObjectAssignment));
    var flightNo = 102;
    var newPilotID = 123;

    using (var ctx = new WWingsContext())
    {
        ctx.Log();
        Flight flight = ctx.FlightSet.Find(flightNo);
        Pilot newPilot = ctx.PilotSet.Find(newPilotID);
    }
}
```

```

    flight.Pilot = newPilot;
    var count = ctx.SaveChanges();
    Console.WriteLine("Number of saved changes: " + count);
}
}

```

Listing 17-2. Assignment via a Foreign Key Property

```

public static void ChangePilotUsingFK()
{
    CUI.Headline(nameof(ChangePilotUsingFK));
    var flightNo = 102;
    var newPilotID = 123;

    using (var ctx = new WWingsContext())
    {
        ctx.Log();
        Flight flight = ctx.FlightSet.Find(flightNo);
        flight.PilotId = newPilotID;
        var count = ctx.SaveChanges();
        Console.WriteLine("Number of saved changes: " + count);
    }
}

```

Using a foreign key property is a bit more efficient because the object does not have to be explicitly loaded. The UPDATE command sent by Entity Framework Core to the database looks the same in both cases (see Figure 17-2).

Figure 17-2. Output of Listing 17-2

If the object to be assigned is already in RAM, you have a choice between both syntax forms. But if you have only the primary key value of the object to be allocated in RAM, then you should use the foreign key property. This situation is common in web applications and web services because the client gets only the primary key value.

Tip Foreign key properties are optional in Entity Framework Core. However, the optimization option in the assignment is a good reason why you should implement foreign key properties in addition to the navigation properties in the entity classes!

Although there is no foreign key property, you can bypass loading the object by using the foreign key column's shadow property in Entity Framework Core (see Listing 17-3). The disadvantage of this procedure, however, is that the name of the foreign key column must then be used as a string in the program code, which is more cumbersome at input time and more error-prone.

Listing 17-3. Assignment via the Shadow Key Property of the Foreign Key Column

```
public static void ChangePilotUsingFKShadowProperty()
{
    CUI.Headline(nameof(ChangePilotUsingFKShadowProperty));
    var flightNo = 102;
    var neuerPilotNr = 123;
    using (var ctx = new WWingsContext())
    {
        ctx.Log();
        Flight flight = ctx.FlightSet.Find(flightNo);
        ctx.Entry(flight).Property("PilotId").CurrentValue = neuerPilotNr;
        var count = ctx.SaveChanges();
        Console.WriteLine("Number of saved changes: " + count);
    }
}
```

Bulk Operations

Entity Framework Core does not support bulk operations on more than one record in its default configuration but handles each record individually for deletion and modification. This chapter discusses the topic using a delete command (DELETE) for 1,000 records. The information also applies to bulk data changes with UPDATE.

Single Delete

Listing 17-4 shows an inefficient way of deleting all records from the Flight table where the primary key has a value greater than 20,000. All records must first be loaded and materialized into .NET objects. Each .NET object is then marked for deletion using the `Remove()` method, and the deletion is eventually translated into a DELETE command by the Entity Framework Core context when the `SaveChanges()` method is executed for each object.

So, if 1,000 flights are to be deleted, you need 1,001 commands (one SELECT and 1,000 DELETE commands). In the implementation, the 1,000 DELETE commands, one at a time, are sent to the database management system because the `SaveChanges()` method occurs after each individual `Remove()` within the loop.

Listing 17-4. Bulk Clear Without Batching with the Entity Framework Core API

```
public static void BulkDeleteEFCAPWithoutBatching()
{
    CUI.Headline(nameof(BulkDeleteEFCAPWithoutBatching));
    var sw = new Stopwatch();
    sw.Start();
    int total = 0;
    using (var ctx = new WWingsContext())
    {
        var min = 20000;
        var flightSet = ctx.FlightSet.Where(x => x.FlightNo >= min).ToList();
        foreach (Flight f in flightSet)
        {
            ctx.FlightSet.Remove(f);
            var count = ctx.SaveChanges();
            total += count;
        }
    }
    sw.Stop();
    Console.WriteLine("Number of DELETE statements: " + total);
    Console.WriteLine("Duration: " + sw.ElapsedMilliseconds);
}
```

Optimization with Batching

In the classic Entity Framework, it does not matter whether `SaveChanges()` is in the loop after each `Remove()` or out of the loop. The old OR mapper always transfers each DELETE command to the database management system one at a time. In Entity Framework Core, there is batching (see Chapter 10), which mitigates the problem.

Listing 17-5, which executes `SaveChanges()` only once at the end, therefore does not lead to 1,000 DELETE round-trips to the database management system, but to solely one (see Figure 17-3). In total, there are only two round-trips left (one for loading with SELECT and one for the 1,000 DELETE commands). The execution time is reduced significantly (see Table 17-1).

Listing 17-5. Bulk Deleting Batching with the Entity Framework Core API

```
public static void BulkDeleteEFCAPiwithBatching()
{
    CUI.Headline(nameof(BulkDeleteEFCAPiwithBatching));
    int total = 0;
    var sw = new Stopwatch();
    sw.Start();
    using (var ctx = new WWWingsContext())
    {
        var min = 20000;
        var flightSet = ctx.FlightSet.Where(x => x.FlightNo >= min).ToList();
        foreach (Flight f in flightSet)
        {
            ctx.FlightSet.Remove(f);
        }
        total = ctx.SaveChanges();
    }
    sw.Stop();
    Console.WriteLine("Number of DELETE statements: " + total);
    Console.WriteLine("Duration: " + sw.ElapsedMilliseconds);
}
```

Table 17-1. Execution Time

Method	Number of Round-Trips	Execution Time
Bulk delete 1,000 Flight records without batching with the Entity Framework Core API	1,001	11,110 seconds

Delete Without Loading with Pseudo-Objects

Even with the use of batching, this operation remains inefficient because initially all records are loaded only to then delete them. When it is running Entity Framework Core expects an entity Object.

Here is the trick to manually construct such an entity object as a pseudo-object in RAM and pass this as a parameter to `Remove()` (see Listing 17-6). This significantly increases performance (see Table 17-2). However, this is possible only under these two conditions:

- The primary keys of the objects to be deleted are known.
- There is no concurrency check by `[ConcurrencyCheck]` running, no `IsConcurrencyToken()` method, and no timestamp column.

Listing 17-6. Bulk Deleting Batching with Entity Framework Core API Using Pseudo-Objects

    {
        for (int i = 20001; i < 21000; i++)
        {
            var f = new Flight() { FlightNo = i };
            ctx.FlightSet.Attach(f);
            ctx.FlightSet.Remove(f);
        }
        total = ctx.SaveChanges();

Using Classic SQL Instead of the Entity Framework Core API

Through the measures taken so far, the duration of implementation has already been significantly reduced, but the duration is still much longer than necessary. Rather than using the Entity Framework Core API here, in a situation where a consecutive set of records is to be dropped, it is much more efficient to issue a single classic SQL command.

```
DELETE dbo.Flight where FlightNo >= 20000
```

You set this SQL command either in the classical way via an ADO.NET command with a `Parameter` object (see Listing 17-7) or more succinctly via the direct SQL support in Entity Framework Core (see Listing 17-8) with the `ExecuteSqlCommand()` method in the `Database` subobject of the Entity Framework Core context. It should be emphasized that the `string.Format()`-based wildcard syntax protects against SQL injection attacks, as shown in the parameterization in Listing 17-7. Here the strings are not simply put together, as the syntax suggests, but SQL parameter objects are generated internally.

The execution time drops in both cases to less than 40 ms, which is not surprising because the program has now nothing more to do than build a database connection and transfer a few characters. The performance difference between the transmission via the Entity Framework Core context or a `Command` object cannot be measured.

The disadvantage of this approach, of course, is that again SQL strings are used, for which there is no compiler check, and thus there is a risk of syntax and type errors that are not noticeable until runtime.

    {
        connection.Open();
        SqlCommand command = new SqlCommand("DELETE dbo.Flight where FlightNo
        >= @min", connection);
```

```

    command.Parameters.Add(new SqlParameter("@min", min));

Lambda Expressions for Mass Deletion with EFPlus

The extension component EFPlus (see Chapter 20) allows to formulate UPDATE and DELETE commands in lambda expressions based on LINQ commands so you can avoid the error-prone SQL.

The EFPlus component implements extension methods named Update() and Delete(). To enable this, using Z.EntityFramework.Plus is necessary.

Listing 17-9 shows how to use `Delete()` on a LINQ command. Unfortunately, as Figure 17-4 shows, the SQL commands generated by EFPlus are suboptimal. They always work with a nested `SELECT`, although this would not be necessary. From the point of view of the authors of EFPlus, this was the simplest implementation because it is easy to use the existing `SELECT` command generation of Entity Framework Core. The execution results in the same performance as using a direct SQL command (see Table 17-3).

Bulk Update with EFPlus

Listing 17-10 shows the formulation of an UPDATE command with the additional component EFPlus (see Chapter 20) with the extension method Update(), which reduces the number of free seats by one on each future flight from Berlin. Figure 17-5 shows the SQL UPDATE command sent to the database management system, which works in the same way as Delete().

        (x.FreeSeats - 1) });
        Console.WriteLine("Changed records: " + count);
    }
}

Performance Optimization Through No-Tracking

As with its predecessor ADO.NET Entity Framework, Entity Framework Core has a no-tracking mode, which significantly speeds up the loading of data records. With the new implementation, Microsoft has improved the practical application of this function by adding a context option.

The performance measurement in Figure 17-6 shows that the optional no-tracking mode provides significant speed advantages over the standard tracking mode—both in the legacy ADO.NET Entity Framework and the new Entity Framework Core. In the no-tracking mode, Entity Framework Core can fetch 10,000 records (13 columns from a table, with no join, int, smallint, nvarchar(30), nvarchar (max), bit, timestamp) in 46 milliseconds over the network and materialize them in RAM into objects. This is almost as fast as an ADO.NET DataReader with manual mapping (self-written lines of code such as `obj.Name = Convert.ToString(dataReader["name"])`). In normal tracking mode, reading the records takes just over twice as long (100 milliseconds).

Figure 17-6. Performance comparison

In comparison, Figure 17-6 also shows Entity Framework 6.x. Here it takes 263 ms in tracking mode. At 53 milliseconds, there is only a marginal difference compared to Entity Framework Core in no-tracking mode. Microsoft has therefore accelerated Entity Framework Core compared to Entity Framework 6.1.3, especially the tracking mode. Nevertheless, the no-tracking mode in Entity Framework Core also pays off.

Activating No-Tracking Mode

In the first versions of the classic Entity Framework, you had to set no-tracking mode using the property `MergeOption` for each entity class or every query with an additional line of code. Since Entity Framework 4.1, you can set the mode at the level of a query with the much more elegant `AsNoTracking()` extension method (see Listing 17-11). In Entity Framework Core, only `AsNoTracking()` is used for this.

Listing 17-11. Activation of No-Tracking Mode with `AsNoTracking()` in Entity Framework 6.x and Entity Framework Core

```
CUI.Headline("No-Tracking mode");
using (WWWingsContext ctx = new WWWingsContext())
{
    var flightSet = ctx.FlightSet.AsNoTracking().ToList();
    var flight = flightSet[0];
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
        State); // Detached
    flight.FreeSeats--;
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
        State); // Detached
    int count = ctx.SaveChanges();
    Console.WriteLine($"Saved changes: {count}"); // 0
}
```

The consequence of no-tracking mode is shown in Figure 17-7, with the output of Listing 17-11. The change tracking feature of Entity Framework Core no longer works if you activate no-tracking mode. In the default case, objects are in the state `Unchanged` after loading, and they change to the state `Modified` after a change. When loading in no-tracking mode, they are `Detached` after loading and remain so even after the change. Execution of the `SaveChanges()` method then sends no change to the database management system because Entity Framework Core does not notice the change.

No-Tracking Mode Is Almost Always Possible

In any case, no-tracking mode should always be used for objects that only display data and should not be modified at all. But even if you want to modify individual objects, you can first load the objects in no-tracking mode and then later attach them to the context class. Therefore you have to change the objects only—in the best case before the change—and add them to the context using the `Attach()` method. This method exists both in the `DbContext` class and in the `dbSet<T>` class.

The `Attach()` method adds an object to Entity Framework Core change tracking. The object is thereby transferred from the state `Detached` to the state `Unchanged`. Of course, only instances of the entity class may be passed to `Attach()`. If you pass instances of classes that the Entity Framework Core context does not know, you will get the following error message: “The entity type `xy` was not found. Ensure that the entity type has been added to the model.”

Listing 17-12 (and the accompanying screen output in Figure 17-8) shows the use of the `Attach()` method in these three scenarios:

- `Attach()` is executed before the actual change. In this case, there is nothing else to do because Entity Framework Core recognizes all changes after `Attach()` and transfers the object independently from the state `Unchanged` to the state `Modified`.
- If a change occurs before `Attach()` is executed, Entity Framework Core knows nothing about the change that occurred. Therefore, you must subsequently register the change with `ctx.Entry(obj).Property(f => f.Property).IsModified = true`.

- If you do not know the changed properties of the object (for example, because the changes have occurred in the calling program code or another process) or it is too annoying to set the individual properties to `IsModified`, you can use `ctx.Entry(Flight).State = EntityState.Modified` to set the state of the whole object.

Listing 17-12. Using the `Attach()` Method

```

    CUI.MainHeadline(nameof(TrackingMode_NoTracking_Attach));

    using (WWWingsContext ctx = new WWWingsContext())
    {
        var flightSet = ctx.FlightSet.AsNoTracking().ToList();
        var flight = flightSet[0];
        Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
            State); // Detached
        ctx.Attach(flight);
        Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
            State); // Unchanged
        flight.FreeSeats--;
        Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
            State); // Modified
        int count = ctx.SaveChanges();
        Console.WriteLine($"Saved changes: {count}"); // 0
    }
    CUI.Headline("Attach() after change (change state per property)");
    using (WWWingsContext ctx = new WWWingsContext())
    {
        var flightSet = ctx.FlightSet.AsNoTracking().ToList();
        var flight = flightSet[0];
        Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
            State); // Detached
```

```

    flight.FreeSeats--;
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Detached
    ctx.Attach(flight);
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Unchanged
    // Register changed property at EFC
    ctx.Entry(flight).Property(f => f.FreeSeats).IsModified = true;
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Modified
    int count = ctx.SaveChanges();
    Console.WriteLine($"Saved changes: {count}"); // 1
}

CUI.Headline("Attach() after change (change state per object)");
using (WWWingsContext ctx = new WWWingsContext())
{
    var flightSet = ctx.FlightSet.AsNoTracking().ToList();
    var flight = flightSet[0];
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Detached
    flight.FreeSeats--;
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Detached
    ctx.Attach(flight);
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Unchanged
    ctx.Entry(flight).State = EntityState.Modified;
    Console.WriteLine(flight + " object state: " + ctx.Entry(flight).
    State); // Modified
    int count = ctx.SaveChanges();
    Console.WriteLine($"Saved changes: {count}"); // 1
}
}

```

As Figure 17-8 shows, the change is saved by `SaveChanges()` in all three cases. Behind the scenes, however, there is a difference between these three scenarios. In the first two scenarios, Entity Framework Core sends a SQL UPDATE command to the database, which updates only the actual `FreeSeats` column.

```
exec sp_executesql N'SET NOCOUNT ON;
UPDATE [Flight] SET [FreeSeats] = @p0
WHERE [FlightNo] = @p1;
```

```

Figure 17-8. Output from Listing 17-12

However, in the third scenario, the developer failed to give Core Entity Framework information about which properties actually changed. Entity Framework Core cannot help but send the values of all properties back to the database, even if they are already known there.

```
UPDATE [Flight] SET [AircraftTypeID] = @p0, [AirlineCode] = @p1, [CopilotId] =
@p2, [FlightDate] = @p3, [Departure] = @p4, [Destination] = @p5,
[FreeSeats] = @p6, [LastChange] = @p7, [Memo] = @p8, [NonSmokingFlight] =
@p9, [PilotId] = @p10, [Price] = @p11, [Seats] = @p12, [Strikebound] = @p13
WHERE [FlightNo] = @p14 AND [Timestamp] = @p15;
SELECT [Timestamp], [Utilization]
FROM [Flight]
WHERE @@ROWCOUNT = 1 AND [FlightNo] = @p14;
```

Note In addition to the fact that unnecessary data is being sent over the line, updating all columns poses a potential data change conflict. If other processes have already changed parts of the record, the changes will mercilessly overwrite those other processes. So, you should always ensure that Entity Framework Core knows the changed columns. If the modifications of the object took place before the `Attach()` method by the caller, then the caller must be obligated to supply corresponding meta-information about the changed properties.

No-Tracking Mode in an Editable Data Grid

When using the method `Attach()`, you can load almost all records in no-tracking mode. Figure 17-9 and Figure 17-10 show the usual data grid scenario. The user can load a (larger) amount of data and change any data sets. The changes are then persisted by clicking Save. (see Figure 17-12).

Figure 17-10. 10,000 records loaded in no-tracking mode in 96 milliseconds

In this case, it is not necessary at all to waste the extra time for tracking mode when loading. It is quite sufficient to use `Attach()` to log the individual records that the user is working on at the Entity Framework context (see Listing 17-13). The DataGrid control supplied by Microsoft for the Windows Presentation Foundation (WPF) uses the `BeginningEdit()` event. In the event handler, `Attach()` transfers the detached object to an attached object (see Figure 17-11) and thus registers the object as part of the change tracking of the Entity Framework context.

However, after loading with `AsNoTracking()`, it is not a good idea to attach all objects in a loop with `Attach()`. `Attach()` takes less than a millisecond per object. This is not noticeable when you attach individual objects to it. But in total, such a loop is slower than loading all the objects in tracking mode directly. So if you know for sure that all objects have to be changed, you should use tracking mode when loading.

  var flight = (Flight)e.Row.Item;

  if (flight.FlightNo > 0) // important so that new flights are not added
  before filling
  {
    // Attach may only be done if the object is not already attached!
    if (!ctx.FlightSet.Local.Any(x => x.FlightNo == flight.FlightNo))
    {
      ctx.FlightSet.Attach(flight);
      SetStatus($"Flight {flight.FlightNo} can now be edited!");
    }
  }
}
}
}

```

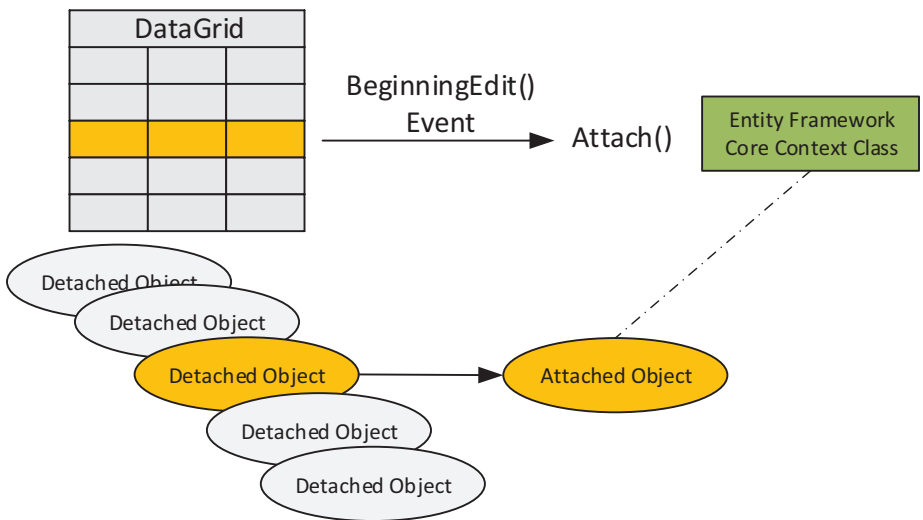

Figure 17-11. The developer logs the object to be changed in the DataGrid to *Attach()* at the Entity Framework context when the change begins

Note `Attach()` may be executed only if the object is not already connected to the context instance. Otherwise, a runtime error will occur. Whether the object is already connected to the context, you cannot ask the object itself. However, the `DbSet<T>` class has a property called `Local` that includes all objects in the local cache of Entity Framework Core. To query this cache, use `ctx.FlightSet.Local.Any (x => x.FlightNo == flight.FlightNo)`.

Warning The property `Local` has a method `Clear()`. Not only does this cause—as you would expect—an emptying of the cache of the Entity Framework Core context, but it also puts all objects contained in it in the state `Deleted`, which would delete them at the next `SaveChanges()`! To actually remove the objects from the cache only, you must set the objects individually to the state `Detached`, as shown here:

```
foreach (var f in ctx.FlightSet.Local.ToList ())
{
    ctx.Entry (f) .State = EntityState.Detached;
}
```

QueryTrackingBehavior and AsTracking()

No-tracking mode dramatically improves performance when reading data with Entity Framework and Entity Framework Core data sets. You have seen in earlier sections that the no-tracking mode should almost always be used. Unfortunately, in the classic Entity Framework, you always had to remember to use `AsNoTracking()` in each of your queries. This is not only annoying but is also easy to forget. In the classical Entity Framework, you need additional solutions, for example an abstraction for accessing `DbSet<T>`, which automatically enabled no-tracking mode each time.

In Entity Framework Core, Microsoft has introduced a more elegant solution: you can put the entire Entity Framework core context into no-tracking mode. There is the enumeration property `QueryTrackingBehavior` in the class `Microsoft.EntityFrameworkCore.DbContext` in the subobject `ChangeTracker`. By default, it is set to `QueryTrackingBehavior.TrackAll`; in other words, the tracking is activated. However, if you change it to `QueryTrackingBehavior.NoTracking`, all queries are executed in no-tracking mode, even without the `AsNoTracking()` extension method. To execute individual queries in tracking mode, there is a new extension method `AsTracking()` for a no-tracking basic mode (see Listing 17-16). Figure 17-13 shows the output.

Listing 17-16. Setting `QueryTrackingBehavior` and Using `AsTracking()`

Consequences of No-Tracking Mode

No-tracking mode has further consequences besides the missing change tracking, listed here:

- The objects do not load in the first-level cache of Entity Framework Core. When accessing the object again (for example, with `DbSet<T>.Find()`), it is always loaded by the database management system.
- There is no relationship fixup. Relationship fixup is a feature of Entity Framework Core that connects two independently loaded objects in RAM if they belong together according to the database. For example, say Pilot 123 has been loaded. Flight 101 is now loaded and has a value of 123 for Pilot in its foreign key relationship. Entity Framework Core will connect Flight 101 and Pilot 123 in RAM so you can navigate from Flight to Pilot and, for bidirectional navigation, from Pilot to Flight.

- Lazy loading does not work with no-tracking, but lazy loading is not currently available in Entity Framework Core anyway.

Best Practices

The new default `QueryTrackingBehavior.NoTracking` and the new extension method `AsTracking()` are meaningful additions in Entity Framework Core. But having seen many poorly performing applications of Entity Framework/Entity Framework Core in practice, for me this does not go far enough. `QueryTrackingBehavior.NoTracking` should be standard so that all developers get a high-performance query execution. Currently, in Entity Framework Core with `QueryTrackingBehavior.TrackAll` as the standard setting, every developer still has to remember to set `QueryTrackingBehavior.NoTracking`. It's best to do this in the constructor of the context class itself, and as a result, you will have no more overhead for tracking queries!

Selecting the Best Loading Strategy

The loading strategies available for Entity Framework Core for related master or detail data (explicit reload, eager loading, and preloading) were discussed in Chapter 9. Unfortunately, I cannot say in general what the best loading strategy is. It always depends on the situation, and the best loading strategy for your situation can be determined only on a case-by-case basis through performance tests. However, some blanket statements are still possible.

Basically, it is advisable not to load connected data records as a whole, if they are not absolutely necessary, but to load connected data sets only when they are actually needed. It depends on the number of potentially connected and connected data sets to determine whether eager loading is worthwhile.

If you know that connected data is needed (for example, in the context of a data export), you should choose eager loading or preloading. The preloading trick shown can significantly increase the performance in many cases compared to eager loading with `Include()`.

If you do not know exactly whether the linked data is needed, then the choice between delayed loading and eager loading is often a choice between the plague and cholera. Reloading slows everything down through the additional round-trips to the server, but eager loading slows everything down through the larger set of results. In most

cases, however, an increased number of round-trips is worse for performance than the bigger result sets.

If you're not sure, do not wire delayed loading or eager loading into the code, but instead allow it to be controlled via a configuration at runtime. Thus, the operator of the application can tune the application with increasing amounts of data and according to the typical user behavior of the application.

Caching

Both web and desktop applications have data that is constantly in use but rarely updated in the data store. In these cases, time-based caching of the data in RAM is useful. The classic .NET has had the component `System.Runtime.Caching.dll` since version 4.0. A precursor to `System.Runtime.Caching` has been around since .NET 1.0 within ASP.NET in the namespace `System.WebCaching` in `System.Web.dll`. The component `System.Runtime.Caching.dll` introduced in .NET 4.0, on the other hand, can be used in all types of applications. `System.Runtime.Caching` inherently offers only one kind of cache: `MemoryCache` for RAM caching. You can develop other cache methods (for example, on dedicated cache servers or in the file system) by deriving from the base class `ObjectCache`. The caching feature of Windows Server's AppFabric is another caching option, but it is not `System.Runtime.Caching`-based.

Note .NET Core replaces `System.Runtime.Caching` with the NuGet package `Microsoft.Extensions.Caching.Memory`. However, `System.Runtime.Caching` is now part of the Windows Compatibility Pack for .NET Core (<https://blogs.msdn.microsoft.com/dotnet/2017/11/16/announcing-the-windows-compatibility-pack-for-net-core>), which is also available for .NET Core.

MemoryCache

Listing 17-17 shows an example of using `MemoryCache` in conjunction with Entity Framework Core. First, `GetFlights1()` checks whether the list of flights from a departure is already in the cache. If the list does not exist, all relevant flights are loaded with a

new Entity Framework context instance. For this data set, `GetFlights1()` creates a cache entry called `FlightSet`. The program code with `policy.AbsoluteExpiration = DateTime.Now.AddSeconds(5)` determines that the cache entry should expire after five seconds. It then automatically disappears from the RAM.

Of course, it would also be possible to create a separate cache entry for each departure location to cache all flights in one entry and then to filter them from the RAM. Then the number of database accesses would be even lower, but you would also have data in RAM that you might not need. This can be considered only if the data volumes are not too large. How much RAM is used for caching can be set in the application configuration file (`app.config/web.config`), either in absolute megabytes (`cacheMemoryLimitMegabytes`) or in a percent of physical memory (`physicalMemoryLimitPercentage`). The check interval for these limits (`pollingInterval`) can also be defined. As an alternative to defining these parameters through the application configuration file, it is possible to pass them to the constructor of `MemoryCache` as a `NameValueCollection`.

The `Demo_MemoryCache()` method in Listing 17-17 tests the operation of `GetFlights1()` by making two calls per second within 15 seconds. Listing 17-17 shows that the caching solution works as expected and reloads the flights only every five seconds. Figure 17-14 shows the output.

Figure 17-14. Output to Listing 17-17

Note Incidentally, `System.Runtime.Caching` can do even more, especially so-called cache invalidation based on resource changes. For example, a cache entry can be removed immediately (even before the expiration of the set cache period) if a file changes (`HostFileChangeMonitor`) or the contents of a database table (`SqlChangeMonitor`) change.

CacheManager

Data access methods such as `GetFlights1()` appear hundreds or even thousands of times in each application. The same program code appearing repeatedly to check for the existence of the cache entry and possibly creating a new entry is certainly not a good solution.

In Listing 17-18, the task is much more concise and tidier. `GetFlights2()` consists only of calling the generic `Get()` method of an instance of the `CacheManager` class. The `CacheManager` receives the cache duration in seconds during instantiation. In addition to the type parameter describing the return type, the `Get()` method expects the cache entry name and a reference to a load method for the data. The third and any subsequent parameters are passed to the load method by `Get()`. The load method `GetFlights2Internal()` is then completely free of cache aspects and is responsible only for loading the data with Entity Framework. It could also be called directly, but this is usually undesirable. Therefore, it is also “private” here.

Listing 17-18. Simplified Implementation of the Task Now with the CacheManager

```

public static void Demo_CacheManager()
{
    CUI.MainHeadline(nameof(Demo_CacheManager));
    DateTime Start = DateTime.Now;
    do
    {
        var flightSet = GetFlight2("Rome");
        // you can process the flights here...
        Console.WriteLine("Processing " + flightSet.Count + " flights...");
        System.Threading.Thread.Sleep(500);
    } while ((DateTime.Now - Start).TotalSeconds < 60);
}

/// <summary>
/// GetFlight with CacheManager (5 sek)
/// </summary>
private static List<Flight> GetFlight2(string departure)
{
    string cacheItemName = "FlightSet_" + departure;
    var cm = new CacheManager<List<Flight>>(5);
    cm.CacheHitEvent += (text) => { CUI.Print($"{DateTime.Now.
    ToLongTimeString()}: Cache hit: " + text, ConsoleColor.Green); };
    cm.CacheMissEvent += (text) => { CUI.Print($"{DateTime.Now.
    ToLongTimeString()}: Cache missed: " + text, ConsoleColor.Red); };
    return cm.Get(cacheItemName, GetFlight2Internal, departure);
}

private static List<Flight> GetFlight2Internal(object[] param)
{
    using (var ctx = new WWWingsContext())
    {

```

```

    ctx.Log();
    string departure = param[0] as string;
    // Load flights
    return ctx.FlightSet.Where(x => x.Departure == departure).ToList();
}
}

```

However, this elegant `CacheManager` class is not a .NET Framework class but a self-implementation. The full source code for this class is shown in Listing 17-20. In addition to the generic `Get()` method used in Listing 17-18, which expects a type parameter and a load method, you can also directly retrieve data from the cache with another overload of `Get()`. If the data does not exist, you get zero back here. With `Save()` you can also save directly. The user of the `CacheManager` class does not see anything of the underlying library `System.Runtime.Caching`.

By its very nature, using the property `SlidingExpiration` instead of `AbsoluteExpiration` sounds seductive for the given task. However, the policy `leads.SlidingExpiration = new TimeSpan(0,0,0,5)` says that the data will never be reloaded after the first load because the time span of 5 seconds set by `TimeSpan(0,0,0,5)` refers to `SlidingExpiration`. The last access, i.e. only five seconds after the last read access the cache entry is removed. To force a reload, you would have to set the duration for `Sleep()` to 5000 or higher in the method `Demo_CacheManager()`.

If you want it to be a bit more succinct, you should look at Listing 17-20, which shows a variant with an anonymous function. It is no longer necessary to write a separate load method; the necessary code is completely embedded in `GetFlights4()`. Thanks to the Closure technique, `Get()` no longer needs to get `Departure` as a parameter, because the anonymous method embedded in `GetFlights3()` can directly access all the variables of the `GetFlights3()` method.

        {
            // Load flights
            return ctx.FlightSet.Where(x => x.Departure == departure).ToList();
        }
    };

Second-Level Caching with EFPlus

The `CacheManager` shown in Listing 17-18 is a general solution that allows you to cache not just Entity Framework objects but any form of data. Caching on Entity Framework Core can be even more elegant! For Entity Framework Core there is a special caching solution within the additional libraries Entity Framework Plus (EFPlus) and `EFSecondLevelCache.Core` (see Chapter 20).

These components implement a context-independent query result cache based on `System.MemoryCache.Runtime.Caching`. Such a cache is called a *second-level cache*. These extra components can manipulate queries so that Entity Framework Core materializes their results into objects and stores them not only in the first-level cache of the context instance but also in a second-level cache at the process level. Another context instance can then look up the same query in this second-level cache and deliver the objects stored there instead of a new query from the database management system (see Figure 17-15).

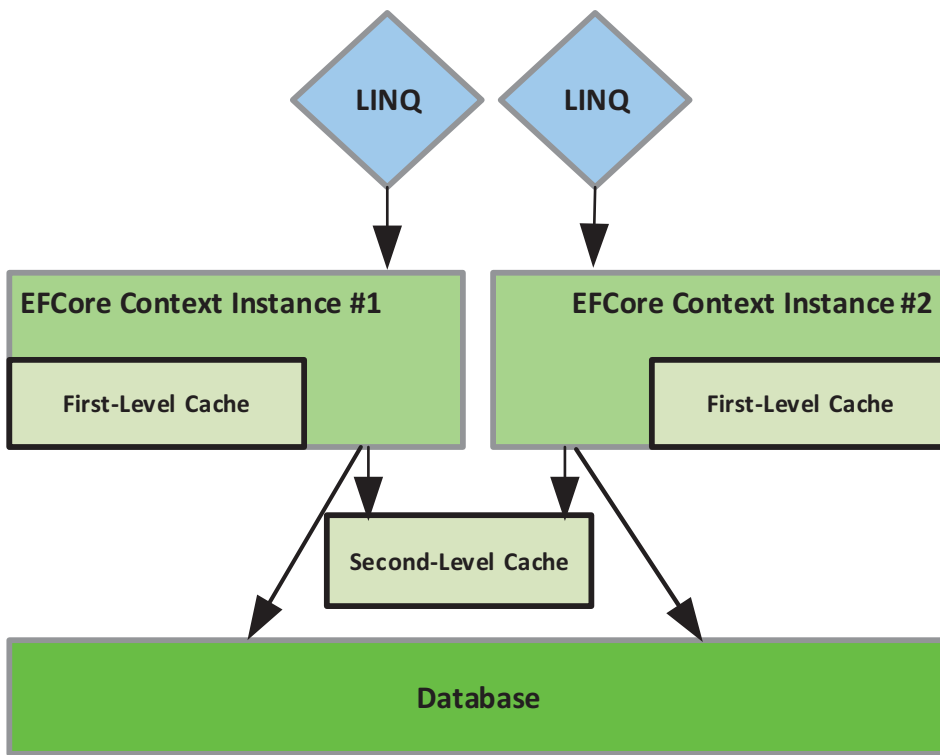

Figure 17-15. How a second-level cache works

Note This section discusses the second-level cache in EFPlus. `EFSecondLevelCache.Core` is much more complex in configuration but also more flexible because in addition to the main memory cache (`MemoryCache`), Redis as a cache is possible.

Setting Up a Second-Level Cache

Setting up a second-level cache in the context class is not necessary with EFPlus.

Using the Second-Level Cache

Listing 17-21 shows the application of the second-level cache in EFPlus. In `GetFlights4()`, the `FromCache()` method is used in the LINQ query, specifying a caching duration (here: five seconds), in the form of an object of type `MemoryCacheEntryOptions` from the NuGet package `Microsoft.Extensions.Caching.Abstractions`.

Alternatively, you can set the cache duration centrally and then omit the `FromCache()` parameter.

```
var options = new MemoryCacheEntryOptions() { AbsoluteExpiration =
DateTime.Now.AddSeconds(5) };
QueryCacheManager.DefaultMemoryCacheEntryOptions = options;
```

Note that `GetFlights4()` creates a new context instance each time it is called, but caching still works, as Figure 17-16 demonstrates.

The screenshot shows a console window titled "H:\TFDemos\EFC\EFC_Samples\EFC_Console\bin\Debug\EFC_Console.exe". The output consists of several repeated blocks of text: "Lade Flights from Rome...", "48 Flights in RAM!", and "Processing 48 flights...". A red error message is visible: "0831:Debug #20100 Microsoft.EntityFrameworkCore.Database.Command.CommandExecuting:Executing DbCommand [Parameters=[@__departure_0='?' (Size = 50)], CommandType='Text', CommandTimeout='30']". Below this, a LINQ query is shown: "FROM [Flight] AS [x] WHERE [x].[Departure] = @__departure_0". The output repeats these blocks multiple times, demonstrating that the cache is being used and refreshed.

Figure 17-16. Output of Listing 17-21

Unfortunately, unlike the solutions that directly use the `MemoryCache` object, you have no way of getting information whether the objects came from the cache or at which time the database was consulted because unfortunately the cache manager of EFPlus in this cases fires no results. So, you can derive the cache behavior from the database accesses, which you do through Entity Framework logging (`ctx.Log()`; see Chapter 12) or via an external profiler (for example, Entity Framework Profiler or SQL Server Profiler).

Listing 17-21. Second-Level Caching with EFPlus

        // you can process the flights here...
        Console.WriteLine("Processing " + flightSet.Count + " flights...");
        System.Threading.Thread.Sleep(500);

CHAPTER 18

Software Architecture with Entity Framework Core

Entity Framework Core undoubtedly belongs to the data access layer. But what does the layer model look like overall when using Entity Framework Core? In this chapter, I briefly discuss several architectural alternatives.

Monolithic Model

Entity Framework Core can be used in a monolithic software model. In other words, the instantiation of the Entity Framework Core context and the execution of the commands (LINQ, stored procedures, SQL) are in the presentation layer (see Figure 18-1). However, this makes sense only in very small applications (see the app *MiracleList Light* in Appendix A).

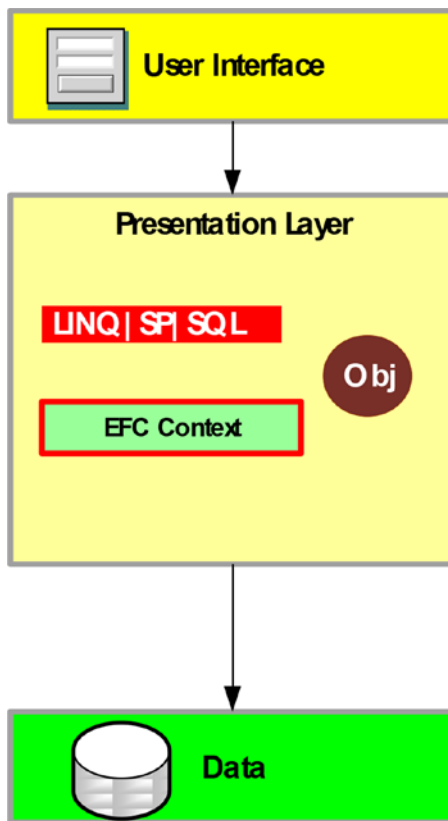

Figure 18-1. Entity Framework Core in the monolithic software architecture model

Entity Framework Core as a Data Access Layer

Figure 18-2 shows the general structure of a multilayer application on the left and shows a simple multilayered software architecture model on the right, using Entity Framework Core for data access. This pragmatic software architecture model dispenses with a dedicated data access layer. Rather, the Entity Framework context is the complete data layer. The overlying layer is the business logic layer, which controls data access through Language Integrated Query (LINQ) commands and the invocation of stored procedures, including direct SQL commands as needed. According to statements in the business logic layer, the Entity Framework context fills the entity classes. Entity classes are passed down through all layers to the presentation layer.

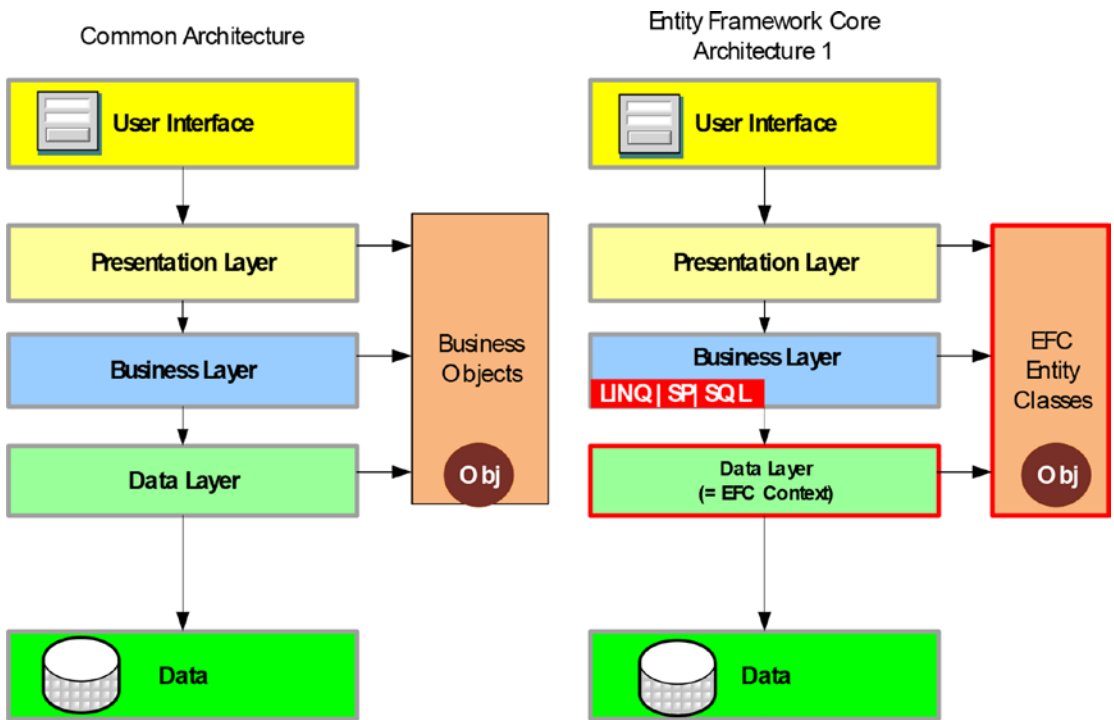

Figure 18-2. The pragmatic Entity Framework Core–based software architecture model

Some software architects criticize this simplified model because the business logic layer is contaminated with data access commands. The business logic layer should not actually contain any database access commands. You can see this if you really equate LINQ with SQL. But you can also understand LINQ as a true abstraction of SQL. After all, LINQ commands are just a sequence of database-neutral method calls; the SQL-like syntax in C# and Visual Basic is just syntactic sugar for the software developer. The C# or Visual Basic compiler immediately makes the LINQ commands a method call string again. You can also use this method call string itself, that is, `collection.Where(x => x.CatID > 4).OrderBy(x => x.Name)` instead of `x` in `collection where x.CatID > 4 orderby x.Name`. But method calls are exactly the form in which business logic and data access control normally communicate with each other; that is, the necessary use of LINQ in the business logic layer does nothing here other than what is common practice between the business logic and the data layer. LINQ is only more generic than most APIs of data layers.

What is actually some contamination of the business logic layer is the use of the Entity Framework context instance in the business logic layer. This means that the business logic layer must have a reference to the Entity Framework Core assemblies.

A subsequent replacement of the object-relational mapper then means a change to the business logic layer. But the clear advantage of this model is the simplicity. You do not have to write your own database access layer, and that saves time and money.

Pure Business Logic

Nevertheless, some software architects will reject the previous pragmatic model as too simple and instead rely on the second model (see Figure 18-3). In doing so, you create your own data access control layer. In this data access control layer, all LINQ calls and stored procedure wrapper methods are packaged again in self-written methods. These methods then call the business logic layer. In this model, only the data access control layer needs a reference to the Entity Framework Core assemblies; therefore, the business logic remains “pure.”

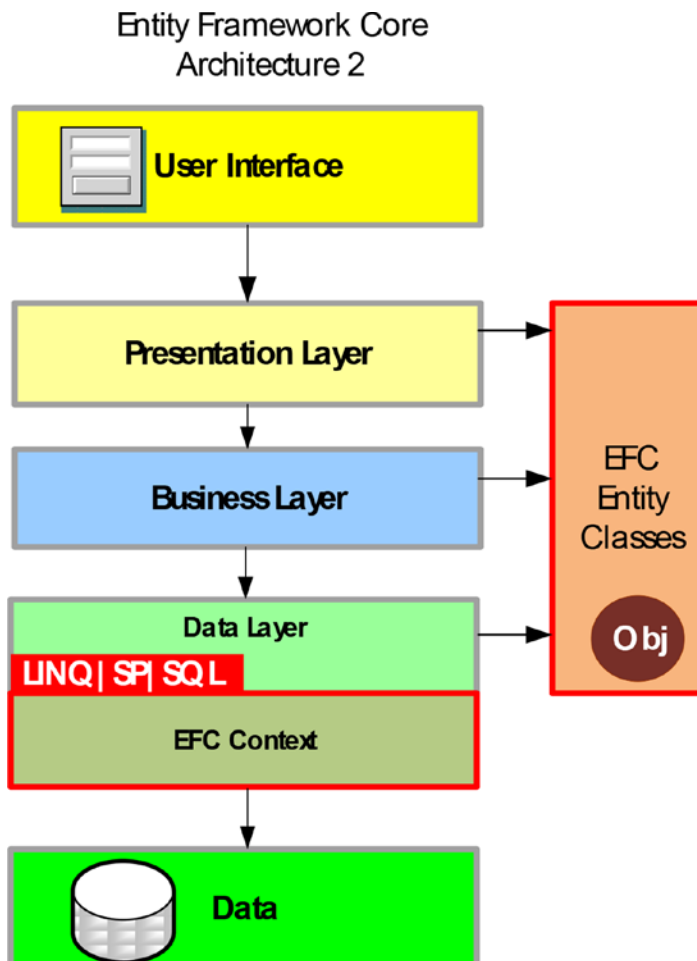

Figure 18-3. The textbook Entity Framework Core-based software architecture model without distribution

This second software architecture model corresponds to the “pure” doctrine, but in practice it also requires much more implementation effort. Especially in cases of “form-over-data” applications with little business logic in the strict sense, the developer has to implement many “annoying” wrapper routines. For LINQ, `GetCustomers()` in the database access layer contains the LINQ command, and `GetCustomers()` in the business logic forwards to `GetCustomers()` in the database access layer. With stored procedure usage, both layers only pass on.

Business Classes and ViewModel Classes

The third software architecture model to be discussed here (see Figure 18-4) goes even further with an abstraction step and also prohibits the entity classes from being passed on to all layers. Rather, a mapping of the entity classes to other classes takes place. These other classes are often called *business (object) classes* and sometimes also called *data transfer objects (DTOs)* in contrast to the data-heavy entity classes. In model 3b (the right side of the figure), these business object classes are again mapped to classes that have been specially formatted for the view as part of the Model-View-ViewModel (MVVM) pattern.

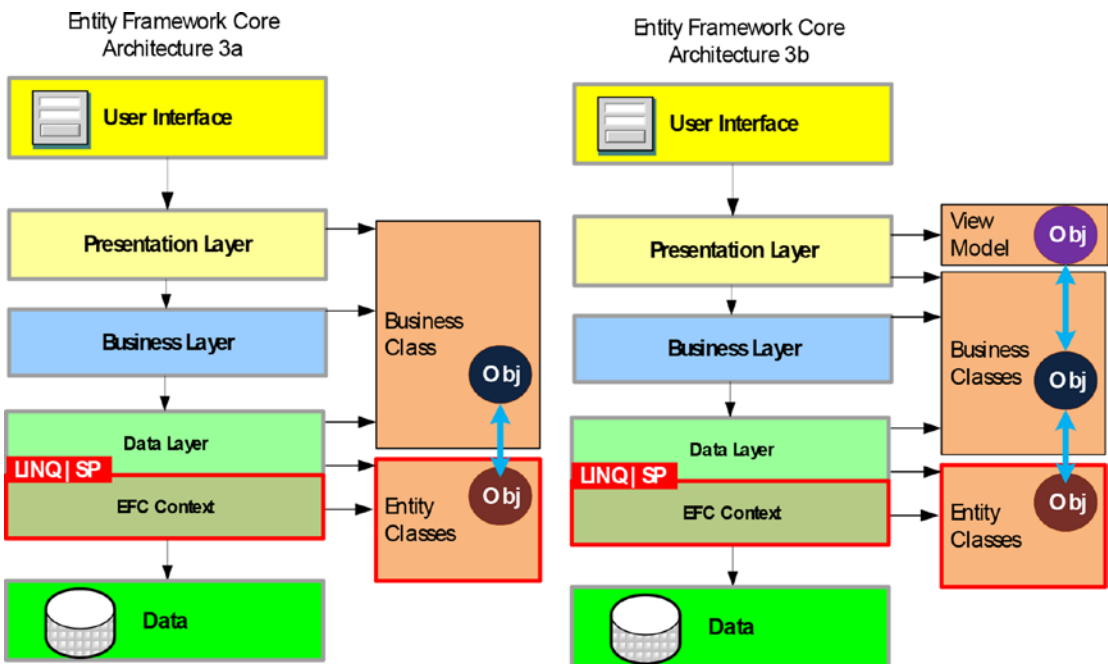

Figure 18-4. Business objects and ViewModel classes

The business class-based software architecture model would be mandatory if the created entity classes had a relationship to Entity Framework Core (something like the `EntityObject` base class in the first version of the classic ADO.NET Entity Framework). But that's not the case in Entity Framework Core. A good reason for using the business class-based model is if the Design of the entity classes match the needs of the presentation layer, for example, because it is a "historically grown" database schema.

However, this business class-based model implies a considerable implementation overhead because all data must be transferred from the entity classes to the business classes. And of course this transfer must be implemented in the opposite direction for new and changed objects. Such an object-to-object mapping (OOM) does not work with an object-relational mapper like Entity Framework Core. However, there are other frameworks for object-to-object mapping, such as AutoMapper (<http://automapper.org>) and ValueInjector (<http://valueinjecter.codeplex.com>). But even with such frameworks, the implementation effort is significant, especially since there is no graphical designer for object-to-object mapping.

Also, the effort is higher not only at development time but also at runtime since the additional mapping requires computation time.

Distributed Systems

Figure 18-5, Figure 18-6, and Figure 18-7 show six software architecture models for distributed systems with Entity Framework Core for data access. There is now no direct access to the database from the client, but there is a service façade on the application server, as well as proxy classes in the client (which call the service façade). In terms of the division of the business logic layer and the data access layer, you have the same options as in architecture 1 and architecture 2. These options are not shown here. It's more about the entity classes. If you use the same classes on the client side as on the server side, this is called *shared contracts*. This is possible whenever the server and client are written in .NET, and therefore the client can reference the assembly with the classes from the server. The case of shared contracts is shown in architecture 4 on the left of Figure 18-5; here the client also uses the Entity Framework Core entity classes.

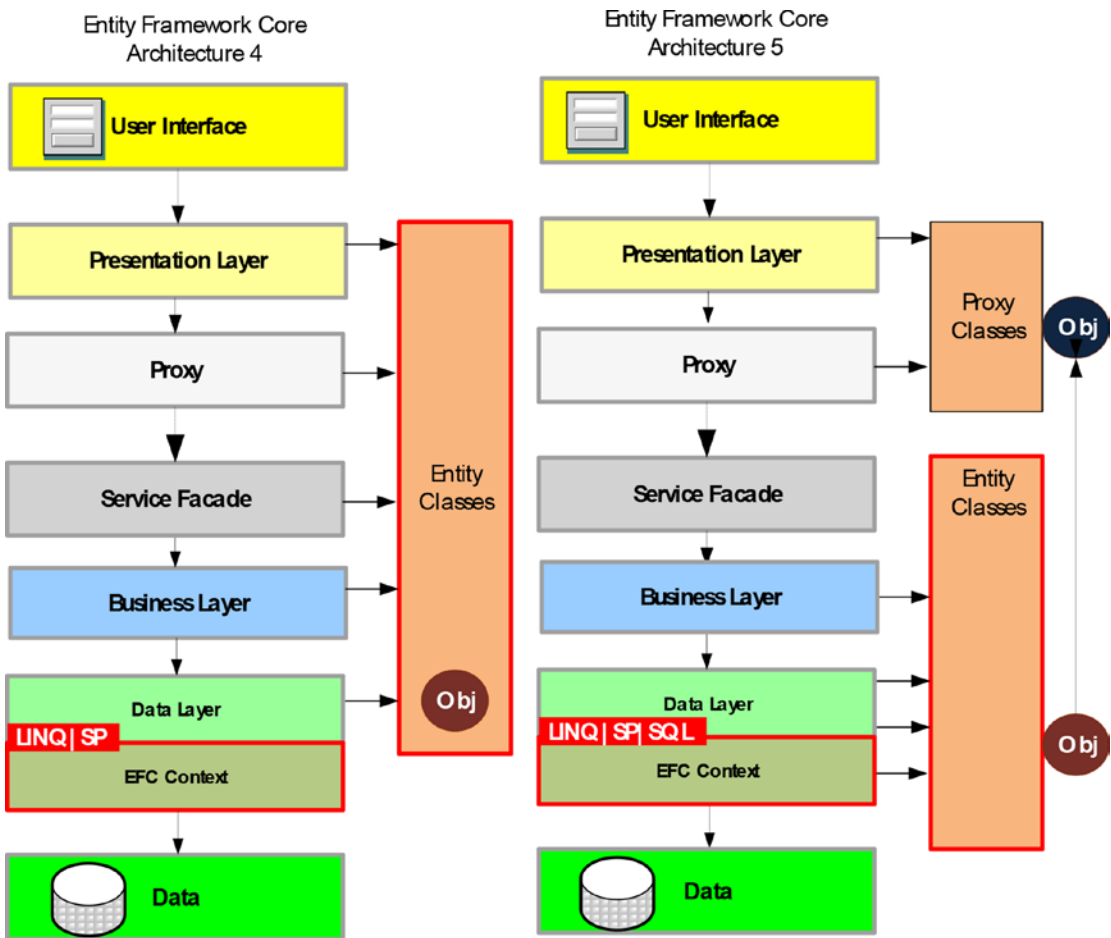

Figure 18-5. Entity Framework Core-based software architecture models in a distribution system

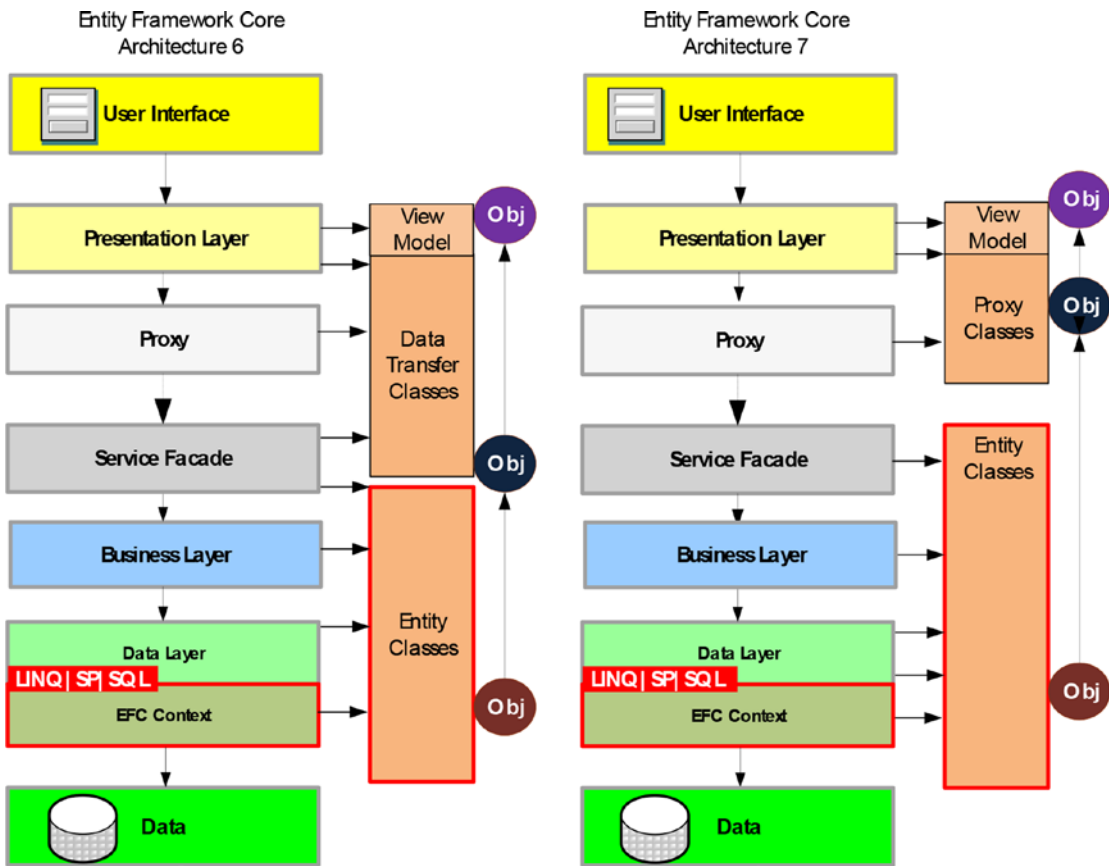

Figure 18-6. Entity Framework Core-based software architecture models in a distribution system

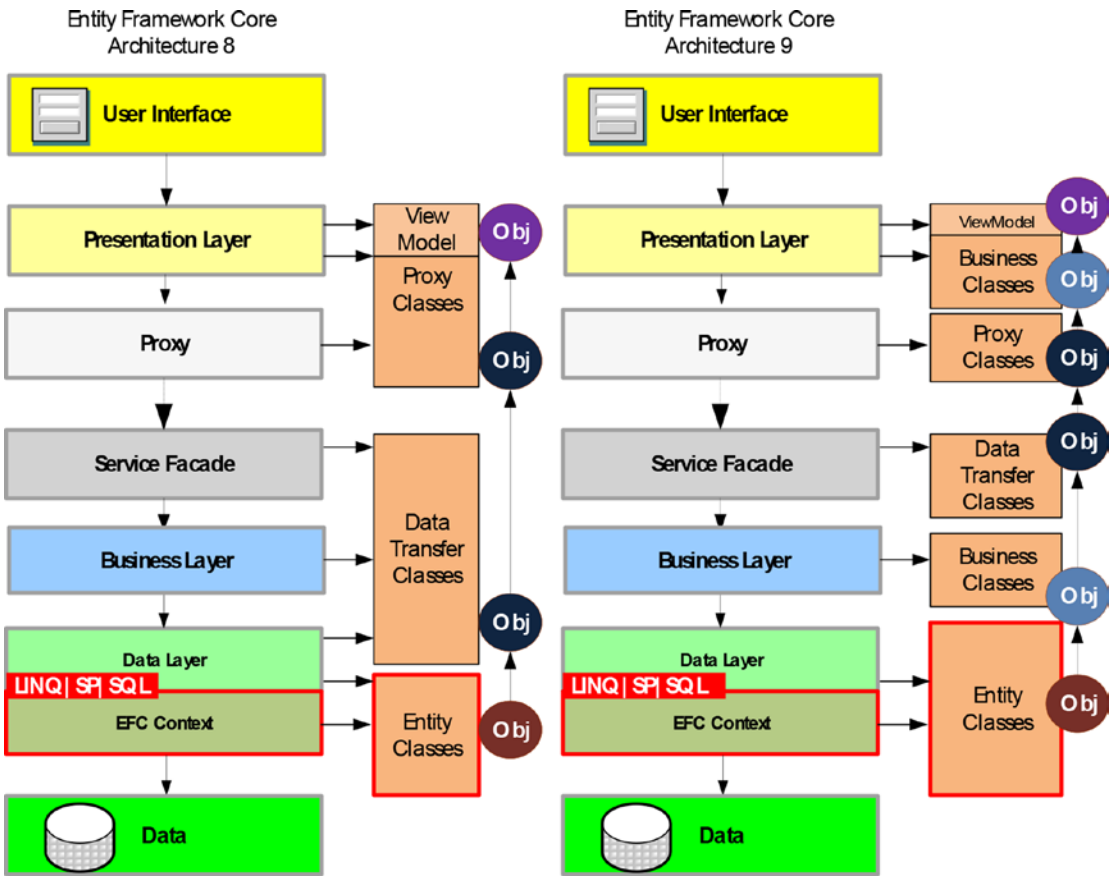

Figure 18-7. More Entity Framework Core-based software architecture models with distribution

If the client has a different platform, then you have to create proxy class for the entity classes. In architecture 5 shown in Figure 18-5, explicit proxy classes are desired or necessary because the client is not .NET.

The architecture models 6 to 9 differ only in terms of the mapping of the entity classes.

- Although architecture 6 works with shared contracts, it maps the entity classes to DTO classes that are optimized for online transmission. In the client, there is another OO mapping to ViewModel classes.
- Architecture 7 assumes proxy classes and an OO mapping to ViewModel classes.

- Architecture 8 uses DTO, proxy, and ViewModel classes.
- The most elaborate model, architecture 9, also uses business object classes in the client.

You might be wondering who uses architecture 9. In fact, I see in my job as a consultant that many software architectures are elaborately designed like this. These are projects in which larger teams work, and nevertheless every small user request needs a long time in the implementation.

Conclusion

Software architects have many architectural options when using Entity Framework Core. The bandwidth starts with a simple, pragmatic model (with a few compromises), where developers have to implement only three assemblies. On the other side of the architectural models presented here, you need at least 12 assemblies.

Which of the architectural models to choose depends on various factors. Of course, this includes the specific requirements, the system environment, and the know-how of the available software developers. But also the budget is an important factor. I experience in my everyday life as a consultant with companies again and again that software architects choose a too-complex architecture because of the “pure” doctrine that is not adapted to the business conditions. In such systems, even the smallest user request (“We still need a field on the left”) is typically extremely time-consuming and costly to implement. Many projects fail because of unnecessarily complex software architecture.

Tip Use as few layers as possible. Think twice before adding another abstraction to your software architecture model.

CHAPTER 19

Commercial Tools

This chapter introduces commercial tools that you can use for Entity Framework Core. I am in no way involved in the development or distribution of these tools.

Entity Framework Core Power Tools

Microsoft offered Power Tools for the classic Entity Framework, but the reissue for Entity Framework Core is now implemented by an external developer. Entity Framework Core Power Tools is a free extension to Visual Studio 2017.

EF Core Power Tools

Tool name	Entity Framework Core Power Tools
Web site	https://www.visualstudiogallery.msdn.microsoft.com/9674e1bb-d942-446a-9059-a8b4bd18dde2
Manufacturer	Erik Ejlskov Jensen (MVP), https://github.com/ErikEJ
Free version	Yes
Commercial version	No

Features

Once installed, Entity Framework Core Power Tools (Figure 19-1) can be accessed via the context menu of a project in the Visual Studio Solution Explorer. The add-on offers the following functions:

- Graphical user interface for the reverse engineering of existing databases in SQL Server, SQL Compact, and SQLite

- The ability to create a diagram for a given Entity Framework Core context
- The ability to create a diagram for a database schema
- The ability to display the SQL DDL commands for creating a database schema for an Entity Framework Core context with its entity classes

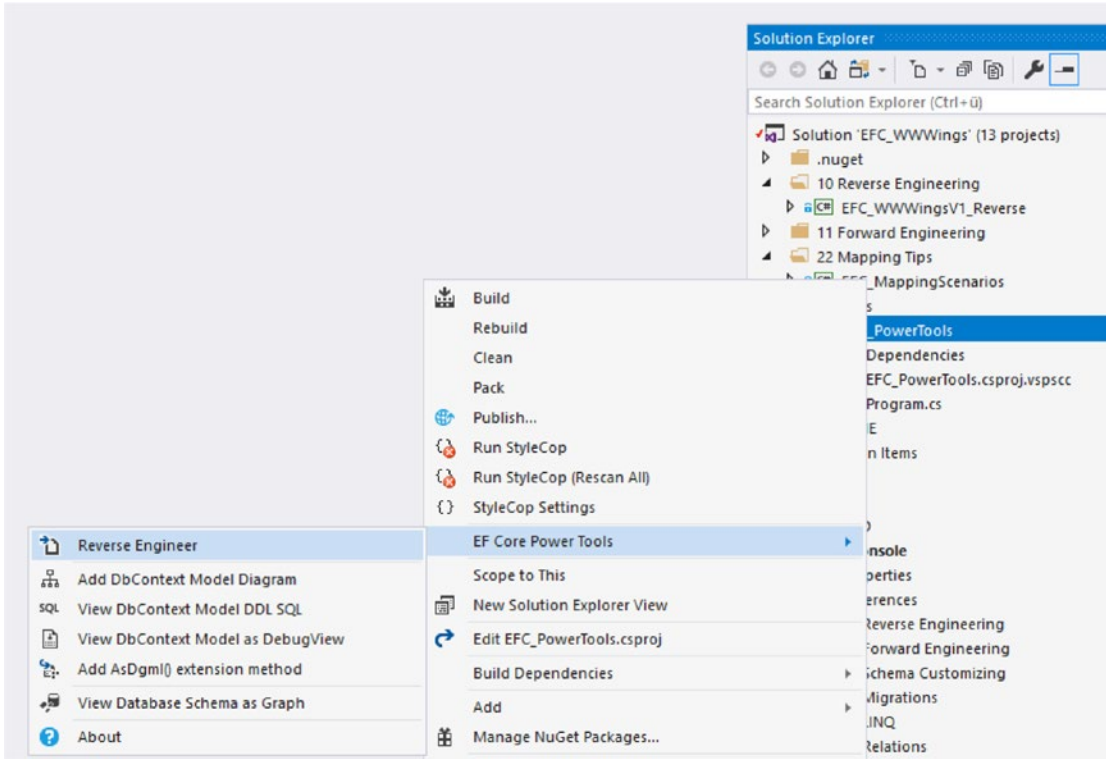

Figure 19-1. Entity Framework Core Power Tools in the context menu of a project in Solution Explorer

Reverse Engineering with Entity Framework Core Power Tools

Reverse engineering with Entity Framework Core Power Tools consists of three steps. In the first step, you select the database via the standard dialog of Visual Studio (Figure 19-2). In the second step, you select the tables (Figure 19-3). You can save the table selection as a text file and reload it for a new call (Figure 19-4). In the third step, you set the options,

that are also allowed by the Scaffold-DbContext cmdlet (Figure 19-5). After that, the code generation is the same as in Scaffold-DbContext (Figure 19-6).

Note Just like with Scaffold-DbContext, updating the program code after changes in the database (Update Model from Database) isn't implemented by Power Tools.

You can also generate this diagram at runtime with the extension method `AsDgml()`, which is available in the NuGet package `ErikEJ.EntityFrameworkCore.DgmlBuilder` (Listing 19-1).

            {
```

```

var path = System.IO.Path.GetTempFileName() + ".dgm1";
System.IO.File.WriteAllText(path, ctx.AsDgml(), System.Text.Encoding.
UTF8);
Console.WriteLine("file saved:" + path);
}
}
}
}
}
}

```

LINQPad

Language Integrated Query (LINQ) is popular among developers because of its static typing. But always having to run a compiler to try a LINQ command can be annoying. When you use the query editor in Microsoft SQL Server Management, you enter a SQL command, press the F5 key (or click Execute), and see the result. Microsoft once thought of allowing LINQ to Entities to run Entity Framework in Management Studio in the same way, but nothing has been published so far.

The third-party tool LINQPad allows the interactive input of LINQ commands and the direct execution in an editor. You can execute LINQ commands against objects in RAM (LINQ to Objects), Entity Framework/Entity Framework Core, and various other LINQ providers.

Tool name	LINQPad
Website	www.linqpad.net
Manufacturer	Joseph Albahari, Australia
Free version	Yes
Commercial version	From \$45

LINQPad is available as a free freeware version. But if you want to be pampered by IntelliSense input support in the style of Visual Studio, you have to buy the Professional or Premium version. In the Premium version, there are also numerous included program code snippets. Likewise, in the Premium version, you can define queries using several databases. The system requirement for the current version 5 is .NET Framework 4.6. At only 5MB in size, the application is very lightweight. The author of the tool says, “It does not slow down your computer when you install it!”

Using LINQPad

LINQPad presents a window for the connections in the top-left corner (see Figure 19-8). Underneath you can choose from a supplied sample collection (from the book *C# 6.0 in a Nutshell*) or save your own commands (under My Queries). In the main area you will find the editor at the top and the output area at the bottom (see the center/right of Figure 19-8).

LINQPad supports the syntax of C#, Visual Basic .NET, and F# as well as SQL and Entity SQL (the latter only for the classic Entity Framework).

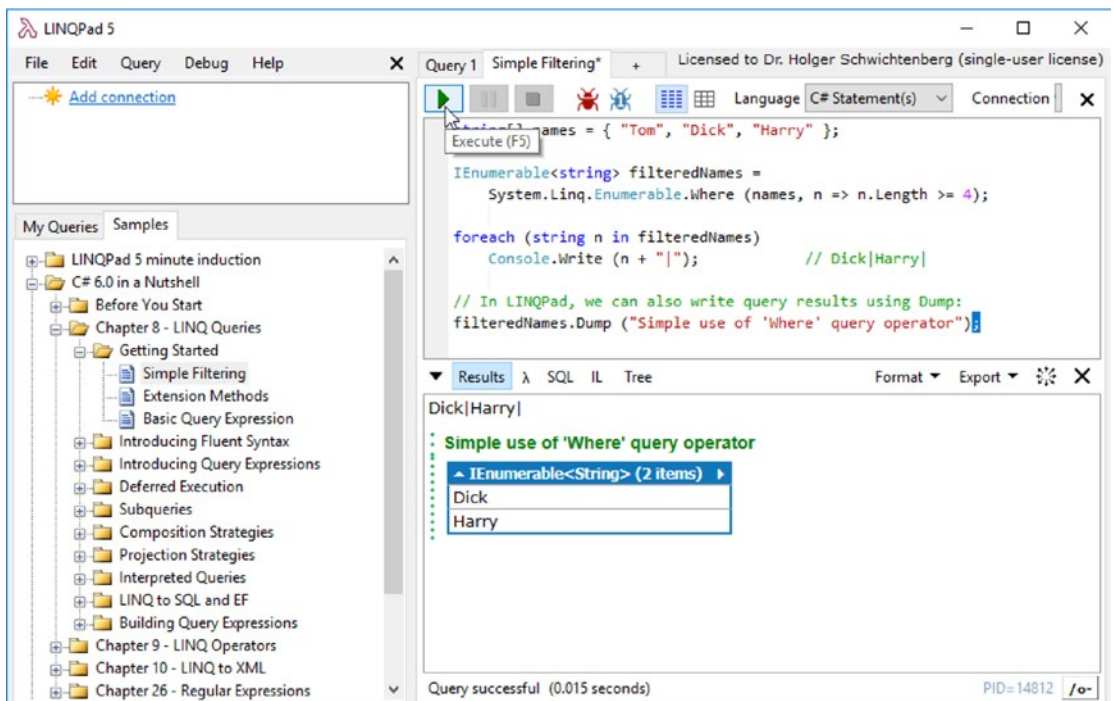

Figure 19-8. LINQPad in action with LINQ to Objects

Including Data Sources

To run LINQ commands against an Entity Framework Core context, you must add a connection using Add Connection. However, the dialog currently only shows drivers for LINQ to SQL and the classic Entity Framework. With View More Drivers, you can download a driver for Entity Framework Core (Figure 19-9).

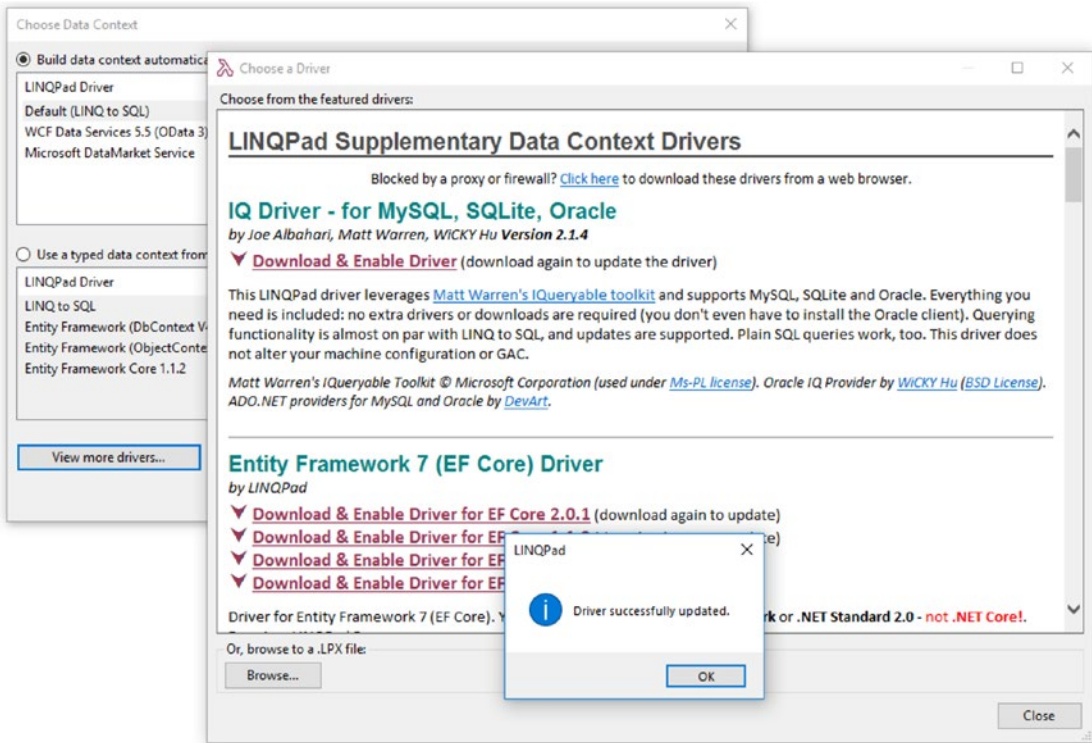

Figure 19-9. Adding Entity Framework Core drivers for LINQPad

After adding the driver, you should be able to select Entity Framework Core (Figure 19-10).

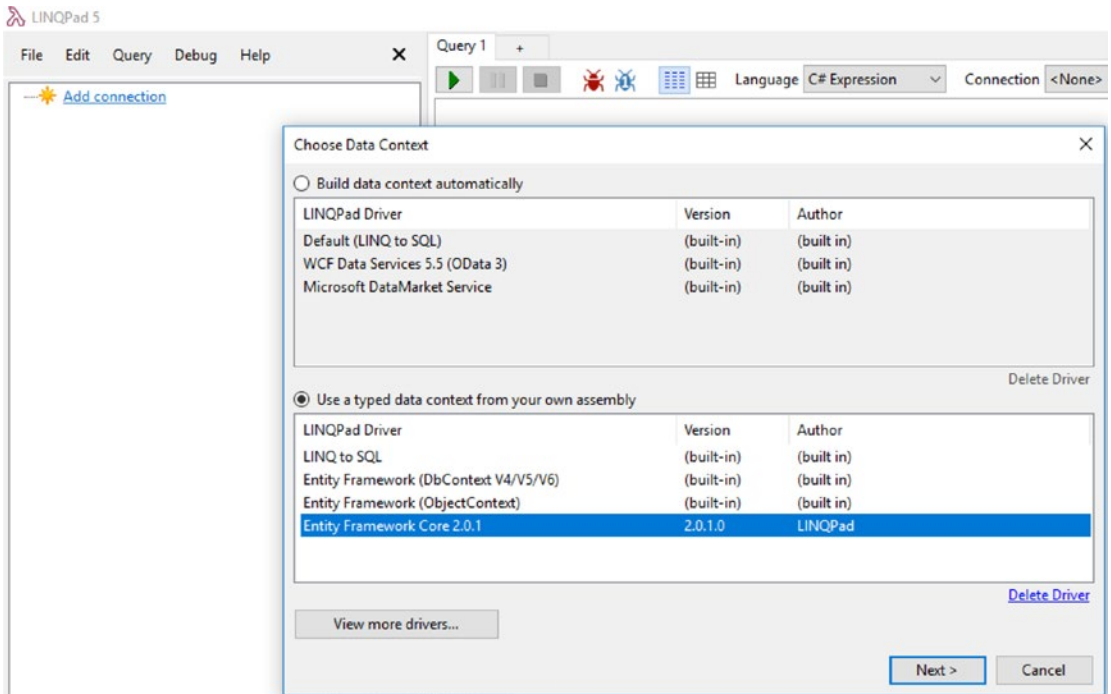

Figure 19-10. Selecting Entity Framework Core as the LINQPad driver

After selecting the provider, you have to integrate an Entity Framework Core context. To do this, use Browse (see Figure 19-11) to select a .NET assembly that implements such a context.

Note LINQPad itself does not create context classes for Entity Framework and Entity Framework Core. You always have to create and compile such a class using Visual Studio or another tool.

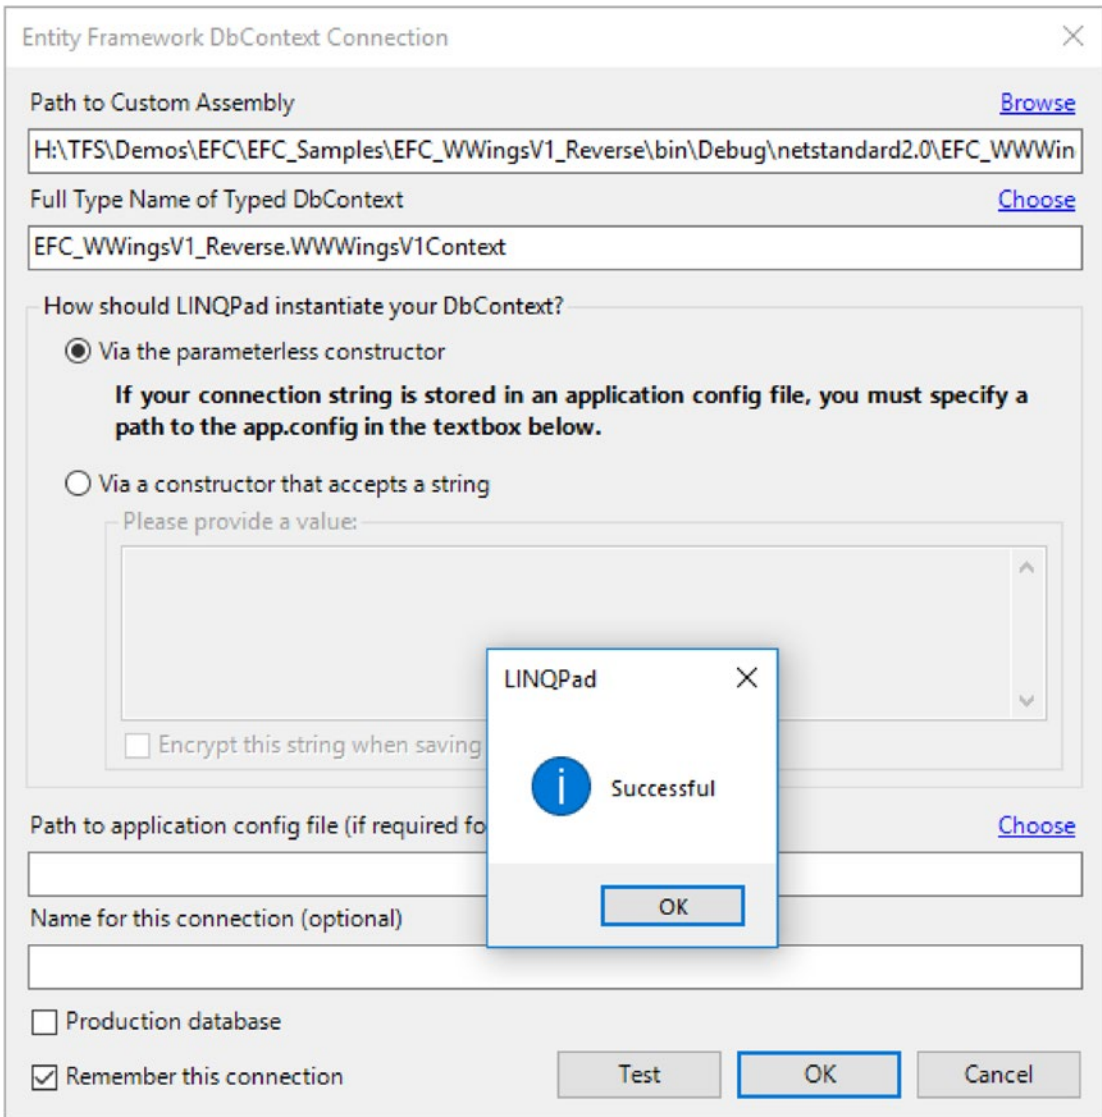

Figure 19-11. An Entity Framework Core context class has been selected

After incorporating the context, you can see the existing entity classes on the left in LINQPad (Figure 19-12).

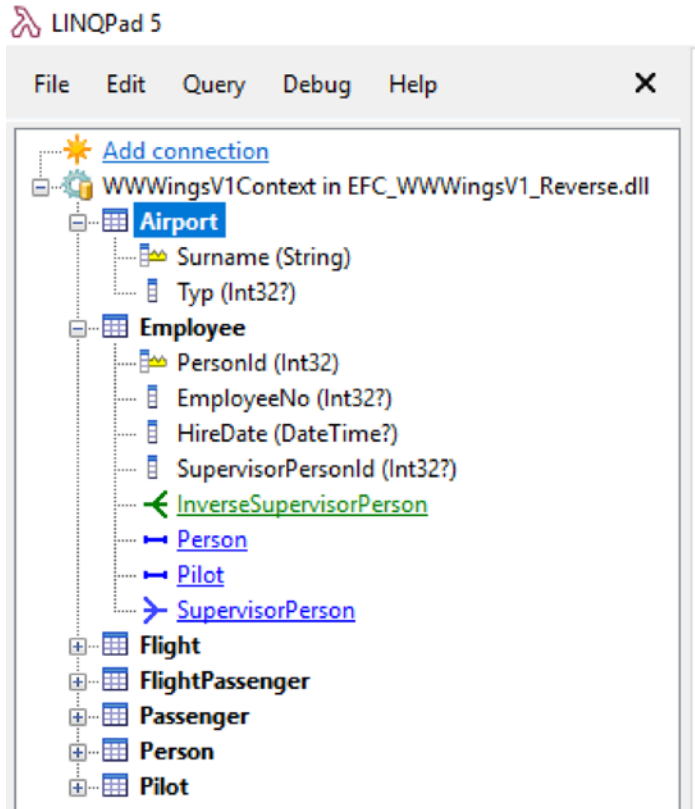

Figure 19-12. After incorporating the context class

Executing LINQ Commands

Some commands can be executed directly from the context menu of the entity classes (see Figure 19-13).

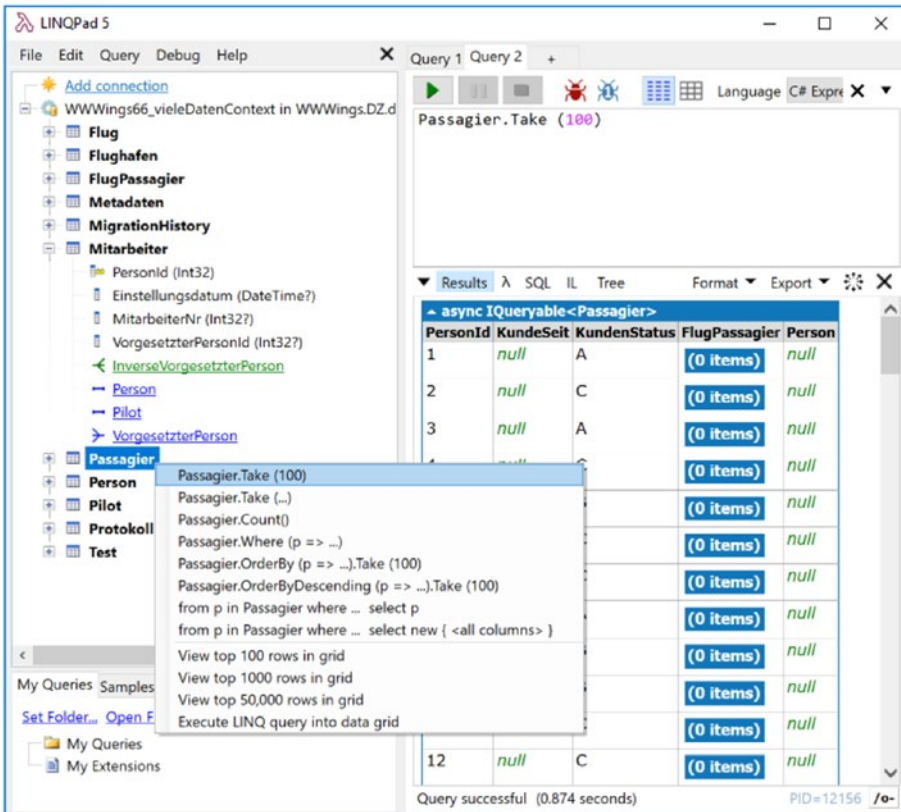

Figure 19-13. Predefined commands in the context menu of the entity class

In the query area you can even enter commands (in the commercial version with input support). Figure 19-14 shows a LINQ command with conditions, projection, and eager loading. The result view is hierarchical in the case of eager loading.

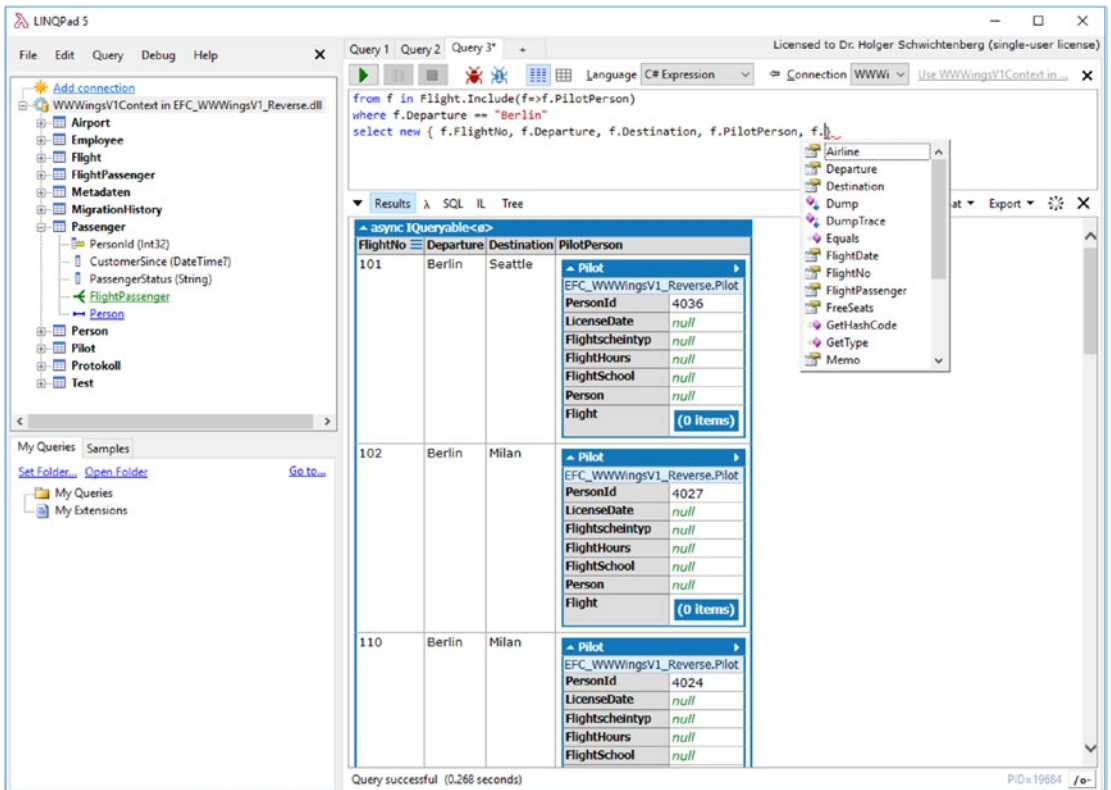

Figure 19-14. Execution of a custom LINQ command in LINQPad

In addition to the result view, you can display the LINQ to Entities command in the other tabs of the output area in the following formats:

- LINQ command in lambda syntax
- LINQ command in SQL form
- LINQ command in Microsoft Intermediate Language (IL)
- LINQ command as expression tree

Saving

Queries can be saved as text files with the file extension `.linq`.

Results can be exported in HTML, Word, and Excel formats.

Other LINQPad Drivers

In addition to Entity Framework and Entity Framework Core drivers, LINQPad offers drivers for other tools, listed here:

- Open Data Protocol (OData) feeds
- The relational databases Oracle, MySQL, SQLite, RavenDB
- The cloud services Microsoft StreamInsight and Azure Table Storage
- Event Traces for Windows (ETW)
- The ORM mappers Mindscape LightSpeed, LLBLGen Pro, DevExpress XPO, DevForce
- The NoSQL database FileDb

Interactive Program Code Entry

In addition to running LINQ commands, the LINQPad tool can execute any other C#, F#, and Visual Basic commands. You can choose between Expression Mode and Statement Mode under Language. Expression Mode captures individual expressions, the result of which is then printed, as in `System.DateTime.Now.ToString(new System.Globalization.CultureInfo("ja-JP"))`. These expressions should be terminated by a semicolon. You can do only one expression at a time. If you have multiple expressions in the editor, you must first mark the expression to be executed.

In Statement Mode, on the other hand, complete program code snippets are recorded, with each command terminated by a semicolon. You issue a command with `Console.WriteLine()`. Listing 19-2 shows a small test program.

Listing 19-2. Small Test Program for LINQPad

```
<Query Kind="Statements" />
for (int i = 0; i < 10; i++)
```

```
{
    Console.WriteLine(i);
}
```

Also the definition of your own types (z.Classes; see Listing 19-3) is possible. However, note that LINQPad embeds the captured code in its own default code. Therefore, the following rules apply:

- The main program code to be executed must be at the top.
- It has to be closed with an additional curly brace before the following type definitions.
- The type definitions must be at the end, and the last type definition must not have a closing curly bracket.

So, internally, LINQPad obviously complements a type definition with a `main()` at the top and a curly bracket at the bottom.

Listing 19-3. Small Test Program for LINQPad with Class Definition

```
<Query Kind="Statements" />
var e = new Result() { a = 1, b = 20 };
for (int i = 0; i < e.b; i++)
{
    e.a += i;
    Console.WriteLine(i + ";" + e.a);
}
} // This extra parenthesis is required!

// The type definition must be after the main program!
class Result
{
    public int a { get; set; }
    public int b { get; set; }
}
// // here you have to omit the parenthesis!
```

Conclusion to LINQPad

LINQPad is a useful tool to learn LINQ, to test LINQ commands and, in general, to test commands in C#, Visual Basic, and F# without having to start a heavyweight program like Visual Studio or install a work-around routine into an existing project. Because of the practical export function, LINQPad can be used not only for development but also in everyday practice as a tool for ad hoc database queries.

Entity Developer

Microsoft does not yet offer GUI development tools for Entity Framework Core. This gap has been closed by DevArt with the product Entity Developer.

In the past, DevArt has offered more tooling capabilities for the classic Entity Framework than Microsoft itself. Now it is again leading with tools for Entity Framework Core. Entity Developer supports both reverse engineering and forward engineering in Entity Framework Core with a graphical designer.

Figure 19-15. Variants of Entity Developer

When installing Entity Developer, the installer already provides a VSIX integration with Visual Studio 2015 and Visual Studio 2017 in addition to the stand-alone Entity Developer application. The application is quite slim, requiring around 60MB of disk space.

Selecting the ORM Technique

Depending on the installed variant, Entity Developer offers different ORM techniques at startup. For Entity Framework Core, an `.efml` file is created, for the classic Entity Framework an `.edml` file is created, for Telerik Data Access a `.daml` file is created, and for NHibernate an `.hbm1` file is created. After selecting EF Core Model (see Figure 19-16), the second wizard step is followed by the decision between reverse engineering (here called Database First) and forward engineering (here called Model First), as shown in Figure 19-17. In addition to Microsoft SQL Server, Entity Developer also supports Oracle, MySQL, PostgreSQL, SQLite, and IBM's DB2 as databases, each in conjunction with DevArt's own Entity Framework Core drivers (see <https://www.devart.com/dotconnect/#database>).

Note When using Entity Developer within Visual Studio, there is no selection wizard for the ORM technique; instead, there are specific element templates such as DevArt EF Core Model and DevArt NHibernate Model.

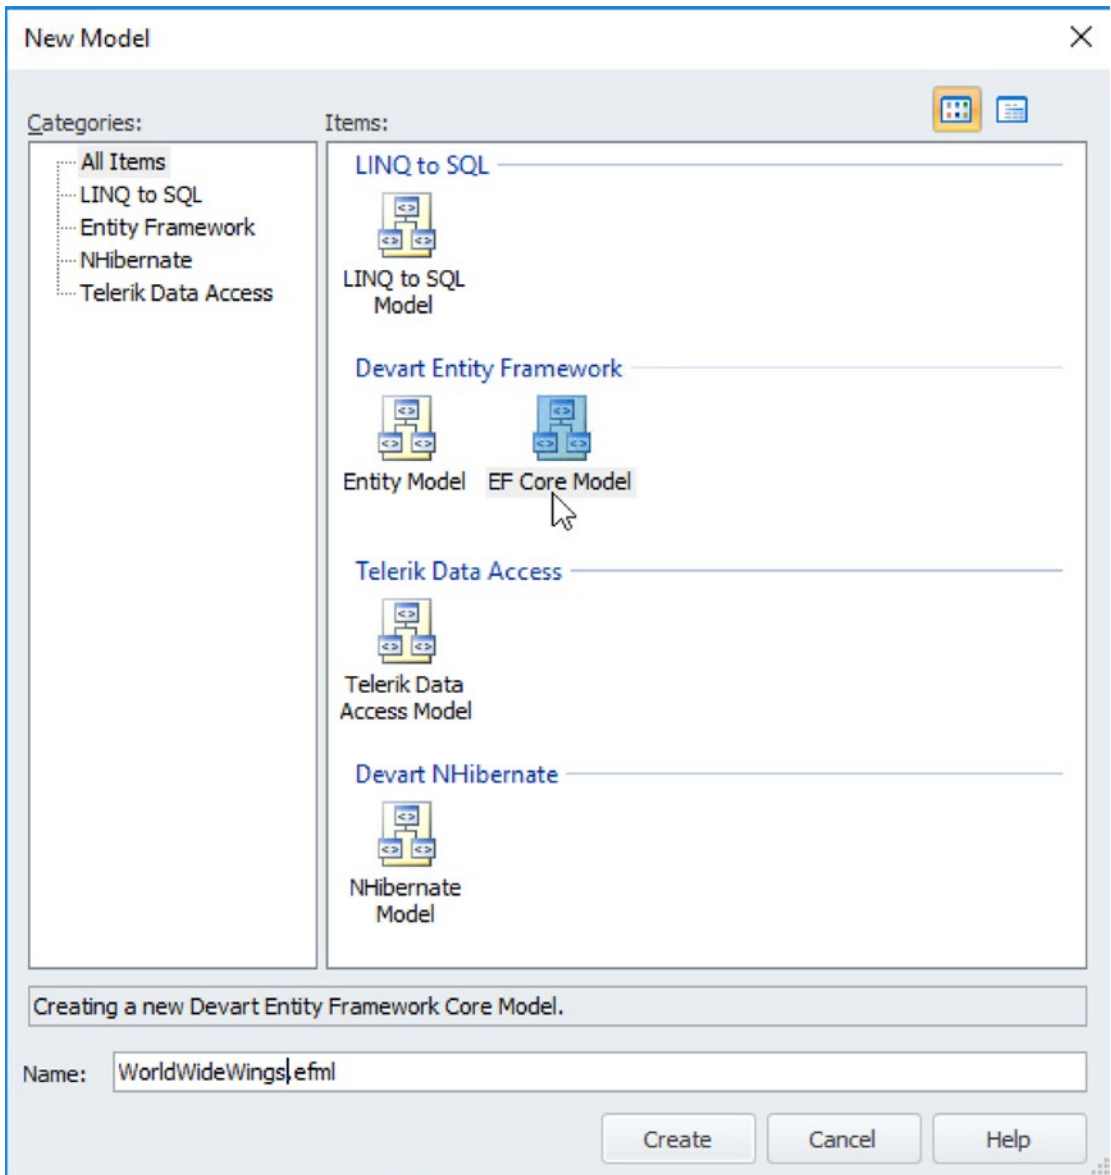

Figure 19-16. Selecting the ORM technique in Entity Developer

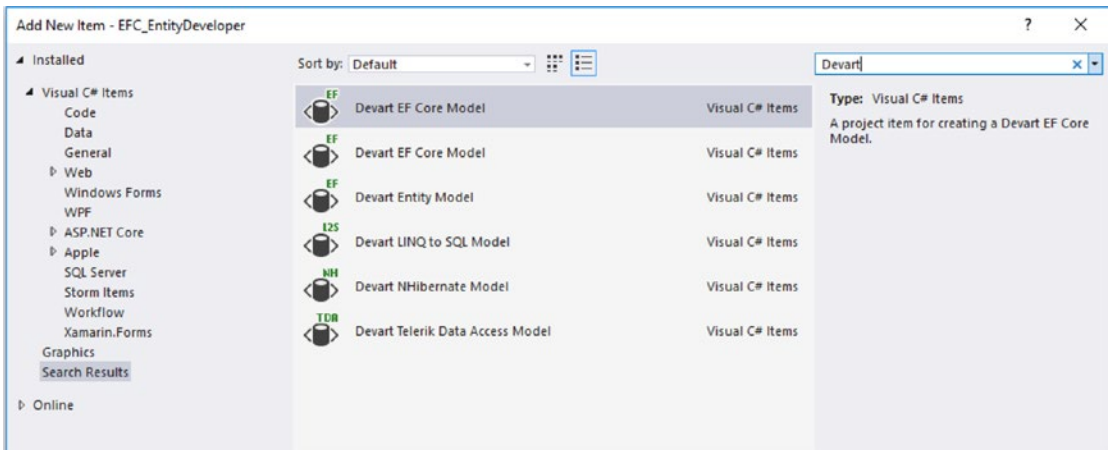

Figure 19-17. Entity Developer templates within Visual Studio

Reverse Engineering with Entity Developer

Database First then selects an existing database and selects the artifacts (tables, views, stored procedures, and table-valued functions), as in the classic Entity Framework wizard in Visual Studio, but with the benefit that the developer may choose down to the column level (Figure 19-18).

This is followed by a page in the code generation naming convention wizard that goes far beyond what Visual Studio has offered so far (Figure 19-19). In the following options page, some options such as the N:M relationships and the table per type inheritance are grayed out because Entity Framework Core does not yet have these mapping capabilities (Figure 19-20). In the penultimate step, you choose whether to have all the artifacts on a chart surface or just selected ones. It is also possible to create one diagram per schema name (Figure 19-21). For each diagram, a .view file is created.

In the last step, you select the code generation template. Entity Developer offers to directly apply multiple code generation templates (Figure 19-22).

Figure 19-23 shows the templates supplied with Entity Developer, which are barely documented at <https://www.devart.com/entitydeveloper/templates.html>. You have to figure out whether the generated code fits your needs. The predefined templates can be copied with the function Copy to Model Folder into a template file in your own application folder and then modified there. The templates are similar to the Text Template Transformation Toolkit (T4) templates used in Visual Studio, but they are not compatible. Unlike the T4 templates, DevArt templates allow code generation to be influenced by the parameters set in a property grid. For example, you can specify the following for the selected template called EF Core:

- You can specify the landing of the entity classes and the context class in different folders (here you can capture a relative or absolute path).
- Partial classes may be generated.
- The interfaces `INotifyPropertyChanging` and `INotifyPropertyChanged` may be implemented in the entity classes.
- You can set, that the entity classes receive the annotations `[DataContract]` and `[DataMember]` for the Windows Communication Foundation (WCF).
- You can set, that the entity classes receive the annotation `[Serializable]`.
- You can override the entity classes `Equals()`.
- You can implement the entity classes of `IClonable`.

The names of the diagrams, the templates and their parameters, and the list of generated files are stored by Entity Developer in an `.edps` file.

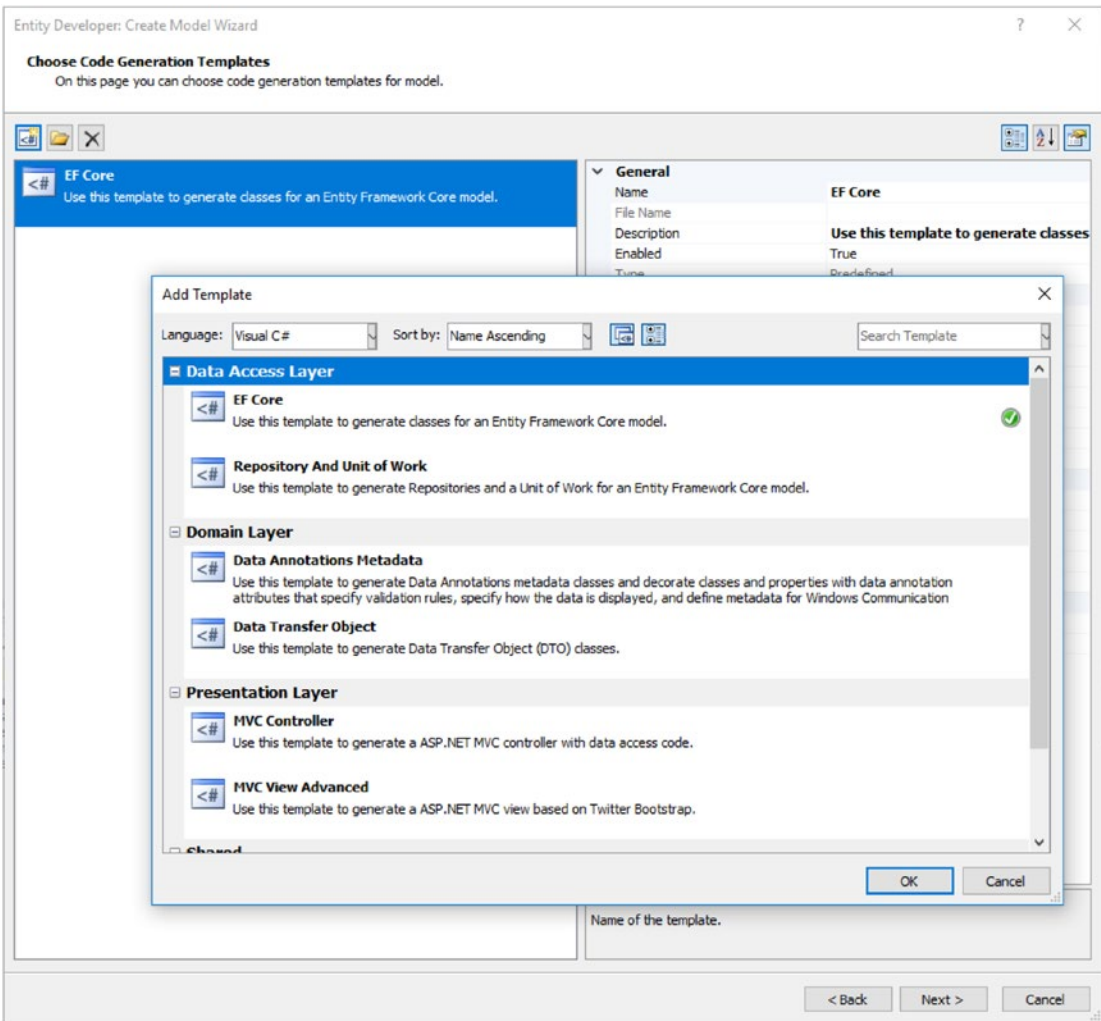

Figure 19-23. *Selecting the code generation template*

After completing the very flexible assistant, when looking at the model in the designer, you might be a little disillusioned, at least if you have selected database views. Entity Developer complains that there is no primary key for this. This is because Entity Framework Core is not yet set to mapping views and handles views like tables, which always need to have a primary key. You have to set one manually in the property window for each database view.

The relationships between the tables are also modeled as associations in Entity Developer in conjunction with Entity Framework Core, even if inheritance were possible. With the classic Entity Framework, Entity Developer has the option of recognizing table per type inheritance, but Entity Framework Core does not yet support table by type inheritance.

You can now adjust the graphs or create new graphs in the Model Explorer (see the left of Figure 19-24). You can drag and drop additional tables, views, procedures, and functions directly into the model from the Database Explorer (see the right of Figure 19-24) instead of having to run the wizard over and over again in Visual Studio. Entity Developer, like the classic Entity Framework tools in Visual Studio, can manage multiple charts per model of overlapping entities. You can change the order of the properties in an entity class by dragging and dropping, while the change of order with Microsoft's tool is, curiously enough, possible only with a cumbersome context menu or keyboard shortcut. Dragging and dropping properties is also possible between different entities. Entity Developer allows colors to be assigned to the entities in the model for better visual separation. The coloring then applies to all diagrams in which the entity occurs. On the chart surface, you can also make comments at any point.

The program code generation is triggered by the menu item Model ► Generate Code (key F7). The standard code generation template EF Core creates the following:

- A context class
- One entity class per table and per view
- A class for each return type of a stored procedure

The program code for using the stored procedures and table-valued functions is in the context class, which can be very long. It is interesting that Entity Developer does not rely on Entity Framework Core for the implementation but instead picks up the data records via `DataReader` and realizes the complete mapping itself (see Listing 19-4). After all, Entity Developer recognizes that the stored procedure `GetFlight` shown in the listing returns the same structure as the table `Flight` and therefore uses the entity class `Flight` in the return type. Entity Developer or the template could also have used Entity Framework Core with the extension method `FromSql()`. The advantage of DevArt's own implementation is that it also works for stored procedures that do not return entity types. Entity Framework Core cannot do that yet. In these cases, Entity Developer creates its own classes for the return type.

    else
        row.Utilization = null;

    result.Add(row);
}
}
}
}
finally
{
    if (needClose)
        connection.Close();
}
return result;
}

```

You can now include the generated program code in a Visual Studio project, if you have not already performed the steps there. The used template files can be adjusted in Entity Developer at any time (see the branch Templates in Model Explorer). Templates can also be edited in Entity Developer, including IntelliSense input support.

Alternatively, you can also use the installed Visual Studio extension. In Visual Studio you will find new entries like DevArt EF Core Model in the element templates under the category Data. Selecting one of these opens the same assistant and, at the end, the same designer (including Model Explorer and template editor) as the stand-alone application. The advantage is that the generated program code automatically belongs to the Visual Studio project, which also contains the .efml file.

If the database schema has changed, you can update the model with the menu item Model ► Update Model from Database. You define the general mapping rules for database types with .NET types under Tools ► Options ► Servers' Options.

The data preview is also helpful (select Retrieve Data in the context menu of an entity class); it includes navigation to linked data records and hierarchical unfolding. You can also access the data preview directly from the diagram in the context menu of each entity or from a table or view in the Database Explorer.

Forward Engineering with Entity Developer

I'll now cover forward engineering with Entity Developer. After selecting Model First, the dialog Model Properties opens because there is no existing database nor are there its artifacts or any naming conventions to choose from. With the settings in Model First Settings, you can set the standards for database schema generation.

- *Default Precision:* For decimal numbers, the number of digits before the comma
- *Default Scale:* For decimal numbers, the number of digits after the decimal point
- *Default Length:* For strings, the maximum number of characters (empty means that the strings are unlimited)

The third and final step of the wizard in the case of Model First is the dialog for selecting the code generation templates.

The empty designer interface then appears, which you can fill with classes, enumerations, associations, and inheritance relationships using the symbols in the Model Explorer. Then you configure them through the Properties window (see Figure 19-25). You can, for example, set the primary key, enable the [ConcurrencyCheck] annotation, and specify that a property be a shadow property that exists in the database but not in the generated entity class. There are some unavailable options in Entity Framework Core, such as an N:M mapping, that Entity Developer does not even offer in a Entity Framework core model.

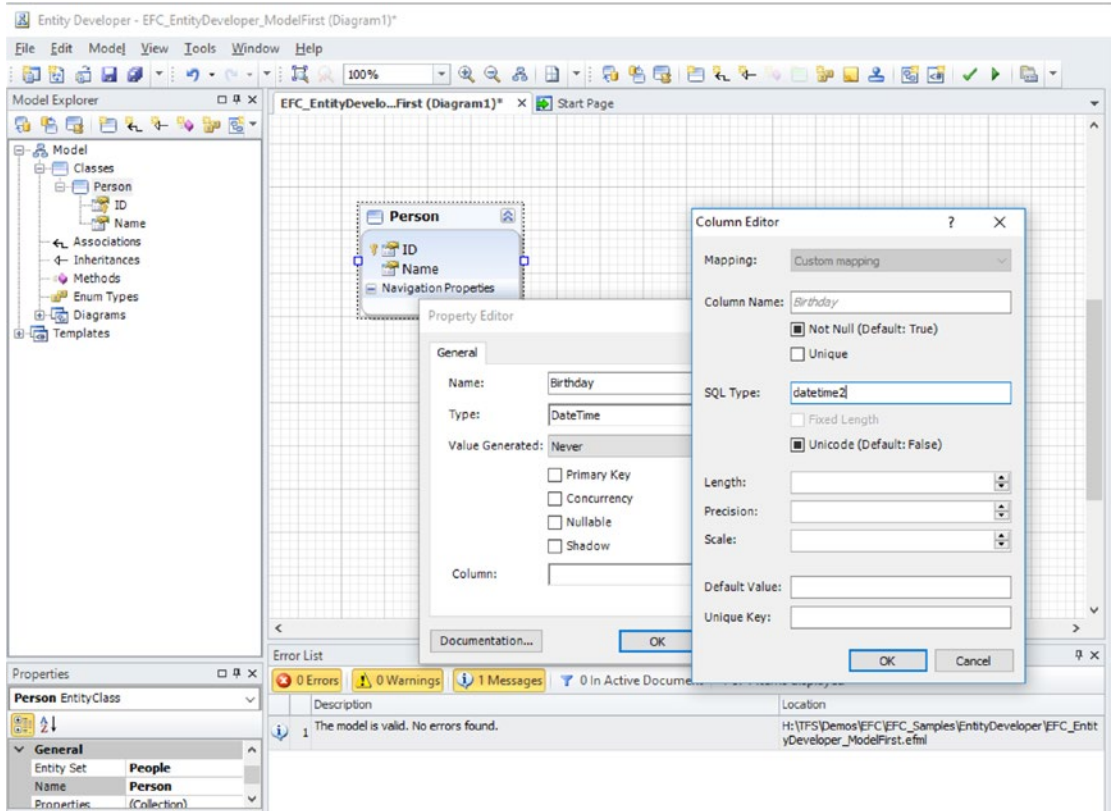

Figure 19-25. Creation and configuration of new properties in Entity Developer

With the function Model ► Update Database from Model, you can create a database schema from it. This wizard asks for a target database, which must already exist. The wizard then displays which schema changes are to be transferred to the database and offers the choice not to transfer certain changes. In the last step, you can view the SQL script to be executed. Entity Developer does not use the command-line schema migration tools of Entity Framework Core (dotnet ef or the PowerShell cmdlets); instead, it uses its own method of comparing the existing schema with the target schema. However, Entity Developer also tries to obtain the data. With the Recreate Database Tables option, you can make existing tables, including their data, disappear. An additional table called __EFMigrationsHistory does not exist in the Entity Developer migrations. You define the conventions for the naming in the database schema to be generated under Model ► Settings ► Synchronization ► Database Naming.

In the Model ► Generate Database Script from Model menu, you can generate a SQL script for the schema to be generated without reference to a specific database. In doing so, you can configure the target database management system and the version (for SQL Server, for example) such as 2000, 2005, 2008, 2012, 2014, and Azure (but not SQL Server 2016).

Entity Developer supports with many little things. For example, the default value of “no name” specified earlier is not only entered in the database schema but also used in the constructor of the entity class (see Listing 19-5), which is generated as in reverse engineering via Model ► Generated Code (F7). In the code generation settings, the settings INotifyPropertyChanging ► INotifyPropertyChanged and WCF Data Contract attribution have been activated. The comments filled in with the class and the property “First name” have already been entered in Entity Developer Designer. Also in Entity Developer you can capture any annotations to entity types and properties. To do this, first select Attributes in the context menu and then select .NET attributes from any .NET assemblies. If the .NET attribute in the constructor requires parameters, you can capture them in the dialog. You can set some annotations such as [DisplayName] and [Range] and [RegularExpression] in the Property window (see “Validation” in the lower-left corner of Figure 19-25). For the validation annotations to actually be immortalized in the generated program code, you must select a validation framework in the code generation template. In addition to the .NET validation annotations, you can choose the old .NET Enterprise library or NHibernate Validator here.

It is also interesting that you can extend the property grid to any settings. These settings can then be considered during code generation. Additional settings are defined under Model ► Settings ► Model in the tree displayed there under Model ► Extended Properties for artifacts such as classes, properties, and associations. You then have to consider the meaning of these additional settings in a separate .tmpl code generation template.

Entity Framework Profiler

Object-relational mapping means abstraction from SQL, and naturally the question arises as to which and how many commands are actually sent to the database management system. You can monitor the communication with a DBMS's own profiler, such as the Microsoft SQL Server Profiler, or with an ORM-specific tool such as the Entity Framework Profiler.

Almost all OR mappers use their own query languages, such as HQL on NHibernate and LINQ on Entity Framework and Entity Framework Core. These languages work on the database-neutral object model, and the OR mapper translates into the SQL dialect of each database management system. This automated generation of SQL commands is always a starting point for a fundamental criticism of ORM, especially regarding the warehouse of the SQL Optimizer. In fact, not all OR statements generated by the OR mapper are always optimal.

Tracking down nonoptimal SQL and unfavorable loading strategies is one of the responsibilities of a software developer using an OR mapper. This is where the Entity Framework Profiler from the company Hibernating Rhinos comes in. It works with both Entity Framework Core and the classic Entity Framework.

 The logo for Entity Framework Profiler, featuring the text "Entity Framework Profiler" in a bold, green, sans-serif font. The words "Entity Framework" are on the top line and "Profiler" is on the bottom line, both centered.

Integrating Entity Framework Profiler

For the Entity Framework Profiler to be able to record the activities between the OR mapper and the database management system, the application to be monitored must be “instrumented.” This requires two changes to the program code.

- The developer must have a reference to the HibernatingRhinos assembly `.Profiler.CreateAppender.dll`.

Tip This assembly ships with the Entity Framework Profiler (folder `/Appender`) in three variations: for `.NET 3.5`, for `.NET 4.x`, and as a `.NET standard assembly` (including `.NET Core`). While you can refer directly to this assembly in a project using the classic `.NET Framework`, in a `.NET Core` project you should not reference the assembly directly from the `/Appender/netstandard/` folder. Instead, you should install it via NuGet (`Install-Package EntityFrameworkProfiler.Appender`). Otherwise, you may be missing dependencies.

- At the beginning of your program (or where you want to start profiling in the program), the program line `HibernatingRhinos.Profiler.Appender.EntityFramework.EntityFrameworkProfiler.Initialize()` appears in the program code.

Tip The Entity Framework Profiler does not require the application to run in the Visual Studio debugger. Recording also works if the application is started directly, even if it was compiled in Release mode. It's a one-line instrumentation code. So, you can make the application so that the instrumentation code is called when needed; for example, it can be controlled by a configuration file.

Monitoring Commands with the Entity Framework Profiler

Start the WPF-based Entity Framework Profiler user interface (EFProf.exe) before the application to be monitored. After starting the application to be monitored, the Entity Framework Profiler (in the list on the left) shows all the created instances of the Entity Framework class `ObjectContext` (or all the derived classes). Unfortunately, the individual context instances are not named; you must designate them in the Entity Framework Profiler user interface yourself.

Each context contains the number of SQL commands executed via the context with the respective execution times, both those in the DBMS and the total time, including the materialization of the objects in RAM. In Figure 19-27, for example, the problem arises that many object contexts are created without any command at all being executed.

Note The Entity Framework Profiler speaks of *object context*, which in the classic Entity Framework was the original base class for the Entity Framework context. In Entity Framework Core, there is only the more modern `DbContext`. The name in the Entity Framework Profiler has not been changed. However, the Entity Framework Profiler works with the `DbContext` base class in both Entity Framework and Entity Framework Core.

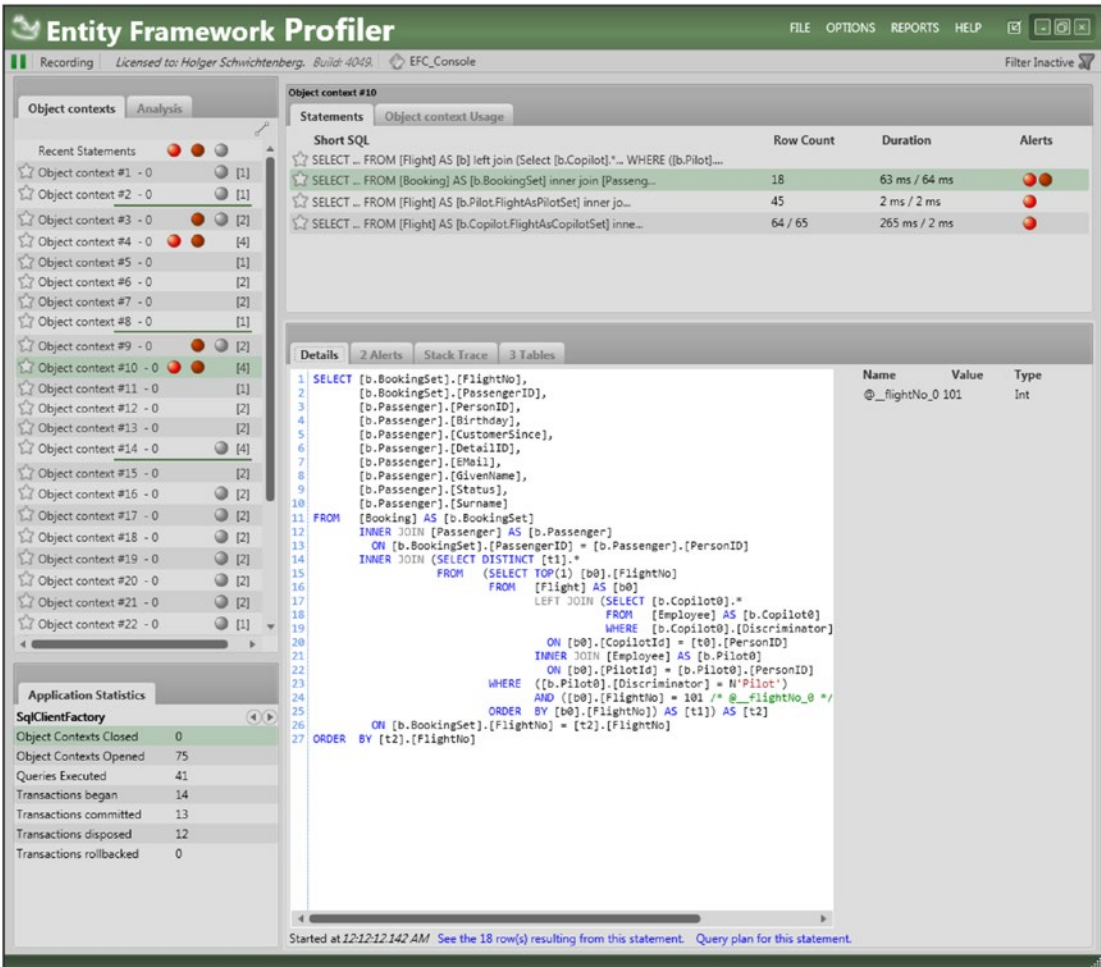

Figure 19-27. Entity Framework Profiler in action

In the right part of the screen you will find a list of executed commands for the currently selected context. Under Details you can see the complete SQL command with parameters and the associated execution plan (see Figure 19-28) as well as the result set. To do this, however, you must enter the connection string in the Entity Framework Profiler (see Figure 19-29).

The Stack Trace tab reveals which method triggered a single SQL command. It's nice that double-clicking an entry in the Stack Trace tab leads directly to the matching code in the open Visual Studio window. This will help you quickly find the LINQ or SQL command that triggered the SQL command.

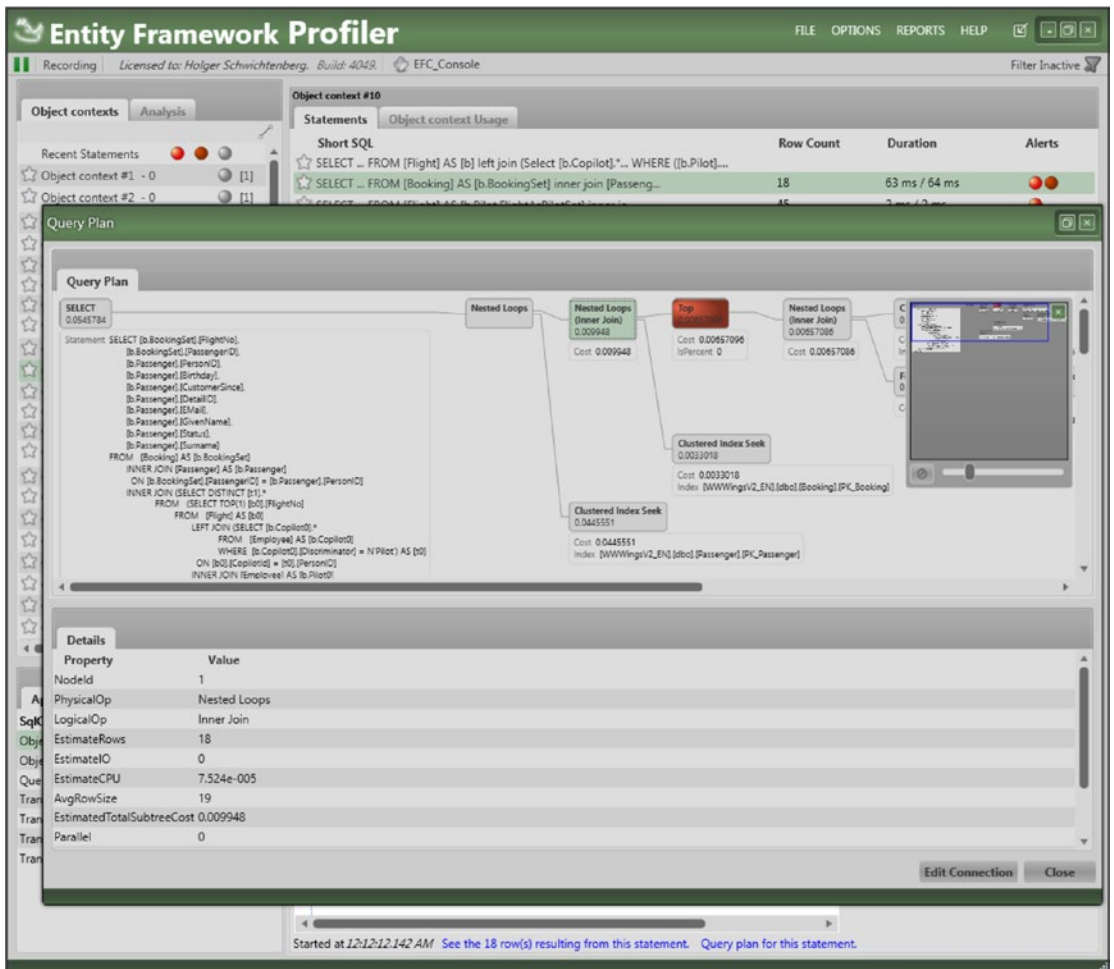

Figure 19-28. Execution plan of the database management system in the Entity Framework Profiler

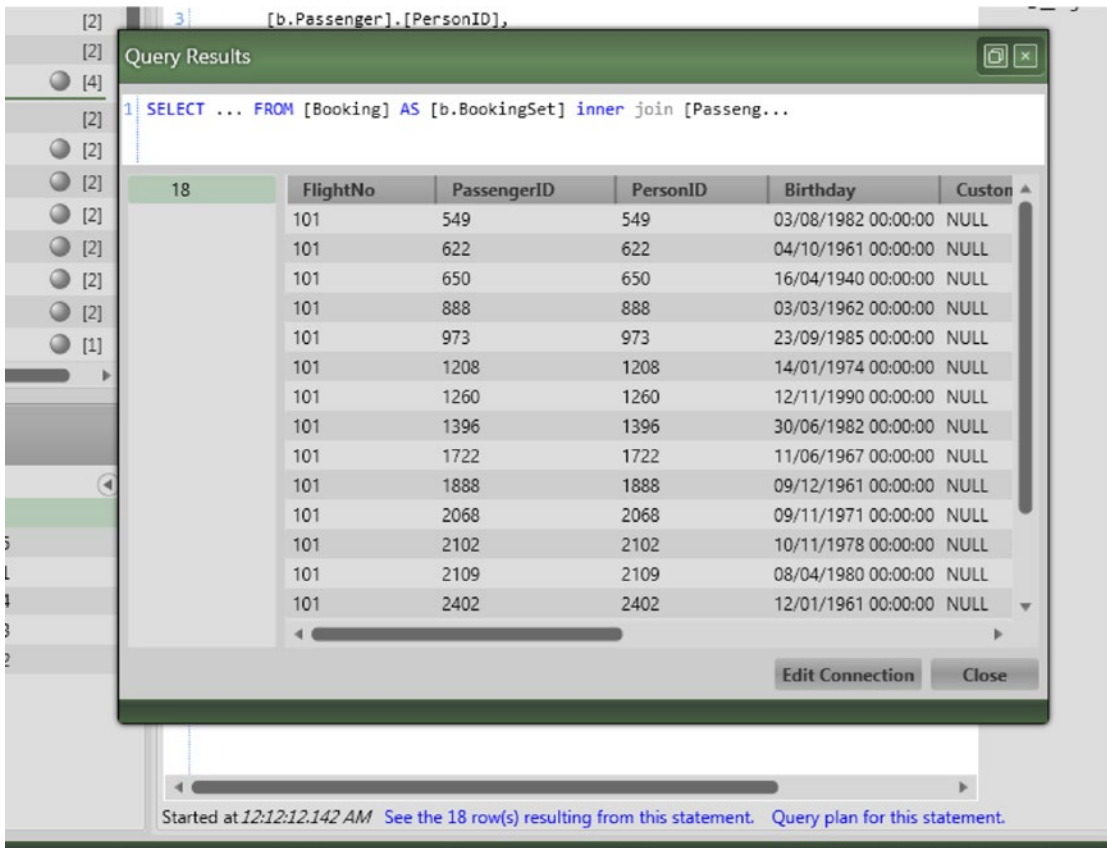

Figure 19-29. Displaying the result in the Entity Framework Profiler

Alerts and Suggestions

Pay special attention to the gray circles (suggestions) and red circles (warnings) (see Figure 19-30). Here the Entity Framework Profiler is helping you discover potential problems. In Figure 19-30, this is what the Entity Framework Profiler calls a SELECT N + 1 problem. A large number of similar SQL commands that are executed one after the other indicates that lazy loading is erroneously used here. You should consider eager loading.

Another problem that the Entity Framework Profiler shows very well is the not recommended use of a context object in different threads. Other hints (see Figure 19-30) exist when a query uses many joins, starts with a wildcard (like % xy), returns many records, and does not contain a TOP statement (unbounded result sets). The last point is arguable. The intent of this proposal is that you should not run the risk of asking for more records than you really anticipate needing. But in practice (except for applications that explicitly display

records using the scrolling feature), you often cannot set an upper limit that will apply permanently. There is also a warning when many INSERT, UPDATE, and DELETE commands are executed, and you should check that this is not mapped by a mass operation.

Figure 19-30. Alerts and suggestions in the Entity Framework Profiler

Analysis

The analysis functions in the Analysis tab are useful. You'll find evaluations that show the following:

- Which methods in the program code triggered which SQL commands (Queries By Method; see Figure 19-31)
- How many different commands exist (despite the name Unique Queries, INSERT, UPDATE, and DELETE commands appear here as well!)
- Which commands lasted the longest (expensive queries)

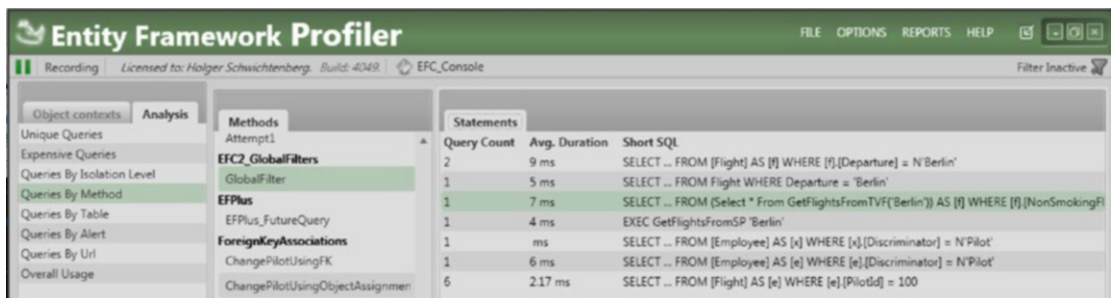

Figure 19-31. Analysis of Queries By Method

An interesting feature is hidden in the File ► Export to File menu. This creates a JavaScript-enriched HTML page that looks like the Entity Framework Profiler. You can view all the context instances and the SQL commands and call the analysis results. However, the stack trace and the warnings are missing.

The normal memory function creates a binary file with the file extension `.efprof`. The program code to be monitored can also generate such a file directly by calling the method `InitializeOfflineProfiling(filename.efprof)` in the start command instead of `Initialize()`. Then, the Entity Framework Profiler UI does not have to run while the application is running. Profiling is thus also possible without problems on target systems.

Command-Line Support and API

In terms of continuous integration, you can also run the Entity Framework Profiler from the command line. But you need one license per computer. The profiler itself also has a programming interface in `HibernatingRhinos.Profiler.Integration.dll`.

Conclusion to Entity Framework Profiler

The Entity Framework Profiler is a useful tool to understand which SQL commands an Entity Framework Core-based application really executes. However, the price is high.

CHAPTER 20

Additional Components

This chapter introduces Entity Framework Core add-on components that extend the capabilities of Entity Framework Core. I am in no way involved in the development or distribution of these tools.

Oracle Database Driver by DevArt

Oracle does not currently support Entity Framework Core for its databases. Basically, Oracle has said it is working on support (www.oracle.com/technetwork/topics/dotnet/tech-info/odpnet-dotnet-core-sod-3628981.pdf), but so far no solution is available. It took Oracle a few years to offer a solution for the classic Entity Framework.

A commercial Oracle driver for Entity Framework Core is available from DevArt as part of the dotConnect for Oracle product.

Component name	dotConnect for Oracle
Web site	https://www.devart.com/dotconnect/oracle/
Source code	No
NuGet	Setup: dcoracleXYpro.exe Install-Package Devart.Data.Oracle.EFCore
Free version	No
Commercial version	\$149.95

Installation

First, the DevArt installation package (`dcoracleXYpro.exe`, where `XY` stands for the version number) should be executed on the system. In addition, the NuGet package `Devart.Data.Oracle.EFCore` should be installed in the project in which the context class is located.

Tools

The Oracle driver works in reverse engineering and forward engineering with the standard Entity Framework Core tools.

```
Scaffold-DbContext "User ID=WWings; Password=secret; Direct=true;
Host=localhost; SID=ITVisions; Port=1521;" Devart.Data.Oracle.Entity.EFCore
-Tables DEPT,EMP
```

Tip Alternatively, you can use DevArt’s Entity Developer if you want a graphical user interface for reverse engineering or forward engineering of Oracle databases.

Context Class

In the context class in `OnConfiguring()`, you can call the method `UseOracle()` with a connection string.

```
protected override void OnConfiguring(DbContextOptionsBuilder builder)
{
    builder.UseOracle(@"User ID=WWings; Password=secret; Direct=true;
Host=localhost; SID=ITVisions; Port=1521;");
}
```

Note The previous connection string uses the so-called Oracle Direct mode. This eliminates the need for Oracle client setup! If you have a connection string like `UserId = WWings; Password = secret; Data Source = Name;`, you will need to install the Oracle client software for it. Otherwise, you will get the following error: “Cannot obtain Oracle Client information from registry. Make sure that Oracle Client Software is installed and that the bitness of your application (x86) matches the bitness of your Oracle Client, or use the Direct mode of connecting to a server.” For information about the data source, see https://docs.oracle.com/cd/B28359_01/win.111/b28375/featConnecting.htm.

Entity Classes

Note that the schema, table, and column names in Oracle can be only 30 characters each (https://docs.oracle.com/database/121/SQLRF/sql_elements008.htm#SQLRF51129). If a name is too long, the following runtime error will appear: “TableName ‘EntityClassWithAllSupportedDataTypes’ is too long. An identifier with more than 30 characters was specified.”

Data Types

Figure 20-1 and Figure 20-2 show the mapping between Oracle column types and .NET data types in the DevArt Oracle driver.

¹ Applicable only to Entity Framework v1 - v6. Not applicable to Entity Framework Core, because Entity Framework Core does not support XML mapping.

² The negative scale cases are taken into account.

³ BINARY_DOUBLE and BINARY_FLOAT data types appeared in Oracle 10g.

⁴ These SSDL types completely identical to the corresponding Oracle data types.

⁵ According to official Oracle recommendations, using of LONG and LONG RAW data types is not recommended.

⁶ All RAW types, except RAW(16).

⁷ Supported in Entity Framework v5 and v6.

System.Single	Single	single	NUMBER(15,5) ²
System.String	String	VARCHAR2	VARCHAR2
System.TimeSpan	Time	INTERVAL DAY TO SECOND	INTERVAL DAY TO SECOND

¹ Applicable only to Entity Framework v1 - v6. Not applicable to Entity Framework Core, because Entity Framework Core does not support XML mapping.

² Note that when mapping corresponding database data type, you will need the .NET type with larger precision. That is because, for example, any Int32 value can be stored in the NUMBER(10) column, but largest NUMBER(10) column value cannot be stored in the Int32 field, it requires Int64 field.

³ Supported in Entity Framework v5 and v6.

⁴ Mapping of this type depends on the [DecimalPropertyConvention](#). If this convention is enabled (it is enabled by default), System.Decimal is mapped to NUMBER(18,2). Otherwise, it is mapped to NUMBER.

Entity Framework Plus

Entity Framework Plus (EFPlus) is an additional component that exists for the classic Entity Framework. Even though the EFPlus web site talks only about Entity Framework, there is also a variant for Entity Framework Core available.

Entity Framework Plus provides several additional features to Entity Framework Core:

- Formulation of UPDATE and DELETE commands as lambda expressions (see Chapter 17)
- Auditing (all changes to records are automatically noted in a change table)
- Global query filter (Entity Framework Core has been able to do this since version 2.0; EFPlus also offers this for Entity Framework Core 1.x)

- A second-level cache as an alternative to `EFSecondLevelCache.Core` (see Chapter 17)
- Query batching (combining multiple `SELECT` queries in one go through the database management system)

Component name	Entity Framework Plus for EFCore

Source code	https://github.com/zzzprojects/EntityFramework-Plus
NuGet	Install-Package Z.EntityFramework.Plus.EFCore
Free version	Yes
Commercial version	No

Note EFPlus 1.6.11 (and newer) supports Entity Framework Core version 2.0.

Second-Level Caching with `EFSecondLevelCache.Core`

The component `EFSecondLevelCache.Core` provides an alternate second-level cache to the second-level cache included in Entity Framework Plus. `EFSecondLevelCache.Core` is much more complex in configuration but also more flexible because in addition to the main memory cache (`MemoryCache`), you can use Redis as a cache.

Object-Object Mapping with AutoMapper

In modern software architectures, typical tasks are the object-relational mapping of relational database structures to objects and the mapping of different object structures to each other. The open source tool AutoMapper facilitates object-to-object mapping (OOM).

The requirement to transform an object type into another type of object is common, for example, in data transfer objects (DTOs) between layers or in ViewModels that contain rendered data for display or expression (see Figure 20-3 and Figure 20-4). The object types to be imaged are often similar but not completely identical. And they usually do not have a common base class or interface that would permit type conversion at the programming language level, that is, by type conversion expression.

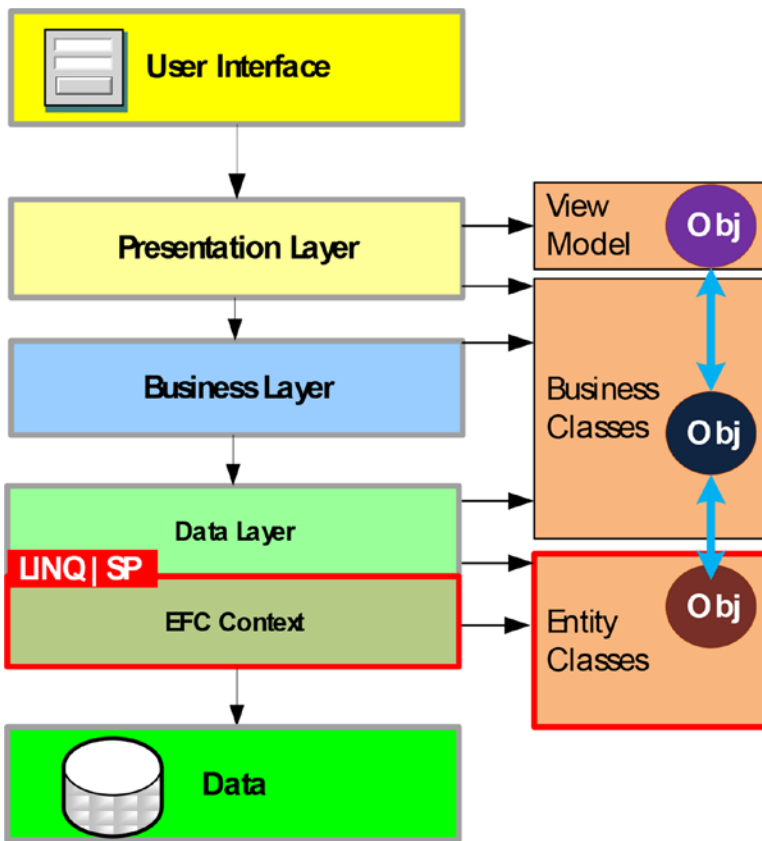

Figure 20-3. Object-to-object mapping is used between entity classes, business objects, and ViewModel classes

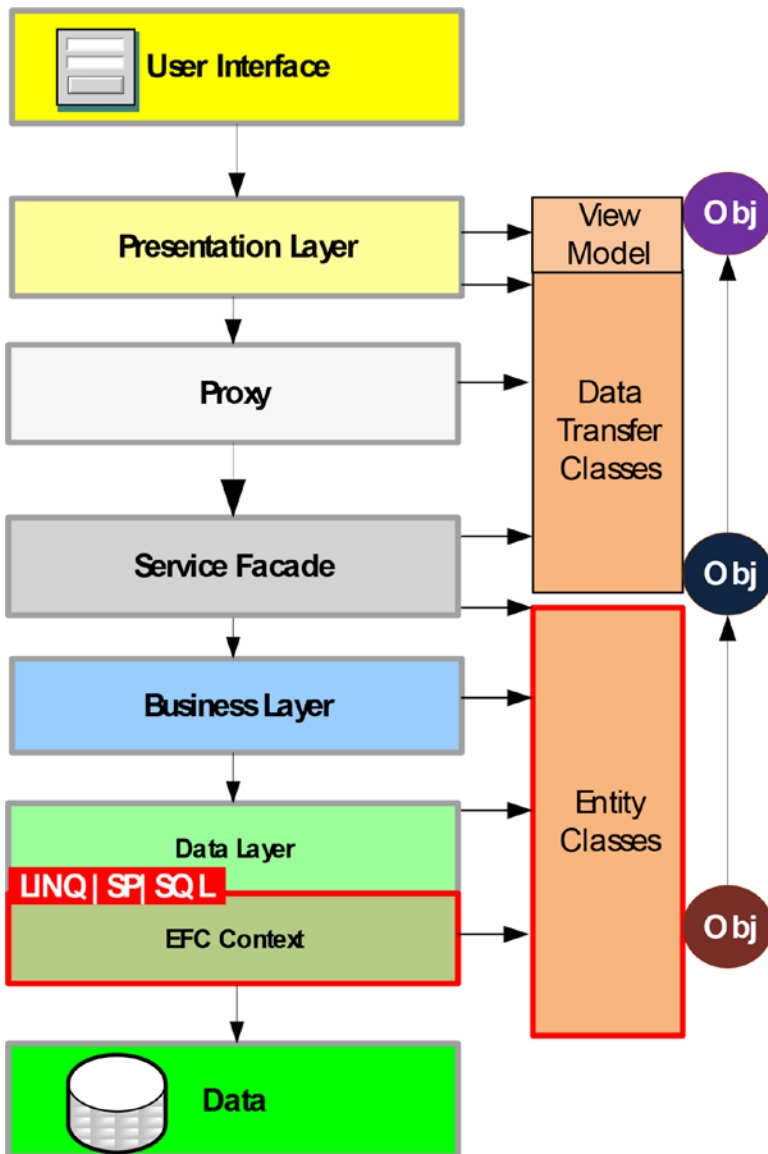

Figure 20-4. Object-to-object mapping is also used between entity classes and data transfer classes in modern software architectures

The .NET Framework and .NET Core class libraries do not include functions that support the mapping of different types of objects (object-to-object mapping). The Type Converter in the .NET Framework Class Library (<http://msdn.microsoft.com/en-us/library/system.componentmodel.typeconverter.asp>) merely defines a common interface for object type mappings. But it does not help with the actual imaging work.

Object-to-Object Mapping via Reflection

Writing the object-to-object mapping manually means creating an instance of *y* for each instance of *x* within an iteration and assigning the relevant attributes of *x* individually to the properties of *y*. For objects that can change in higher layers of the software architecture, you will also find the reverse program code, which maps the attributes of *y* back to the attributes of *x*.

Writing this object-object-mapping program code is not an intellectual challenge but an annoying task, where it's easy to forget properties. If such mapping tasks are manually programmed, the maintenance effort for an application always increases. After all, with each new database field, the mapping program code must be changed at many different points in the application.

If the attributes are the same and have the same data type, you can easily do the object-to-object mapping yourself via reflection. Listing 20-1 and Listing 20-2 show the two extension methods of the class `System.Object` that follow this simple convention. However, if the names differ (irregularly) or the attribute values do not map 1:1, the primitive approach does not help.

    {
        FieldInfo t = toType.GetField(f.Name);
        if (t != null)

AutoMapper

The open source library AutoMapper by Jimmy Bogard has established itself in the .NET developer world for object-to-object mapping. The NuGet package AutoMapper (<https://www.nuget.org/packages/AutoMapper>) consists of AutoMapper.dll, whose central class is AutoMapper.Mapper.

Component name	AutoMapper
Web site	https://github.com/AutoMapper
NuGet	Install-Package Automapper
Free version	Yes
Commercial version	No

AutoMapper runs on the following .NET variants:

- .NET
- .NET Core
- Silverlight
- .NET for Windows Store apps/Windows Runtime
- Universal Windows Platform (UWP) apps
- Xamarin.iOS
- Xamarin.Android

You can find the source code (<https://github.com/AutoMapper/AutoMapper>) and a wiki (<https://github.com/AutoMapper/AutoMapper/wiki>) on GitHub. You can find other resources (for example, a video) on the AutoMapper web site (<http://automapper.org>). Overall, however, the available documentation is (as with so many open source projects) scarce, incomplete, and sometimes outdated. Many functions of AutoMapper are not described in the wiki, so look at blog entries and forums to fully understand AutoMapper. So far, there is no documentation on the differences between the stable version 3.3.1 and the current prerelease version 4.0. Even I, having been working with AutoMapper on my projects for a long time, had to spend many hours researching to discover further, undocumented features in the software component.

Note This chapter describes version 6.1.1 of AutoMapper. Unfortunately, AutoMapper has had major changes in the past, so the commands shown here only partially work in older versions.

Looking at an Example

In this example, parts of the World Wide Wings version 2 object model (shown in Figure 20-5) will be mapped onto the simplified object model in Figure 20-6. The classes Pilot, Employee, and Person are dissolved. The information about the Pilot is shown on a string directly in the FlightView class and on a detail object called PilotDetailView. The new PassengerView class also includes personal data from the Person class. A lot of information (e.g., from the entity Employee) is deliberately no longer used here.

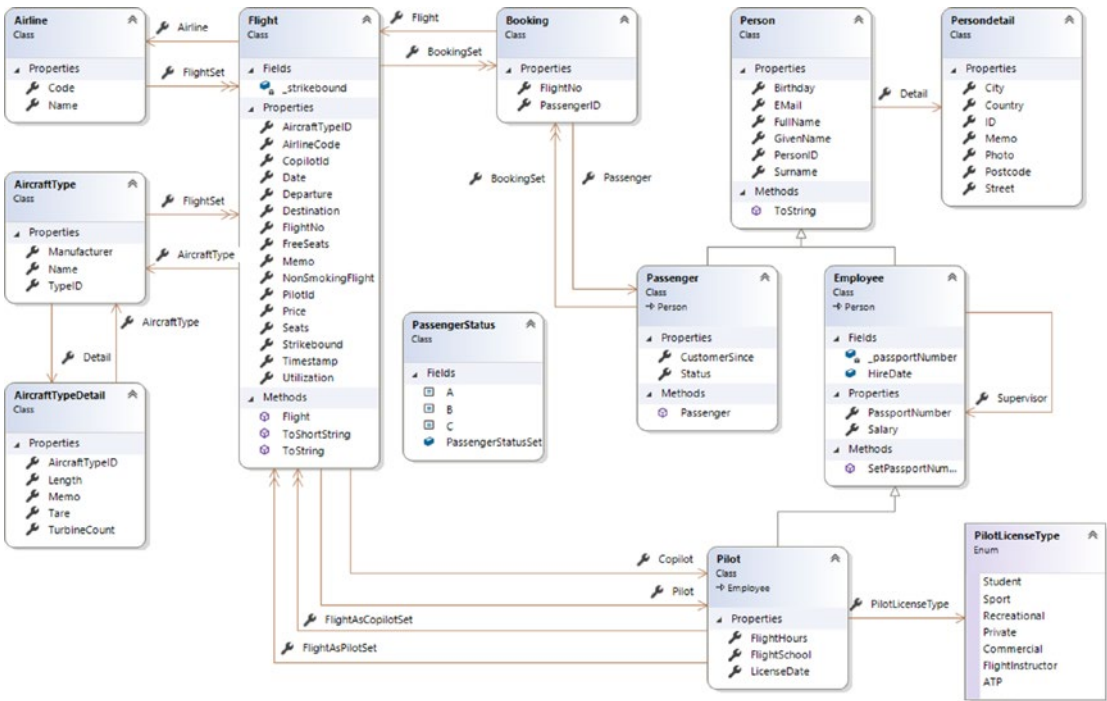

Figure 20-5. The World Wide Wings version 2 object model that uses Entity Framework Core

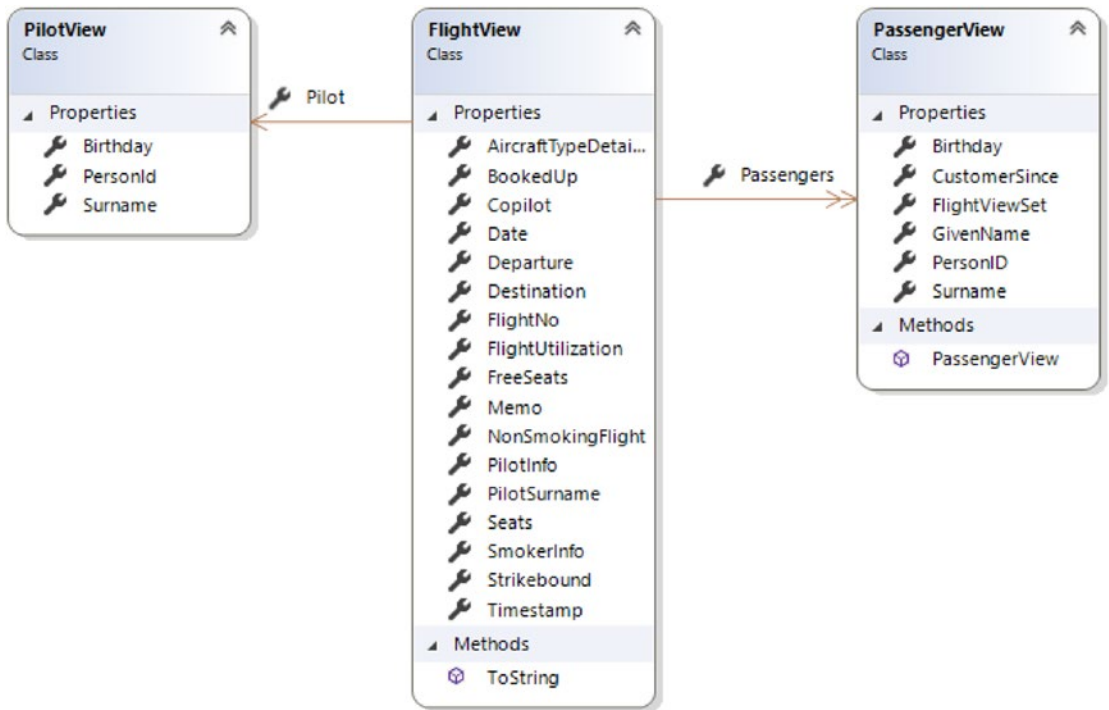

Figure 20-6. The simplified target model to be created from the model from Figure 20-5 using object-to-object mapping

Listing 20-3 shows these three classes.

    {
        this.FlightViewSet = new HashSet<FlightView>();
    }

}
}

Configuring Mappings

Before you can do a mapping with AutoMapper, you have to register the mapping with the classes involved in AutoMapper once per application domain. You do this with the method `Initialize()`.

Attention If `Initialize()` is called several times in a method, only the last executed configuration is valid!

Within `Initialize()`, the `CreateMap()` method is used for the concrete mapping definition between two classes. `CreateMap()` expects two type parameters.

- The first parameter is always the source type.
- The second is the target type.

If you need a conversion in both directions, you have to create it explicitly.

```

Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Flight, FlightView>();
    cfg.CreateMap<FlightView, Flight>();
}

```

```

    cfg.CreateMap<Passenger, PassengerView>();
    cfg.CreateMap<PassengerView, Passenger>();
    cfg.CreateMap<Pilot, PilotDetailView>();
    cfg.CreateMap<PilotDetailView, Pilot>();
});

```

Alternatively, you can use the `ReverseMap()` method to create the mapping in both directions in a row.

```

Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Flight, FlightView>().ReverseMap();
    cfg.CreateMap<Passenger, PassengerView>().ReverseMap();
    cfg.CreateMap<Pilot, PilotDetailView>().ReverseMap();
});

```

The order of multiple calls to `CreateMap()` within `Initialize()` is not relevant.

For a single class, there can be a mapping to a class as well as several other classes.

Here's an example:

```

Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Flight, FlightView>();
    cfg.CreateMap<Flight, FlightDTOShort>();
    cfg.CreateMap<Flight, FlightDTO>();
});

```

Which of these mappings (that is to say, on which target type) is then actually used is decided by the parameters of the `Map()` method, which performs the actual mapping.

Running the Mapping with `Map()`

`AutoMapper's Map()` method has three options.

For option 1, you can map to a new object and then specify the target type as the generic type parameter and the source object as the parameter of the method.

```
FlightView flightView1 = Mapper.Map<FlightView>(flight);
```

For option 2, if you use the nongeneric variant of `Map()`, the program code becomes more extensive. Now, enter the source object type after the source object as the second parameter and the target type as the third parameter. In addition, `Map()` returns only the type `System.Object`, making a type cast with `FlightView` necessary.

```
FlightView flightView2 = (FlightView) AutoMapper.Mapper .Map
(flight, flight.GetType(), typeof ( FlightView ));
```

For option 3, you map an object to another existing object. This is the third variant of `Map()`. In this case, no type parameter is necessary for the method, but the source and target objects are to be transferred as parameters.

```
var flightView3 = new FlightView();
flightView3.Memo = "test";
Mapper.Map(flight, flightView3);
```

Using the Nonstatic API

In addition to the static API, `AutoMapper` has a nonstatic API (the Instance API) for configuring the mapping (Listing 20-4). You configure an instance of the `MapperConfiguration` class and use it to create an object with an `IMapper` interface using `CreateMapper()`. This object then has the `Map()` method.

Listing 20-4. Nonstatic API

```
var config = new MapperConfiguration(cfg => {
    cfg.CreateMap<Flight, FlightView>();
    cfg.CreateMap<Pilot, PilotView>();
    cfg.CreateMap<Passenger, PassengerView>();
    cfg.AddProfile<AutoMapperProfile2>();
});
config.AssertConfigurationIsValid();

IMapper mapper = config.CreateMapper();
var flightView4 = mapper.Map<Flight, FlightView>(flight);
```

Mapping Conventions

AutoMapper not only maps attributes of the same name but also contains other standard conventions, listed here:

- If an attribute `x` is not found in the source object, a `GetX()` function is searched for and, if necessary, called.
- If the name of the attribute contains multiple capital letters and there are dependent objects, then each word is understood as a level and separated by a period. For example, the name `obj.AircraftTypeDetail.Length` is mapped to `obj.AircraftType.Detail.Length`. AutoMapper calls the feature *flattening*.
- AutoMapper ignores any null reference runtime errors.
- AutoMapper accesses private getters and setters, but only if the individual getter or setter is private. If the whole property is declared private, it will be ignored.
- In AutoMapper, the treatment of uppercase and lowercase letters as well as underscores is very exciting. AutoMapper looks for suitable properties also in changed cases and with or without an underscore. Even the order of the property declaration in the classes is relevant!

Table 20-1 shows several cases of a property `Free Spaces` with four different spellings: `FreeSeats`, `freeSeats`, `Free_Seats`, and `free_Seats`. It is always assumed that there is only the variant of the `FreePoints` property in the source object, which is also set in column 1 of the table. Also, the target object always contains all four variants of the property, and the properties are in the same order in which they are in the table.

Table 20-1. *AutoMappers Convention-Based Mapping Behavior Regarding Underscore and Case*

Values in the Source Object	Values in the Target Object	Comment
f.FreeSeats = 1	f.FreeSeats = 1 f.freeSeats = 1 f.Free_Seats = 1 f.free_Seats = 1	The value from one property in the source object is copied by AutoMapper into all four variants in the target object.
f.FreeSeats = 1 f.freeSeats = 2	f.FreeSeats = 1 f.freeSeats = 1 f.Free_Seats = 1 f.free_Seats = 1	The value of a property FreeSeats is ignored because FreeSeats has already mapped its value to all target properties.
f.FreeSeats = 1 f.freeSeats = 2 f.Free_Seats = 3	f.FreeSeats = 1 f.freeSeats = 1 f.Free_Seats = 3 f.free_Seats = 3	The first property without an underscore maps to all properties without an underscore, and the first one with an underscore maps to all properties with an underscore.
f.FreeSeats = 1 f.freeSeats = 2 f.free_Seats = 4	f.FreeSeats = 1 f.freeSeats = 1 f.Free_Seats = 4 f.free_Seats = 4	The first property without an underscore maps to properties without an underscore, and the first one with an underscore maps to all properties with an underscore.
f.FreeSeats = 1 f.freeSeats = 2 f.Free_Seats = 3 f.free_Seats = 4	f.FreeSeats = 1 f.freeSeats = 1 f.Free_Seats = 3 f.free_Seats = 3	The first property without an underscore maps to all properties without an underscore, and the first one with an underscore maps to all properties with an underscore.

Changing Mapping Conventions

You can override the convention of accepting underscores as delimiters. To do this, you write your own convention class (see Listing 20-6), which overrides the rendering of underscores by setting `SeparatorCharacter` to an empty string and using no regular expression in `SplittingExpression`.

Listing 20-6. A Separate Convention Class for AutoMapper That Overrides the Rendering of Underscores

```

using AutoMapper;
using System.Text.RegularExpressions;

namespace EFC_Console.AutoMapper
{
    /// <summary>
    /// No use of underscores when mapping

```

```

/// </summary>
class NoNamingConvention : INamingConvention
{
    #region INamingConvention Members
    public string ReplaceValue(Match match)
    {
        return "";
    }

    public string SeparatorCharacter
    {
        get { return ""; }
    }

    public Regex SplittingExpression
    {
        get { return new Regex(""); }
    }
    #endregion
}
}

```

Your own convention has to be included in the configuration, as shown here:

```

Mapper.Initialize(cfg =>
{
    cfg.SourceMemberNamingConvention = new NoNamingConvention();
    cfg.DestinationMemberNamingConvention = new NoNamingConvention();

    cfg.CreateMap<Flight, FlightView>().ReverseMap();
    cfg.CreateMap<Passenger, PassengerView>().ReverseMap();
    cfg.CreateMap<Pilot, PilotDetailView>().ReverseMap();
});

```

Profile Classes

You can outsource the AutoMapper configuration to so-called profile classes, which inherit from the base class Profile.

```

using AutoMapper;
using BO;

namespace EFC_Console.AutoMapper
{
    /// <summary>
    /// Simple profile class for AutoMapper
    /// </summary>

    public class AutoMapperProfile1 : Profile
    {
        public AutoMapperProfile1()
        {
            this.SourceMemberNamingConvention = new NoNamingConvention();
            this.DestinationMemberNamingConvention = new NoNamingConvention();
            this.CreateMap<Flight, FlightView>().ReverseMap();
            this.CreateMap<Passenger, PassengerView>().ReverseMap();
            this.CreateMap<Pilot, PilotDetailView>().ReverseMap();
            this.CreateMap<Flight, FlightDTOShort>();
            this.CreateMap<Flight, FlightDTO>();
        }
    }
}

```

This profile class is then called in `Initialize()` via `AddProfile()`.

```

Mapper.Initialize(cfg =>
{
    cfg.AddProfile<AutoMapperProfile1>();
});

```

Ignoring Subobjects

If the source and target objects all have a subobject and the property name maps according to one of the AutoMapper conventions but there is no mapping for that object type, AutoMapper complains with the following error: “Missing type map configuration or unsupported mapping.” Either you have to create a mapping with `CreateMap()` for the subobject type or you have to tell AutoMapper explicitly that you do not want to map the subobjects.

Ignoring is done through the Fluent API of the `CreateMap()` method using the `Ignore()` method after calling `ForMember()`.

```
AutoMapper.Mapper.CreateMap<Passenger, PassengerView>().ForMember(z =>
z.PilotView, m => m.Ignore());
```

Note Flattening still works after an `Ignore()` call for a subobject. That is, `AutoMapper` will continue to populate the property `PilotSurname` in class `FlightView` with the values from `Pilot.Surname`, even if `flightView.PilotView` is set to null by the `Ignore()` statement.

Custom Mappings

The developer of `AutoMapper` offers numerous ways to manipulate a mapping. Using the Fluent API of the `CreateMap()` method, you can define the mappings of the properties of the source object to mappings of the properties of the target object, called *projections*. A manual mapping uses the `ForMember()` method. The first parameter to be specified is a lambda expression for the target property (variable name `z` for the target), and the second parameter is a lambda expression for the value (variable name `q` for the source), whereby one or more properties of the source object can be referenced.

Listing 20-7 shows the following ten possibilities:

- Mapping a property to a static value using `UseValue()`.
- Mapping a property to the result of an expression to a source property using `MapFrom()`, where the result is a Boolean value.
- Mapping a property to a calculation of multiple source properties using `MapFrom()`, where the value is a number.
- Mapping a property with `MapFrom()` to the result of the `ToString()` method in a subobject of the source object.
- Mapping a property with `MapFrom()` to an object containing values from multiple source properties.
- Mapping a property with a `ValueResolver` class using `ResolveUsing()` and the `IValueResolver` interface.

- Mapping zero values to another value with the `NullSubstitute()` method.
- Specify that the properties of the target object must not be overwritten with a value of the source object. This is done with the `UseDestinationValue()` method.
- The penultimate case shows how `Condition()` maps only if the source value (`SourceValue`) meets a specific condition.
- The last case shows the conversion of an N:M mapping into a 1:N mapping. Here the intermediate entity `booking`, which connects `Flight` and `Passenger`, is eliminated. The destination class `FlightView` has a property of the type `List<Passenger>`.

Since such mapping definitions can often become very extensive, it is usually advisable to outsource them to a profile class (see Listing 20-7) instead of spreading them somewhere in the program code. Listing 20-8 shows the resolver class.

Listing 20-7. Manual AutoMapper Mappings with `ForMember()`

```
public AutoMapperProfile2()
{
    #region Mappings for class Flight
    CreateMap<Flight, FlightView>()

    // 1. Set Memo to static value
    .ForMember(z => z.Memo,
               q => q.UseValue("Loaded from Database: " + DateTime.Now))

    // 2. Mapping for a bool property
    .ForMember(z => z.BookingUp, q => q.MapFrom(f => f.FreeSeats <= 0))

    // 3. Mapping with calculation
    .ForMember(z => z.FlightUtilization,
               q => q.MapFrom(f => (int)Math.Abs(((decimal)f.FreeSeats /
               (decimal)f.Seats) * 100)))

    // 4. Mapping to a method result
    .ForMember(z => z.PilotInfo, m => m.MapFrom(
               q => q.Pilot.ToString()))
}
```

```

// 5. Mapping to a method result with object construction
.ForMember(z => z.Pilot,
    m => m.MapFrom(
        q => new Pilot { PersonID = q.Pilot.PersonID, Surname = q.Pilot.
            FullName, Birthday = q.Pilot.Birthday.GetValueOrDefault() })))

// 6. Mapping with a value resolver
.ForMember(z => z.SmokerInfo,
    m => m.ResolveUsing<SmokerInfoResolver>())

// 7. Mapping if source value is null
.ForMember(z => z.Destination, q => q.NullSubstitute("unknown"))

// 8. No Mapping for existing values
.ForMember(z => z.Timestamp, q => q.UseDestinationValue())

// 9. Conditional Mapping
.ForMember(z => z.Seats, x => x.Condition(q => q.FreeSeats < 250))

// 10. Map n:m to zu 1:n (for Flight->Booking->Passenger)
.ForMember(dto => dto.PassengerViewSet, opt => opt.MapFrom(x =>
    x.BookingSet.Select(y => y.Passenger).ToList()))

// 11. Include reverse Mapping
.ReverseMap();
#endregion

#region Other class mappings
CreateMap<Pilot, string>().ConvertUsing<PilotStringConverter>();
// Map n:m to zu 1:n (for Passenger->Booking->Flight)
CreateMap<Passenger, PassengerView>()
    .ForMember(z => z.FlightViewSet, m => m.MapFrom(q => q.BookingSet.
        Select(y => y.Flight)));
#endregion

#region Typkonvertierungen

CreateMap<byte, long>().ConvertUsing(Convert.ByteToLong);
#endregion
}

Listing 20-8. A Value Resolver Class for AutoMapper

```

namespace EFC_Console.AutoMapper
{
    /// <summary>
    /// Value Resolver for Automapper, converts true/false to
    /// string property "SmokerInfo"
    /// </summary>
    public class SmokerInfoResolver : IValueResolver<Flight, FlightView,
    string>
    {
        public string Resolve(Flight source, FlightView destination, string
        member, ResolutionContext context)
        {
            if (source.NonSmokingFlight.GetValueOrDefault()) destination.SmokerInfo
            = "This is a non-smoking flight!";
            else destination.SmokerInfo = "Smoking is allowed.";
            return destination.SmokerInfo;
        }
    }
}

```

Type Conversions

When mapping elementary data types (string, int, decimal, bool, and so on), AutoMapper maps easily if the types are the same or if the target type is string. In the case of the target type string, AutoMapper can always get to a string by calling ToString(). Number types are automatically converted both up and down. This allows AutoMapper to map from byte to long, but also from long to byte. However, some of this flexibility is new since version 4.0. Version 3.3.1 responded to the attempt to map long to byte with the following error: “Missing type map configuration or unsupported mapping. Mapping types: System.Byte -> System.Int64.” Also in AutoMapper 4.0, if the value to be mapped does not fit into the target number type, the following runtime error occurs: “AutoMapper.AutoMapperMappingException: Value was either too large or too small for an unsigned byte.”

Of course, AutoMapper cannot map if the types are completely different. For example, if the property `BirthDay` has the type `DateTime` in the source object but `Integer` is used in the target object, the runtime error will always occur (`AutoMapper.AutoMapperMappingException`). In the error message, you will find detailed information about the problem, as shown here:

System.DateTime ► *System.Int32*

Destination path:

PassengerView.Birthday

Source value:

01.10.1980 00:00:00

For type images that AutoMapper does not carry out automatically or that should be done differently than AutoMapper does it in the standard version, you must provide AutoMapper with a type converter (Listing 20-9 and Listing 20-10). Such a type converter can be implemented in a simple method that takes type `x` and returns `y`. This converter method is then registered with AutoMapper.

```
CreateMap<byte, long>().ConvertUsing(ConvertByteToLong);
CreateMap<DateTime, Int32>().ConvertUsing(ConvertDateTimeToInt);
```

If necessary, you can call a standard converter method of the .NET Framework.

```
CreateMap<byte, long>().ConvertUsing(Convert.ToInt64);
```

Listing 20-9. Method-Based Type Converter for AutoMapper

```
/// <summary>
/// Converts bytes to long with special case 0
/// </summary>
/// <param name="b">Byte value</param>
/// <returns></returns>
public static long ConvertByteToLong(byte b)
{
    if (b == 0) return -1;
    else return (long) b;
}
```

Listing 20-10. Another Method-Based Type Converter for AutoMapper

```

/// <summary>
/// Converts bytes to long with special case 0
/// </summary>
/// <param name="d">DateTime value</param>
/// <returns></returns>
public static Int32 ConvertDateTimeToInt(DateTime d)
{
    return d.Year;
}

```

You can also implement the type converter as a class that implements the `ITypeConverter` interface using the `Convert()` method (see Listing 20-11). This custom converter class is then registered with a generic variant of `ConvertUsing()`.

```
CreateMap<Pilot, string>().ConvertUsing<PilotStringConverter>();
```

Listing 20-11. Class-Based Type Converter for AutoMapper

```

/// <summary>
/// Converts a Pilot to a string
/// </summary>
public class PilotStringConverter : ITypeConverter<Pilot, string>
{
    public string Convert(Pilot pilot, string s, ResolutionContext context)
    {
        if (pilot == null) return "(Not assigned)";
        return "Pilot # " + pilot.PersonID;
    }
}

```

The conversions shown so far are global for all images in all classes. This, of course, is a powerful feature because it avoids having to repeat some mappings. But you should also be careful here because you may create images that you do not want so that data can be lost.

It may also be that you do not want such a conversion at all globally, but only for a single property image in individual classes. In this case, you can write a `ValueResolver` (see subchapter before ‘Custom Mappings’).

Collections

Even if you always configure AutoMapper to map individual classes, AutoMapper can map not only individual instances but also arbitrarily large amounts of these classes to each other using `Map()`.

Here's an example:

```
List<FlightView> FlightviewList = AutoMapper.Mapper.Map <List<Flight View
>> (Flight list);
```

AutoMapper supports the following types of volumes (Listing 20-12):

- IEnumerable
- IEnumerable <T>
- ICollection
- ICollection <T>
- IList
- IList<T>
- List<T>
- Arrays

Listing 20-12. Mapping of an Entire List

```
public static void Demo_ListMapping()
{
    CUI.Headline(nameof(Demo_ListMapping));

    Mapper.Initialize(cfg =>
    {
        cfg.AddProfile<AutoMapperProfile2>();
    });

    using (var ctx2 = new WWWingsContext())
    {
        var flightSet = ctx2.FlightSet.Include(f => f.Pilot).Include(f =>
            f.BookingSet).ThenInclude(x => x.Passenger).Where(f => f.Departure ==
                "Berlin").OrderBy(f => f.FlightNo).Take(5).ToList();
```

```

// map all objects in this list
List<FlightView> flightviewListe = Mapper.Map<List<FlightView>>
(flightSet);
foreach (var f in flightviewListe)
{
    Console.WriteLine(f.ToString());
    if (f.Passengers!= null)
    {
        foreach (var pas in f.PassengerViewSet)
        {
            Console.WriteLine("  - " + pas.GivenName + " " + pas.Surname + " has
" + pas.FlightViewSet.Count + " Flights!");
        }
    }
}
}
}
}
}

```

Inheritance

To illustrate the behavior of AutoMapper in inheritance relationships, the example from Listing 20-13 uses the Person, Woman, and Man classes, as well as the associated data transfer object (DTO) classes PersonDTO, MsDTO, and MannDTO. The differences between Man and Woman are, according to an old cliché, based on the possession of a significant number of cars (in Man) or shoes (in Woman). The DTO classes are distinguished by the data type of the number values (bytes instead of integers) as well as the combination of the first name and last name as property names. In addition, the birthday in the DTO classes saves only the year and not the complete date.

Listing 20-13. Class Hierarchy for the Inheritance Example

```

class Person
{
    public string GivenName { get; set; }
    public string Surname { get; set; }
    public DateTime Birthday { get; set; }
}

```

```

class Man : Person
{
    public int NumberOfCars { get; set; }
}

class Woman : Person
{
    public int NumberOfShoes { get; set; }
}

class PersonDTO
{
    public string Name { get; set; }
    public int YearOfBirth { get; set; }
}

class ManDTO : PersonDTO
{
    public byte NumberOfCars{ get; set; }
}

class WomanDTO : PersonDTO
{
    public byte NumberOfShoes{ get; set; }
}

```

Basically, you have to define a mapping for each individual class in the inheritance hierarchy in an inheritance relationship.

```

Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Person, PersonDTO>();
    cfg.CreateMap<Woman, WomanDTO>();
    cfg.CreateMap<Man, ManDTO>();
});

```

While AutoMapper automatically handles type casting integers in bytes, the name and birth date mapping is missing. The type conflict in the case of the date of birth leads to a runtime error during mapping (`AutoMapper.AutoMapperMappingException`).

It is not enough to set the manual mappings with `ForMember()` and `MapFrom()` only on the base class.

```
cfg.CreateMap<Person, PersonDTO>()
    .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
q.Surname))
    .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.Year));
cfg.CreateMap<Woman, WomanDTO>();
cfg.CreateMap<Man, ManDTO>();
```

After that, only the mapping for the class `Person` is done correctly. The classes `Man` and `Woman` continue to produce a runtime error. `AutoMapper` expects that there will be manual mapping configuration for each class in the inheritance hierarchy, as shown here:

```
Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Person, PersonDTO>()
        .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
q.Surname))
        .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
Year));
    cfg.CreateMap<Man, ManDTO>()
        .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
q.Surname))
        .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
Year));
    cfg.CreateMap<Woman, WomanDTO>()
        .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
q.Surname))
        .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
Year));
});
```

But you can avoid this program code repetition by using `AutoMapper`'s `Include()` methods (not to be confused with the `Entity Framework`'s `Include()` method!).

```
Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Person, PersonDTO>()
        .Include<Man, ManDTO>()
        .Include<Woman, WomanDTO>()
        .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
            q.Surname))
        .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
            Year));
    cfg.CreateMap<Man, ManDTO>();
    cfg.CreateMap<Woman, WomanDTO>();
});
```

Listing 20-14 shows an example of the Person, Man, and Woman mapping, including a gender transformation of a man into a woman, with the number of cars being converted into ten times the number of shoes. After defining this mapping, the actual transformation from Man to Woman with AutoMapper is comparatively painless.

Listing 20-14. Mapping with Person, Man, and Woman

```
public static void Inheritance()
{
    CUI.Headline(nameof(Inheritance));

    Mapper.Initialize(cfg =>
    {
        cfg.CreateMap<Person, PersonDTO>()
            .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
                q.Surname))
            .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
                Year));
        cfg.CreateMap<Man, ManDTO>()
            .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
                q.Surname))
            .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
                Year));
```

```

cfg.CreateMap<Woman, WomanDTO>()
    .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
q.Surname))
    .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
Year));
});

// or shorter using include()
Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Person, PersonDTO>()
        .Include<Man, ManDTO>()
        .Include<Woman, WomanDTO>()
        .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " "
+ q.Surname))
        .ForMember(z => z.YearOfBirth, map => map.MapFrom(q =>
q.Birthday.Year));
    cfg.CreateMap<Man, ManDTO>();
    cfg.CreateMap<Woman, WomanDTO>();
});

var m = new Man()
{
    GivenName = "John",
    Surname = "Doe",
    Birthday = new DateTime(1980, 10, 1),
    NumberOfCars = 40
};

PersonDTO mDT01 = Mapper.Map<PersonDTO>(m);
Console.WriteLine(mDT01.Name + " *" + mDT01.YearOfBirth);

ManDTO mDT01b = Mapper.Map<ManDTO>(m);
Console.WriteLine(mDT01b.Name + " *" + mDT01b.YearOfBirth);

ManDTO mDT02 = (ManDTO)Mapper.Map(m, m.GetType(), typeof(ManDTO));
Console.WriteLine(mDT02.Name + " *" + mDT02.YearOfBirth + " owns " +
mDT02.NumberOfCars + " cars.");

```

```

ManDTO mDTO3 = Mapper.Map<ManDTO>(m);
Console.WriteLine(mDTO3.Name + " *" + mDTO3.YearOfBirth + " owns " +
mDTO3.NumberOfCars + " cars.");

// gender transformation: man -> woman
Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Man, Woman>()
        .ForMember(z => z.NumberOfShoes, map => map.MapFrom(q =>
            q.NumberOfCars * 10));
});

Woman f = Mapper.Map<Woman>(m);
Console.WriteLine(f.GivenName + " " + f.Surname + " *" + f.Birthday + "
owns " + f.NumberOfShoes + " shoes.");
}

```

What happens if a derived class has a manual mapping that contradicts a base class mapping? According to the documentation (<https://github.com/AutoMapper/AutoMapper/wiki/Mapping-inheritance>), the evaluation is done by AutoMapper with the following priorities:

- Explicit mapping in the derived class
- Inherited explicit mapping
- Mappings with `Ignore()`
- AutoMapper conventions that work only in the last step

Generic Classes

AutoMapper also helps with generic classes. It's pretty basic for AutoMapper to map generic lists (see Listing 20-15).

Listing 20-15. Mapping Generic Lists, Here the Example `List<T>`

```

public static void GenericHomogeneousList()
{
    CUI.Headline(nameof(GenericHomogeneousList));
}

```

```

var PersonSet = new List<Person>();
for (int i = 0; i < 100; i++)
{
    PersonSet.Add(new Person() { GivenName="John", Surname="Doe"});
}

// define Mapping
Mapper.Initialize(cfg =>
{
    cfg.CreateMap<Person, PersonDTO>()
.ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + " " +
q.Surname))
.ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.Year));
});

// Convert list
var PersonDTOSet = Mapper.Map<List<PersonDTO>>(PersonSet);

Console.WriteLine(PersonDTOSet.Count());
foreach (var p in PersonDTOSet.Take(5))
{
    Console.WriteLine(p.Name + ": " + p.YearOfBirth);
}
}

```

AutoMapper can also map entire generic types to other generic types. Sticking to the example with Person, Woman, and Man, Listing 20-16 defines two generic types for a partnership: a registered partnership and a marriage.

Listing 20-16. Generic Types for Partnership and Marriage

```

// see https://europa.eu/youreurope/citizens/family/couple/registered-
partners/index_en.htm
class RegisteredPartnership<T1, T2>
    where T1 : Person
    where T2 : Person
{
    public T1 Partner1 { get; set; }
}

```

```

public T2 Partner2 { get; set; }
public DateTime Date { get; set; }
}

class Marriage<T1, T2>
  where T1 : Person
  where T2 : Person
{
  public T1 Partner1 { get; set; }
  public T2 Partner2 { get; set; }
  public DateTime Date { get; set; }
}

```

This allows same-sex registered partnerships as well as same-sex marriages! You can even allow a registered partnership to be automatically converted into a marriage. For example, converting the type of registered partnership `<husband, husband>` into marriage `<husband, husband>` is no problem for AutoMapper. All you have to do is define a general mapping between the generic classes. By no means do you have to write a mapping for all possible variants of type parameters of these generic classes.

```

Mapper.Initialize (cfg =>
{
  cfg.CreateMap (typeof (RegisteredPartnership <,>), typeof (Marriage <,>));
}
30.4

```

Listing 20-17 shows the application of this mapping.

Listing 20-17. Mapping Your Own Generic Types from Listing 20-16

```

// A registered partnership between two men
var m1 = new Man() {first name = "Heinz" , last name = "Müller" };
var m2 = new Man() {first name = "Gerd" , last name = "Meier" };
var ep = new RegisteredPartnership < Man , Man >() {Partner1 = m1,
Partner2 = m2, Date = new DateTime (2015,5,28)};

// The general mapping between the generic classes
Mapper.Initialize (cfg =>
{

```

```
cfg.CreateMap (typeof (RegisteredPartnership <,>), typeof (Marriage <,>));
30.4
```

```
// Then every figure with concrete type parameters is allowed!
Marriage < husband , husband > marriage = AutoMapper.Mapper .Map < marriage
< man , man >> (ep);
Console .WriteLine (before.Partner1.Name + "+" + marriage.Partner2.Name +
":" + marriage.- DateToShortDateString());
```

An additional mapping of the generic parameters is possible, such as RegisteredPartnership<man, man> to Marriage <ManDTO, ManDTO>. Of course this requires the following:

- That the generic class marriage <T1, T2> as a type parameter also allows ManDTO or PersonDTO (which it does not yet do). So, you have to change it like this:

```
class Marriage<T1, T2>
    where T1 : PersonDTO
    where T2 : PersonDTO
{
    public T1 Partner1 { get; set; }
    public T2 Partner2 { get; set; }
    public DateTime Date { get; set; }
}
```

- It is also necessary to define a mapping between Man and ManDTO, as shown here:

```
Mapper.Initialize(cfg =>
{
    cfg.CreateMap(typeof(RegisteredPartnership<,>),
typeof(Marriage<,>));
    cfg.CreateMap<Man, ManDTO>()
        .ForMember(z => z.NumberOfCars, map => map.MapFrom(q =>
q.GivenName + " " + q.Surname))
        .ForMember(z => z.YearOfBirth, map => map.MapFrom(q =>
q.Birthday.Year));
});
```

After that, the mapping between `RegisteredPartnership<Man, Man>` and `Marriage<ManDTO, ManDTO>` can be done.

```
Marriage<ManDTO, ManDTO> marriageDTO = Mapper.Map<Marriage<ManDTO,
ManDTO>>(ep);
Console.WriteLine(marriageDTO.Partner1.Name + " + " + marriageDTO.
Partner2.Name + ": " + marriage.Date.ToShortDateString());
```

Additional Actions Before and After the Mapping

`AutoMapper` allows mapping actions to be performed before mapping or after mapping. The `BeforeMap()` method in the Fluent API of `CreateMap()` sets the upstream actions; `AfterMap()` sets the downstream. Both methods can be called multiple times, as Listing 20-18 shows with the example of `BeforeMap()`. Both methods each expect an expression that gets both the source object (briefly named `q` in the listing) and the target object (briefly named `z` in the listing). It is possible to call a method as part of the expression. This is also shown in Listing 20-18 using the example of `AfterMap()`.

The example in Listing 20-18 does the following when mapping `Person` to `PersonDTO`:

- If the first name or last name is empty, the entry in the source object is replaced with a question mark.
- If the name `??` appears in the target object because the first and last names are empty, the value "error" or "no information" will be delivered depending on the year of birth. The business process rule behind it is as follows: All people born before 1980 may remain anonymous. All people born after that are required to give a name. If the name is still missing, there must be an error.

Of course, you can set such business logic outside of `AutoMapper`. These are the advantages of integrating with `AutoMapper`:

- You have all the mapping actions in one place.
- You do not have to explicitly preprogram an iteration over the objects before or after the mapping.

Listing 20-18. BeforeMap() and AfterMap() in Action

```

public static void BeforeAfterDemo()
{
    CUI.Headline(nameof(BeforeAfterDemo));

    var PersonSet = new List<Person>();
    for (int I = 0; i < 10; i++)
    {
        PersonSet.Add(new Person()
        {
            GivenName = "Joh",
            Surname = "Do",
            Birthday = new DateTime(1980, 10, 1),
        });
    }

    // Define mapping
    Mapper.Initialize(cfg =>
    {
        cfg.CreateMap<Person, PersonDTO>()
            .ForMember(z => z.Name, map => map.MapFrom(q => q.GivenName + "" +
            q.Surname))
            .ForMember(z => z.YearOfBirth, map => map.MapFrom(q => q.Birthday.
            Year))
            .BeforeMap((q, z) => q.GivenName = (String.IsNullOrEmpty(q.
            GivenName) ? q.GivenName = "" : q.GivenName))
            .BeforeMap((q, z) => q.Surname = (String.IsNullOrEmpty(q.Surname) ?
            q.Surname = "" : q.Surname))
            .AfterMap((q, z) => z.Name = GetName(z.Name, z.YearOfBirth));
        cfg.CreateMap<DateTime, Int32>().ConvertUsing(ConvertDateTimeToInt);
    });

    // Map list
    var PersonDTOSet = Mapper.Map<List<PersonDTO>>(PersonSet);

    foreach (var p in PersonDTOSet)
    {

```

```

    Console.WriteLine(p.Name + " in born in year" + p.YearOfBirth);
}

Performance

AutoMapper does not use reflection for each fetch and set of values for the mapping. Rather, `CreateMap()` generates the program code at runtime using `Reflection.Emit()`. This raises the question of how long it takes to map large amounts of data.

In Table 20-2, three mapping paths are compared.

- Explicit, hard-coded object-object mapping (i.e., $x_a = y_a$, for each property)

- Reflection-based object-object mapping with the program code at the beginning of this chapter
- Object-object mapping with AutoMapper

So that you do not compare apples with pears, in Table 20-2 a mapping takes place between two exactly identically constructed types. In other words, all properties are called the same way in both classes and also have the same data type. The performance test measures the values for 1, 10, 100, 1,000, 10,000 and 100,000 objects that are in a generic list.

When looking at the results table, it is clear that AutoMapper is significantly slower. Generating the mapping code with `CreateMap()` always takes about 208 milliseconds. If a mapping of a type occurs repeatedly in a process, this happens only once. With repeated calls, it takes approximately 7 milliseconds. However, AutoMapper is slower than explicit mapping in all cases and even slower than reflection-based mapping for data sets up to 1,000 objects.

Table 20-2. *Speed Comparison of Three Methods for Object-to-Object Mapping (in Milliseconds)*

Number of Objects	Explicit (Hard-Coded) Mapping		Reflection Mapping		AutoMapper	
	One-time initialization effort per application domain	Effort for the mapping	One-time initialization effort per application domain	Effort for the mapping	One-time initialization effort per application domain	Effort for the mapping
1	0	0	0	0	208	18
10	0	0	0	0	208	18
100	0	0	0	1	208	18
1,000	0	0	0	10	208	19
10,000	0	1	0	104	208	30
100,000	0	29	0	1010	208	63

Conclusion to AutoMapper

AutoMapper offers flexible imaging options between different object structures. The performance of AutoMapper is very disappointing at first glance. However, you must not forget that AutoMapper saves a lot of programming work compared to explicit mapping and can do much more than reflection mapping.

However, developers such as Andrew Harcourt (http://www.uglybugger.org/software/post/friends_dont_let_friends_use_automapper) criticize not only the performance of AutoMapper but also dislike the conventions. Mapping properties of the same name becomes a problem when you rename a property that will be mapped, unless you also think about writing a custom mapping with `ForMember()`. Harcourt advocates explicitly programming all mappings, which makes automatic name refactoring possible. To reduce the programming work for the explicit mapping, he has written a code generator for the matching mapping code. Unfortunately, he does not provide the code generator to the public.

Tools that generate an explicit mapping include OTIS-LIB (<http://code.google.com/p/otis-lib>) and Wayne Hartmann's Object To Object Mapping Utility (<http://waynehartman.com/download?file=d2333998-c0cc-4bd4-8f02-82bef57d463c>). However, not everyone likes generator-generated program code. Therefore, this chapter ends without a clear recommendation for or against AutoMapper. It depends on the application (the size and number of objects) and your own preference.

Case Studies

This chapter describes some practical applications for Entity Framework Core that are outside the World Wide Wings example.

Using Entity Framework Core in an ASP.NET Core Application

In 2015, Microsoft paid more than \$100 million to acquire the Berlin-based app publisher Wunderlist (<https://www.theverge.com/2015/6/2/8707883/microsoft-wunderlist-acquisition-announced>). MiracleList is a reprogramming of the Wunderlist task management app as a web application and cross-platform application for Windows, Linux, macOS, Android, and iOS with a cross-platform back end in the cloud. See Figure A-1, Figure A-2, and Figure A-3.

The logged-in user can create a list of task categories and then create a list of tasks in each category. A task consists of a title, a note, an entry date, and a due date, and it can be marked as done. Beyond the functions of Wunderlist, in MiracleList a task can have three (A, B, or C) instead of just two levels of importance (yes/no) and an effort (number). The effort has no unit of measure; the user can decide whether to set the effort to hours, days, or a relative value such as 1 (for low) to 10 (for high).

Like with Wunderlist, a task can have subtasks, with a subtask having only one title and one status. Some details from the original are missing in MiracleList, such as the ability to upload files to tasks, move tasks between categories, search for hashtags, duplicate and print lists, and exchange tasks among users. Some features, such as clickable hyperlinks in the text of a task, are not implemented to prevent misuse.

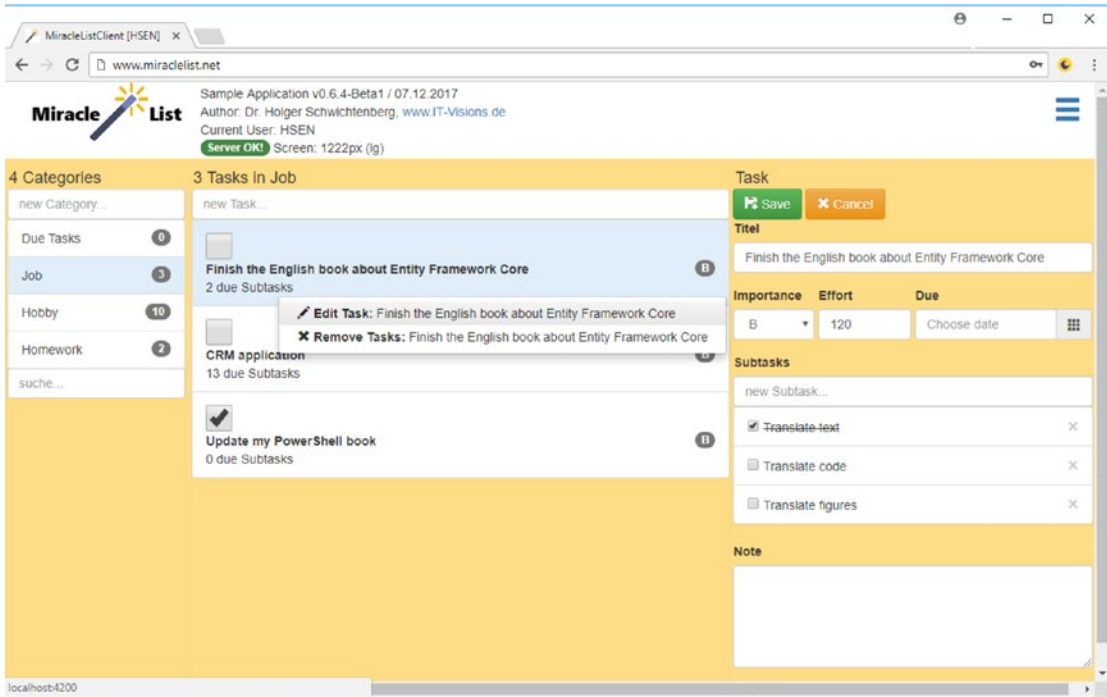

Figure A-1. MiracleList web application

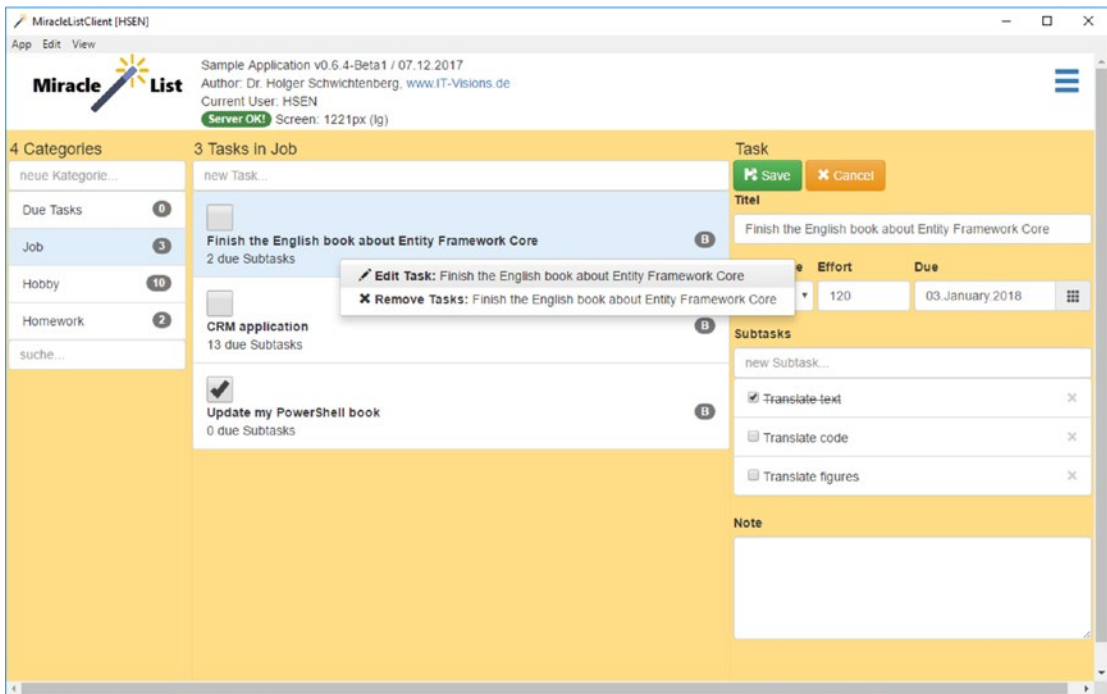

Figure A-2. MiracleList desktop client for Windows

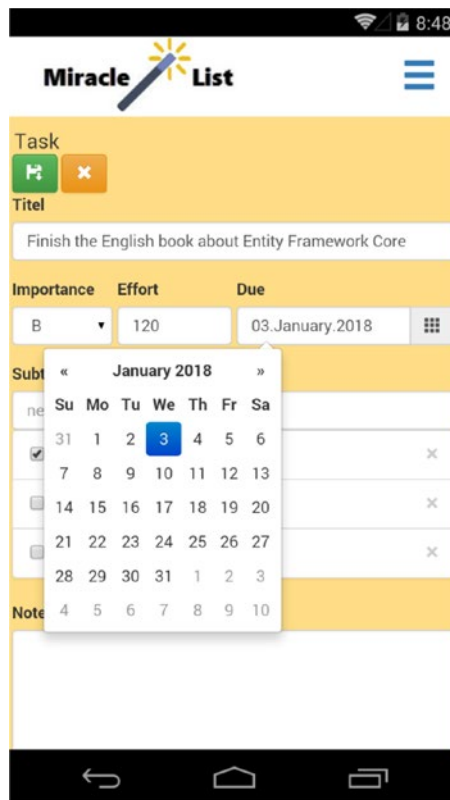

Figure A-3. *MiracleList client for Android*

In addition to the web API, the back end also has a web interface that offers the following (Figure A-4):

- Version information for the web API
- OpenAPI specification for the web API
- Help page for the web API
- The ability to request a client ID to create your own client
- The ability to download the desktop clients

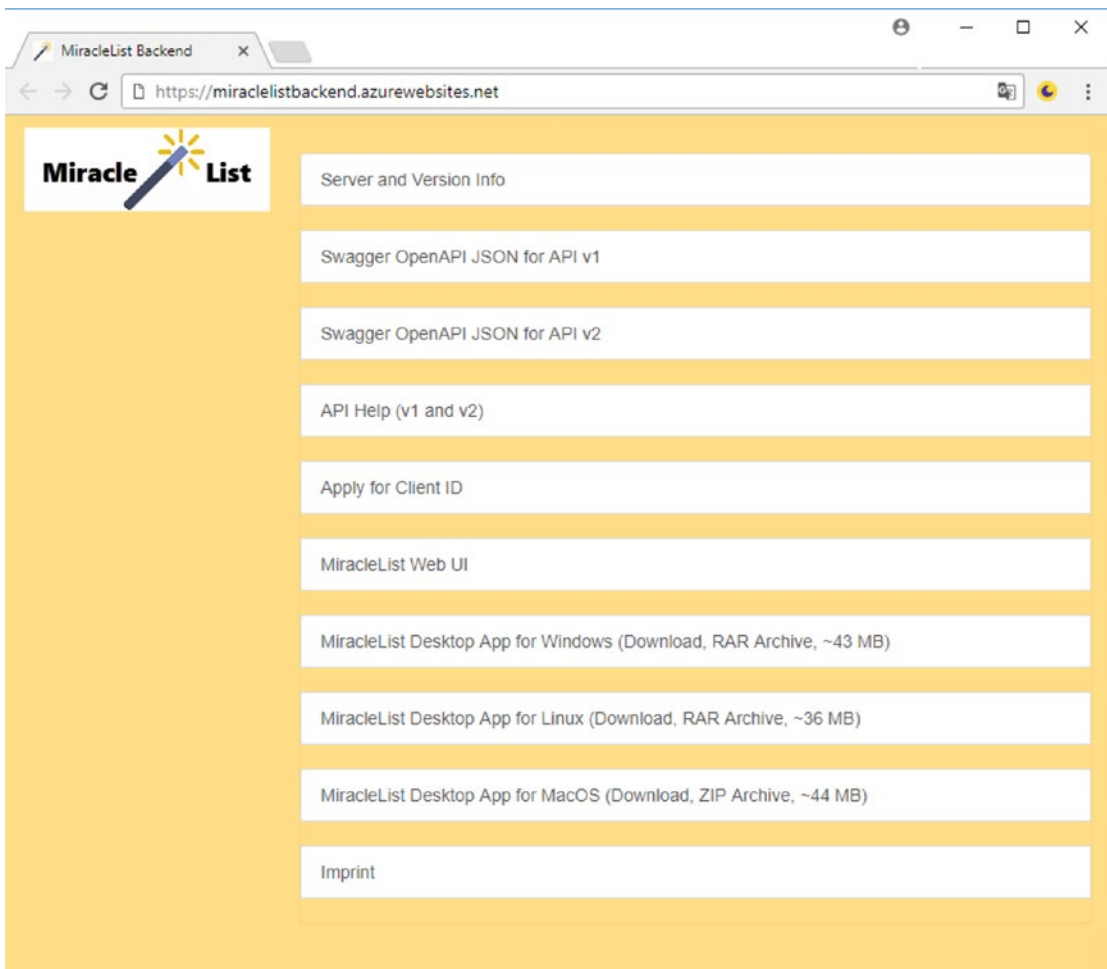

Figure A-4. Web interface of the back end

In this book, only excerpts from the back end are discussed because it is there that Entity Framework Core is used.

You can find more information at the following sites:

- *Web application and client download:* <http://www.miraclelist.net>
- *Back end:* <https://miraclelistbackend.azurewebsites.net>
- *Source code for the back end:* <https://github.com/HSchwichtenberg/MiracleListBackend>
- *Source code for the front end:* <https://github.com/HSchwichtenberg/MiracleListClient>

Architecture

MiracleList uses the following techniques:

- *Back end:* .NET Core, C# , ASP.NET Core Web API, Entity Framework Core, SQL Azure, Azure Web App, Swagger/Swashbuckle. AspNetCore, Application Insights
- *Front end:* SPA with HTML, CSS, TypeScript, Angular, Bootstrap, MomentJS, ng2-datetime, angular2-moment, angular2-contextmenu, angular2-modal, Electron, Cordova

The back end for MiracleList is available for anyone to use at <https://miraclelistbackend.azurewebsites.net>. It runs on C# 6.0 and .NET Core 2.0 and was built using SQL Azure as the database, Entity Framework Core 2.0 as the OR mapper, and ASP.NET Core 2.0 as the web server framework. It is hosted in Microsoft's Azure cloud as a web app.

The MiracleList back end provides a clear separation of layers. The solution (see Figure A-5) consists of the following:

- *Business objects (BOs):* This contains the entity classes used for Entity Framework Core. These classes are deliberately implemented in such a way that they can also be used as input and output types in the Web API, meaning that additional object-to-object mapping with AutoMapper or other tools is unnecessary.
- *Data access layer (DAL):* This layer implements the Entity Framework core context (Context.cs).
- *Business logic (BL):* Here, “manager” classes are implemented that implement the back-end functionality using the Entity Framework Core context.
- *MiracleList_WebAPI:* Here the controllers for the web API are realized.
- *EFTools:* This contains Entity Framework Core tools for forward engineering.
- *UnitTests:* This contains unit tests with XUnit.

Entity Framework Core Context Class

The context class derived from `DbContext` always has a property of type `DbSet<T>` for the four entity classes (Listing A-6). In the `OnConfiguring()` method, `UseSqlServer()` sets the Entity Framework Core database provider, passing in the connection string. The connection string is realized as a public static class member, so it can be set externally.

In the `OnModelCreating()` method additional indexes on columns are set, which allow searching. In addition, it is specified globally for all entity classes that the table names in the database should not be named like the `dbSet<T>` properties but like the classes (in other words, table `Task` instead of table `TaskSet`). The exceptions are only the classes that have a `[Table]` annotation, so you have the opportunity to set individual deviations from the rule.

Lifetime of Context Class in ASP.NET Core Applications

When using Entity Framework Core in ASP.NET and ASP.NET Core-based web applications and web services/web APIs, the lifetime of an instance of the context class must not exceed the lifetime of processing a single HTTP request.

For each incoming HTTP request, ASP.NET Core creates a new instance of the controller class using different threads. If you were to use an instance of the context class in more than one HTTP request, you would use the context instance in different threads, which does not support it. The context class is not thread-safe, so it does not support multithreading. Multithreading with a context instance causes the following error at runtime: “System.InvalidOperationException : ‘A second operation started on this context before a previous operation completed. Any instance members are not guaranteed to be thread safe.’”

Note Also, the context classes `ObjectContext` and `DbContext` in the classic Entity Framework are not thread-safe. In the classic Entity Framework, however, there was not a clear error message when using the multithreading context. There were just curious crashes somewhere in the depths of Entity Framework.

In addition, you would encounter a problem with the Entity Framework core cache because a second request would find in the context instance the data of a previous request. However, a second HTTP request may affect another user. Setting an Entity

Framework core context in a user-based variable is not a good solution because it greatly reduces the scalability of the web application.

It is therefore appropriate to limit the lifetime of the context instance to the lifetime of processing a single HTTP request. As part of an HTTP request, you create one or possibly more instances of the context class, which are then destroyed when the request is completed.

The architecture shown in this practice solution elegantly accommodates this without directly using the context classes in the ASP.NET/ASP.NET core controller. The usage happens indirectly through manager classes that provide the business logic.

Each instance of a manager class creates a new context instance. The lifetime of instances of the manager classes is tied to the lifetime of the instance of the WebAPI controller. As a result, a context instance does not live beyond processing the HTTP request.

Business Logic

Listing A-7 shows an example of the class `TaskManager`. This implementation is based on the generic base class `EntityManagerBase <contextType, entity type>`. In turn, `EntityManagerBase` is based on `DataManagerBase <contextType>`.

These two helper classes provide basic functions that do not always have to be realized in every manager class. This includes the following (Listing A-7, Listing A-8, and Listing A-9):

- `Creating a context instance when creating the Manager class`
- `Destroying the context instance when calling Dispose()`
- `Update(): Adding an object to the context in the “modified” state and saving the change`
- `New(): Adding a new object and saving the new object directly`
- `Remove(): Deleting an object and executing the deletion directly`
- `IsLoaded(): Checking whether an object exists in the local cache`

Web API

The MiracleList back end offers an HTTPS-based REST service in two versions.

- In version 1 of the REST service, the authentication token is passed in the URL.
- In version 2 of the REST service, the authentication token is passed in the HTTP header.

Version 1 of the REST service provides the following operations:

- POST/Login: Logging in with a client ID, username, and password. This operation/login sends back a GUID as a session token, to be given in all following operations.
- GET/Logout/{token}: Logging out the user.
- GET/CategorySet/{token}: Listing categories.
- GET/TaskSet/{token}/{id}: Listing tasks in a category.
- GET/Task/{token}/{id}: Listing details about a subtask task.
- GET/Search/{token}/{text}: Full-text searching in tasks and subtasks.
- GET/DueTaskSet/{token}: Listing tasks due.
- POST/CreateCategory/{token}/{name}: Creating a category.
- POST/CreateTask/{token}: Creating a task to submit in the body in JSON format (including subtasks).
- PUT/ChangeTask/{token}: Changing a task to be submitted in the body in JSON format (including subtasks).
- DELETE/DeleteTask/{token}/{id}: Deleting a task with all subtasks.
- DELETE/DeleteCategory/{token}/{id}: Deleting a category with all tasks and subtasks.

Version 2 of the REST service also offers the following operations:

- POST/Login: Logging in with a client ID, username, and password. This operation returns a GUID as the session token to be included in all subsequent operations.
- GET/CategorySet/: Listing categories.
- GET/TaskSet/{id}: Listing tasks in a category.
- GET/Task/{id}: Listing details of a task with subtasks.
- POST/CreateCategory/{name}: Creating a category.
- POST/CreateTask and PUT/ChangeTask: Creating or changing a task to be submitted in the body in JSON format (including subtasks).

For all REST operations, metadata is available in the Swagger OpenAPI Specification for RESTful APIs (<http://swagger.io>). See <https://miraclelistbackend.azurewebsites.net/swagger/v1/swagger.json> for a formal description of REST services, and see <https://miraclelistbackend.azurewebsites.net/swagger> for an appropriate help page. The back end also supports cross-origin resource sharing (CORS) to allow access to any other hosted web site (<https://www.w3.org/TR/cors>).

The client ID specified at /Login must be requested once by each client developer at <https://miraclelistbackend.azurewebsites.net/Client>. The number of tasks is limited to 1,000 per client ID. On the other hand, it is not necessary to create user accounts in the back end. Since this is an example application, a user is automatically created if the one you have submitted does not already exist. Each new account automatically has three categories (Work, Home, and Leisure) with example tasks such as Set up a Team Meeting, Bringing out Garbage, and Training for MTB Marathon.

Listing A-10 shows the startup code of the ASP.NET Core application, which enables and configures the various components, listed here:

- ASP.NET Core MVC.
- CORS to allow any web client to access the web API.
- Application Insights for monitoring and telemetry data. Application Insights is a cloud service from Microsoft.
- Disabling serialization of circular references in the JSON serializer. (Circular references are not standardized in JSON. There are community solutions, but you should avoid this if you do not need to be dependent on these community solutions.)
- Swagger for creating an OpenAPI specification and help pages for the REST operations.

Listing A-11 shows the implementation of the WebAPI controller in version 1 of the REST service, including the use of Application Insights to collect telemetry data. The WebAPI controller is completely free of data access code. So, Entity Framework Core is not being used here. All data operations are encapsulated in the business logic layer. The WebAPI controller only uses the manager classes implemented there.

Using Entity Framework Core via Dependency Injection

When creating a new ASP.NET Core application in Visual Studio with the option Individual User Accounts or Store User Accounts In-App, Entity Framework Core also creates an Entity Framework Core context (`ApplicationDbContext`), which is created by the base class `Microsoft.AspNetCore.Identity.EntityFrameworkCore`.

IdentityDbContext<T> inherits and uses the class ApplicationUser as the type parameter, which in turn is provided by Microsoft.AspNetCore.Identity. IdentityUser inherits. The class ApplicationUser can be extended if required. In addition, a schema migration is created. The connection string is stored in appsettings.json. It points to a local database (Microsoft SQL Server LocalDB).

```
{  
  "ConnectionStrings": {  
    "DefaultConnection": "Server=(localdb)\\mssqllocaldb;Database=aspnet-  
    ASPNETCore20-53bc9b9d-9d6a-45d4-8429-2a2761773502;Trusted_Connection=Tr  
    ue;MultipleActiveResultSets=true"  
  }  
}
```

You can change a connection string if necessary. After an Update-Database command, the database is created to manage the local users (Figure A-7).

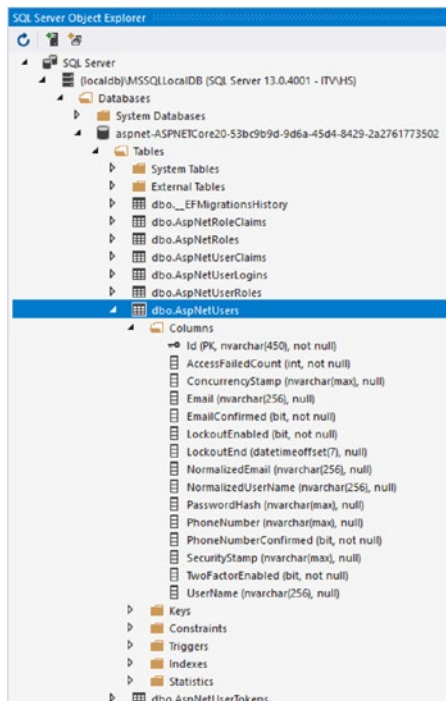

Figure A-7. Created database for managing users of the ASP.NET Core web application

There is no instantiation of the context class `ApplicationDbContext` in the web application. Rather, this is used by dependency injection. In `Startup.cs`, you will find two lines (see Listing A-12).

- The `AddDbContext()` extension method registers the context class as a dependency injection service and passes a provider and connection string. The method `AddDbContext()` is provided by `Microsoft.EntityFrameworkCore.dll` in the Microsoft class `Microsoft.Extensions.DependencyInjection.EntityFrameworkServiceCollectionExtensions`.
- The `AddEntityFrameworkStores()` extension method tells the ASP.NET Identity component which context class to use. `AddEntityFrameworkStores()` is provided by `Microsoft.AspNetCore.Identity.EntityFrameworkCore.dll` in the Microsoft class `Extensions.DependencyInjection.IdentityEntityFrameworkBuilderExtensions`.

Note ASP.NET Identity ensures that the context class is instantiated when needed and, in addition, lives no longer than it takes to process an HTTP request.

Listing A-12. An Extract from `Startup.cs`, an ASP.NET Core Web Application Created with the Project Template in Visual Studio, with Individual Local User Accounts

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("Default
            Connection")));

    services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();
}
```

Tip You can also use `AddDbContext()` for your own context classes. In this case, you register the context class in the startup class with `AddDbContext()`, as shown here:

```
services.AddDbContext<EFCore_Kontext.WWWingsContext>(options =>
options.UseSqlServer(Configuration.GetConnectionString("WWWings
Connection")));
```

When using the standard dependency injection component of ASP.NET Core (`Microsoft.Extensions.DependencyInjection`), dependency injection can be done only via constructor injection (see Listing A-13).

Listing A-13. The Class `FlightManager` Receives the Context Instance via Dependency Injection

```
using GO;
using EFCore_Context;
using System.Collections.Generic;
using System.Linq;

namespace ASPNETCore_NETCore.BL
{
public class FlightManager
{
private WWWingsContext ctx;

/// <summary>
/// constructor
/// </ summary>
/// <param name="ctx">context instance comes via DI!</ Param>
public FlightManager(WWWingsContext ctx)
{
this.ctx = ctx;
}

public List<Flight> GetFlightSet string departure, int from, int to)
{
```

```

var FlightSet = ctx.Flight
    .Where(x => x.Departure == departure)
    .Skip(from).Take(to - from).ToList();
return FlightSet.ToList();
}
}
}

```

Note, however, that ASP.NET Core injects the context instance only to the constructor of the `FlightManager` class if the instance of the `FlightManager` class itself is generated by the dependency injection (DI) container. To do this, the class `FlightManager` must be registered in the startup class for dependency injection with `AddTransient()`.

```

Services.AddTransient<Flight manager>();

```

`AddTransient()` causes a new instance of `FlightManager` to be generated each time an instance is requested. `AddScoped()` would ensure that the same instance is always returned as part of an HTTP request; this may be desired because then the cache of the Entity Framework core context is filled. `AddSingleton()` would always provide the same instance across multiple HTTP requests. This cannot work because the Entity Framework core context does not support multithreading.

An ASP.NET MVC controller then expects an instance of `FlightManager` via constructor injection (Listing A-14).

Listing A-14. The `WWWingsController` Class Receives an Instance of `FlightManager` via Dependency Injection

```

public class WWWingsController: Controller
{
    private FlightManager fm;
    public WWWingsController(FlightManager fm)
    {
        this.fm = fm;
    }
    ...
}

```

Practical Example: Context Instance Pooling (DbContext Pooling)

Ever since Entity Framework Core 2.0, you can use `AddDbContextPool()` instead of `AddDbContext()`. This method creates a set of context instances managed in a pool, similar to the ADO.NET connection pool. When dependency injection asks for a context instance, a free context instance is taken out of the pool. Entity Framework Core can also reset an already used context instance and release it for reuse. This somewhat improves the performance of web applications that use Entity Framework Core.

```
int poolSize = 40;
services.AddDbContextPool<ApplicationDbContext>(options => options.
UseSqlServer(Configuration.GetConnectionString("DefaultConnection")),
poolSize);
```

Using Entity Framework Core in a Universal Windows Platform App

The MiracleList Light app used in this section is a sample application for simple local task management, implemented as a Universal Windows Platform (UWP) app for Windows 10 with a local SQLite database as the data store and no back end in the cloud (Figure A-8). This app allows you to save tasks that are due on a specific date. In the current version of the software, tasks always have exactly three subtasks (planning, execution, retrospective) that cannot be changed. Tasks can be removed from the list by clicking Done or Remove All.

Note To use Entity Framework Core 2.0 in a UWP, you need UWP version 10.0.16299 in the Windows 10 Creators Fall 2017 update.

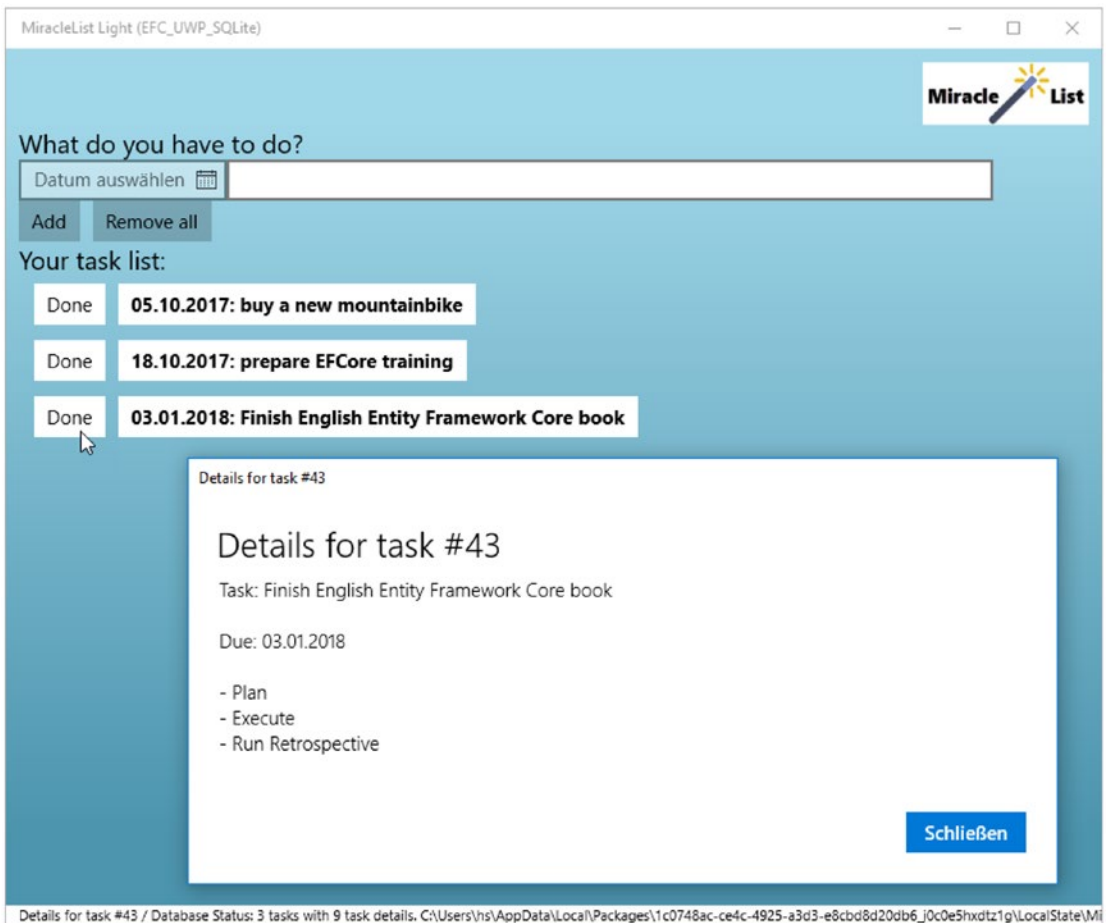

Figure A-8. The MiracleList Light app for Windows 10

Architecture

The app is implemented as a monolithic app in a Visual Studio project because of the limited code size. The project was created with the project template Windows Universal/Blank App. For this template, the Windows 10 SDK must be installed in the version appropriate for your Windows installation. Using or compiling the program on an older operating systems is not supported by Microsoft.

The app references the NuGet package `Microsoft.EntityFrameworkCore.Sqlite`.

The app uses forward engineering for the database. If necessary, the database file with the appropriate database schema is generated at runtime if it does not exist when the app starts. Figure A-9 shows the structure of the project.

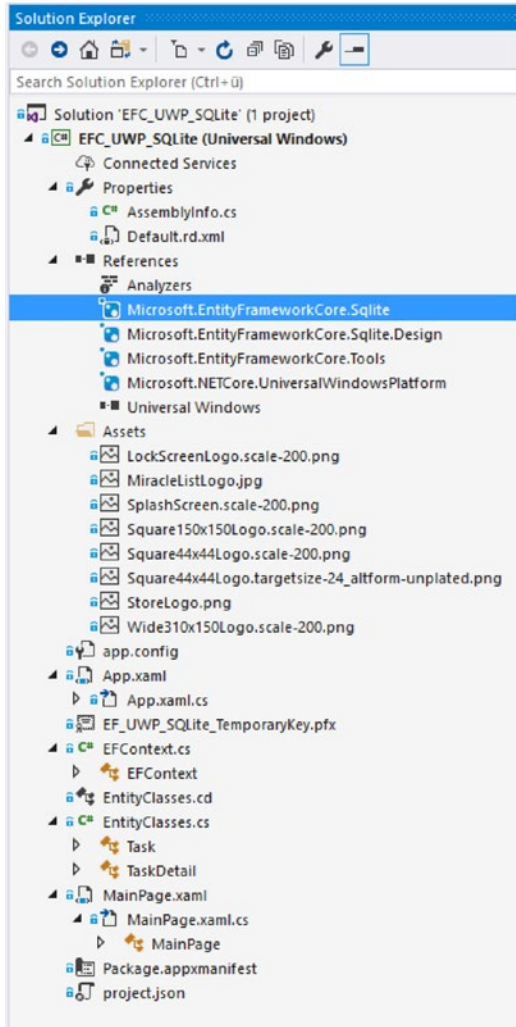

Figure A-9. Structure of the project

Entity

There are only two entity classes necessary.

- *Task class for a task:* A Task object has a List<TaskDetail> in the Details property.
- *TaskDetail class for a subtask:* Each TaskDetail object uses the Task property to point to the task to which the subtask belongs. In addition, the TaskDetail class in the TaskID foreign key property knows the primary key of the parent task.

Data annotations of entity classes are not necessary in this case because Entity Framework Core can create the database schema based purely on the built-in conventions. Figure A-10 shows the object model of the application, and Listing A-15 shows the implementation.

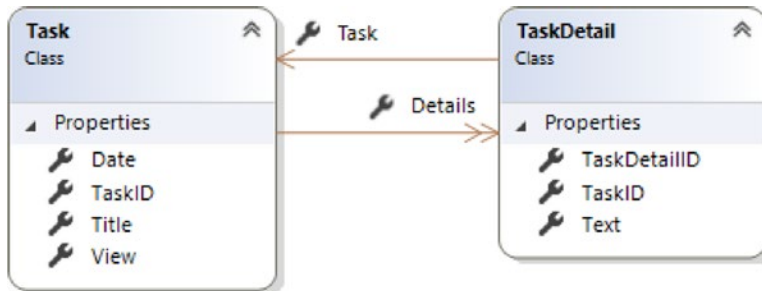

Figure A-10. Object model of the application

Listing A-15. Implementation of the Two Entity Classes in the EntityClasses.cs File

```

using System;
using System.Collections.Generic;

namespace EFC_UWP_SQLite
{
    /// <summary>
    /// Entity class for tasks
    /// </summary>
    public class Task
    {
        // Basic properties
        public int TaskID { get; set; } // PK
        public string Title { get; set; } // TEXT
        public DateTime Date { get; set; } // DateTime

        // Navigation properties
        public List<TaskDetail> Details { get; set; } = new List<TaskDetail>();

        public string View { get { return Date.ToString("d") + ": " + Title; } }
    }
}
  
```

```

/// <summary>
/// Entity class for subtasks
/// </summary>
public class TaskDetail
{
    // Basic properties
    public int TaskDetailID { get; set; } // PK
    public string Text { get; set; }

    // Navigation properties
    public Task Task { get; set; }
    public int TaskID { get; set; } // optional: Foreign key column for
    navigation relationship
}
}

```

Entity Framework Core Context Class

The context class derived from `DbContext` always has a property of type `DbSet<T>` for the two entity classes. In the `OnConfiguring()` method, `UseSqlite()` sets the Entity Framework Core database provider, passing in as a parameter only the name you want for the SQLite database file. An implementation of `OnModelCreating()` is not necessary in this case because Entity Framework Core can create the database schema based purely on the built-in conventions (Listing A-16).

Listing A-16. Implementation of the Context Class in the File `EFCContext.cs`

```

using Microsoft.EntityFrameworkCore;

namespace EFC_UWP_SQLite
{
    /// <summary>
    /// Entity Framework core context
    /// </summary>
    public class EFCContext : DbContext
    {
        public static string FileName = "MiracleList.db";
    }
}

```

```

public DbSet<Task> TaskSet { get; set; }
public DbSet<TaskDetail> TaskDetailSet { get; set; }

protected override void OnConfiguring(DbContextOptionsBuilder
optionsBuilder)
{
    // Set provider and database filename
    optionsBuilder.UseSqlite($"Filename={FileName}");
}
}
}

```

Start Code

When the application starts, the `App.xaml.cs` database file uses the `Database` method. `EnsureCreated()` is created if the database file does not yet exist. The English source code comments come from the project template of Microsoft. See Listing [A-17](#).

Listing A-17. Extract from the `App.xaml.cs` File

    using (var db = new EFContext())
    {
        db.Database.EnsureCreated();
    }
}

...
}
}
```

Generated Database

The generated database can be made visible and used interactively with the tool DB Browser for SQLite, as shown in Figure A-11, Figure A-12, and Figure A-13.

Data Access Code

The data access code is not separate from the presentation layer in this simple case study. It also deliberately does not use the Model-View-ViewModel (MVVM) pattern, what will keep the program code in this book manageable.

The data access uses the asynchronous methods of Entity Framework Core to keep the UI responsive.

When creating subtasks and deleting all tasks, two variants are shown (Listing A-18). The commented-out variant is the less efficient one. Thus, deleting all tasks and subtasks without using SQL involves unnecessarily loading all tasks and sending a DELETE command for each task. Explicit deletion of the subtasks is not necessary in both cases since cascading deletion is active in the standard system.

Using Entity Framework Core in a Xamarin Cross-Platform App

The MiracleList Light case study in this section is a portrayal of the Universal Windows Platform (UWP) app for Windows 10 that was discussed in the previous section. Here, it's a cross-platform app that is not limited to Windows 10 as the UWP app; it also runs on Android and iOS (Figure A-14 and Figure A-15). For the GUI, Xamarin.Forms is used.

Note For Entity Framework Core 2.0, you need UWP version 10.0.16299 in the Windows 10 Creators Fall 2017 update.

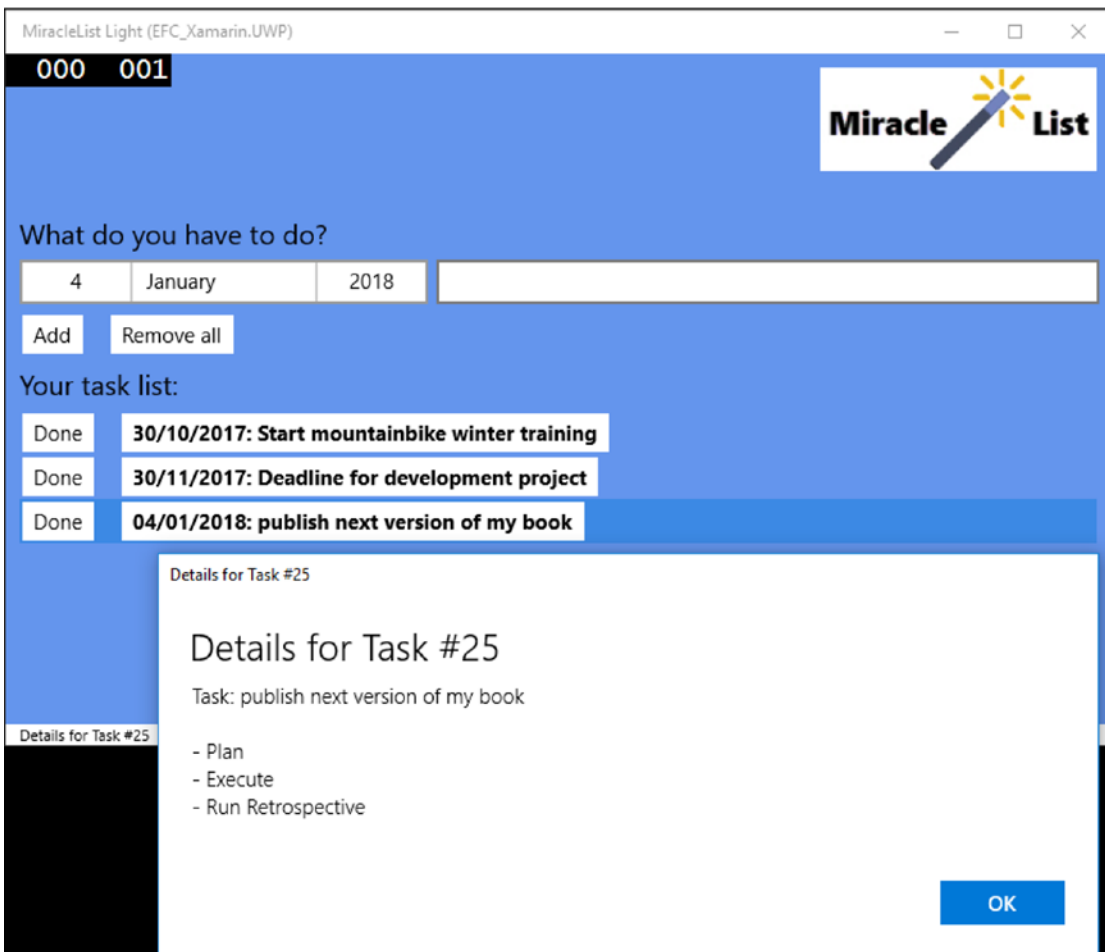

Figure A-14. The MiracleList Light cross-platform app for Windows 10

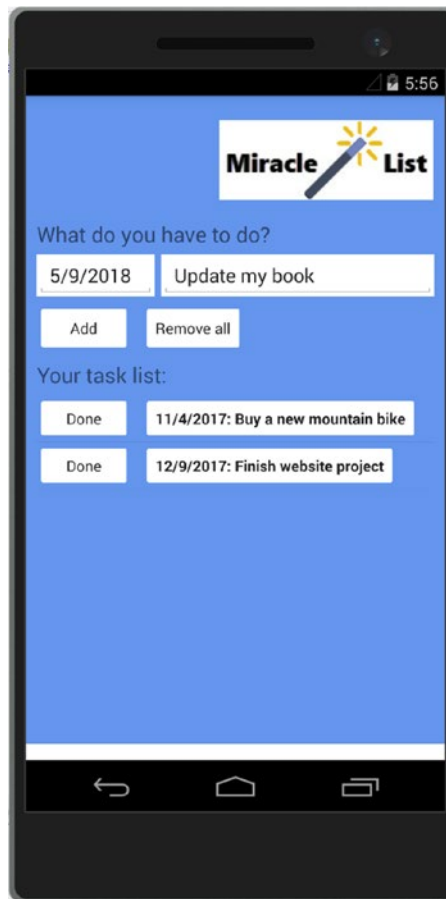

Figure A-15. *The MiracleList Light cross-platform app for Android*

Architecture

Unlike the implementation of this app as a UWP app, this cross-platform version is multilayered.

- The BO project contains the entity classes. The project is a .NET standard library and does not require additional references.
- The DAL project includes the Entity Framework Core context class. The project is a .NET standard library and requires the NuGet packages `Xamarin.Forms` and `Microsoft.EntityFrameworkCore`.
- The UI project contains the UI that uses Xamarin Forms. The project is a .NET standard library and requires the NuGet packages `Xamarin.Forms` and `Microsoft.EntityFrameworkCore`.

- The projects Android, iOS, and UWP contain the platform-specific start code as well as platform-specific declarations for the app.

The app uses forward engineering for the database. If necessary, the database file with the appropriate database schema is generated at runtime if it does not exist when the app starts. Figure A-16 shows the structure of the project.

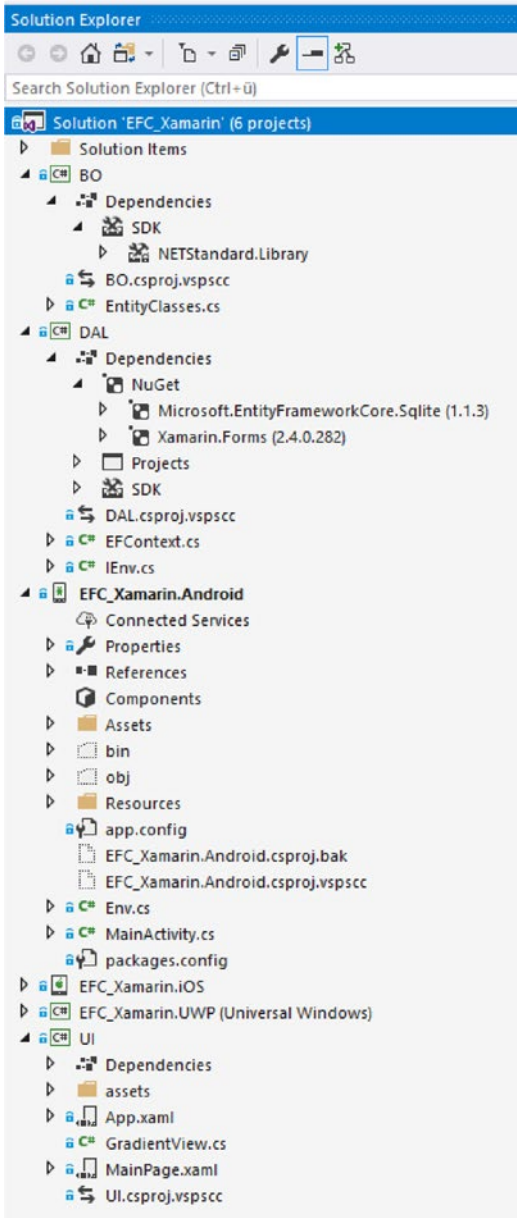

Figure A-16. Structure of the project

Entity

The entity classes for the Xamarin app correspond to the entity classes from the UWP case study.

Entity Framework Core Context Class

The context class for the Xamarin app differs slightly from the context class of the UWP case study because not every operating system can be specified in the connection string in `UseSQLite()` simply as a file name without a path. There are platform-specific differences to consider. Therefore, the path for the database file is supplied by dependency injection in an implementation of the self-defined interface `IEnv` of each of the three frame applications (Listing A-20 and Listing A-21).

Note The DAL library requires the NuGet package `Xamarin.Forms` because dependency injection uses the dependency injection framework built into `Xamarin.Forms`.

Start Code

When the application starts, the database file is created in `App.xaml.cs` by the method `Database.EnsureCreated()` if the database file does not yet exist (Listing A-25).

Generated Database

The generated database for the Xamarin app corresponds to the database from the UWP case study.

Data Access Code

The data access code is not separate from the presentation layer in this simple case study. It also deliberately does not use the pattern Model-View-ViewModel (MVVM) to keep the program code manageable for printing in this book.

The data access uses the asynchronous methods of Entity Framework Core to keep the UI responsive.

When creating subtasks and deleting all tasks, two variants are shown (Listing A-26). The commented-out variant is the less efficient one. Thus, deleting all tasks and subtasks without using SQL involves unnecessarily loading all tasks and sending a DELETE command for each task. However, explicitly deleting the subtasks is not necessary in both cases since cascading deletion is active in the standard system.

Many-to-Many Relationship to Oneself

Geography poses a seemingly simple task: Say a country has borders with any number of other countries. The question is, how do you express this in an object model so that Entity Framework Core makes it an N:M relationship of a table on itself?

The first naive approach would look like this: The Country class has a list of “borders” that lead back to Country objects. You would establish a relationship between Denmark and Germany like this: `dk.Borders.Add(de)`.

But that does not satisfy the requirements.

- In Entity Framework Core, there is no N:M mapping. Therefore, there must be an explicit Border class in the object model, just as in the data model. This can be encapsulated with a helper method; see `AddBorderToCountry(Country c)`.
- A single relationship between two countries is not enough because by creating a relationship such as `dk.Borders.Add(de)`, Denmark now knows that it borders Germany, but Germany knows nothing of its luck to have the Danes as neighbors.

The problem is that a navigation property describes a unidirectional relationship, but you need a bidirectional relationship so that both countries know about the relationship. Therefore, you have to create a navigation property in the class Country for both directions of a neighborhood relationship; see `IncomingBorders` and `OutgoingBorders` in the Country class as well as `IncomingCountry` and `OutgoingCountry` in the Border class. In `OnModelCreating()` in the context class, `WorldContext` `IncomingCountry` is connected via the Fluent API with `IncomingBorders`, and `OutgoingCountry` is connected with `OutgoingBorders`.

Entity Framework Core is then smart enough to build the counter-relationship when a relationship is established. This is ensured by the internal feature relationship fixup, which is always running when you call `DetectChanges()` or a method that triggers this automatically (for example, `SaveChanges()`).

If you apply the relationship from Denmark to Germany via `OutgoingBorders` from Denmark, Denmark will also appear in `IncomingBorders` from Germany after the next relationship fixup.

Listing A-28 shows the entity classes and the context class. Figure A-17 shows the resulting database in Microsoft SQL Server.

Listing A-28. Solution with Entity Framework Core

```
using Microsoft.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore.Metadata;
using System.Collections.Generic;
```

```

using System.Linq;

class Border
{
    // foreign key for IncomingCountry
    public int Country_Id { get; set; }
    // foreign key for OutgoingCountry
    public int Country_Id1 { get; set; }

    public virtual Country IncomingCountry { get; set; }
    public virtual Country OutgoingCountry { get; set; }
}

class Country
{
    public int Id { get; set; }
    public string Name { get; set; }

    // N-M relationship via Borders
    public virtual ICollection<Border> IncomingBorders { get; set; } = new
    List<Border>();
    public virtual ICollection<Border> OutgoingBorders { get; set; } = new
    List<Border>();

    public void AddBorderToCountry(Country c)
    {
        var b = new Border() {Country_Id = this.Id, Country_Id1 = c.Id};
        this.OutgoingBorders.Add(b);
    }
}

class WorldContext : DbContext
{
    public DbSet<Country> Countries { get; set; }
    public DbSet<Country> Borders { get; set; }
    protected override void OnConfiguring(DbContextOptionsBuilder optionsBuilder)
    {

```

```

optionsBuilder.UseSqlServer(@"Server=.;Database=EFC_NMSelf;Trusted_
Connection=True;MultipleActiveResultSets=True");
}

protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    // Configure primary key
    modelBuilder.Entity<Border>().HasKey(x => new {x.Country_Id, x.Country_Id1});
    // Configure relationships and foreign keys
    modelBuilder.Entity<Border>().HasOne<Country>(x => x.IncomingCountry).
    WithMany(x => x.IncomingBorders).HasForeignKey(x=>x.Country_Id1).
    OnDelete(DeleteBehavior.Restrict);
    modelBuilder.Entity<Border>().HasOne<Country>(x => x.OutgoingCountry).
    WithMany(x => x.OutgoingBorders).HasForeignKey(x => x.Country_Id).
    OnDelete(DeleteBehavior.Restrict); ;
}

/// <summary>
/// Get all neighbors by the union of the two sets
/// </summary>
/// <param name="countryId"></param>
/// <returns></returns>
public IEnumerable<Country> GetNeighbours(int countryId)
{
    var borders1 = this.Countries.Where(x => x.IncomingBorders.Any(y =>
    y.Country_Id == countryId)).ToList();
    var borders2 = this.Countries.Where(x => x.OutgoingBorders.Any(y =>
    y.Country_Id1 == countryId)).ToList();
    var allborders = borders1.Union(borders2).OrderBy(x=>x.Name);
    return allborders;
}
}

```

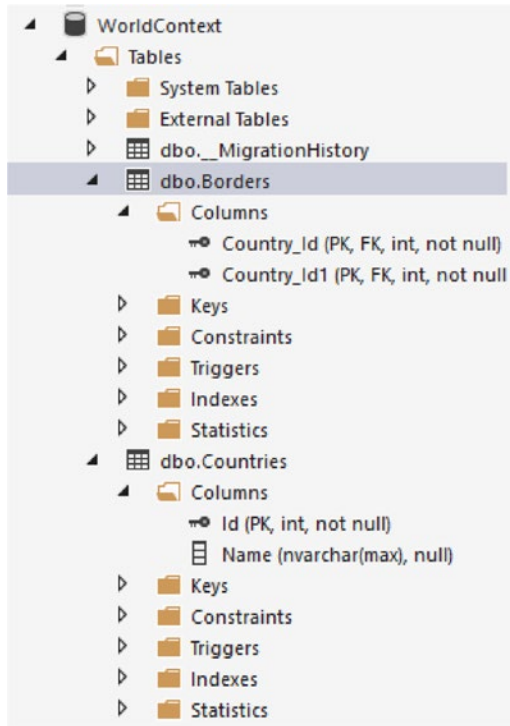

Figure A-17. *N:M relationship between country objects via Borders in the data model*

Although the database can now store all necessary relationships, you cannot get just a list of all border relations since these are distributed on two lists (OutgoingBorders). So, you would have to form the union with the LINQ operator `Union()` and write each time.

```
var borders1 = country.OutgoingBorders;
var borders2 = ctx.Countries.Where(x => x.OutgoingBorders.Any(y => y.Id ==
country.Id)).ToList();
var borders = borders1.Union(borders2).OrderBy(x=>x.Name);;
```

However, the user of the class should not care if the relationship Germany to Denmark or the relationship Denmark to Germany was created.

In the classic Entity Framework, you could elegantly encapsulate this union in the Country class and use lazy loading to load the connected objects. Since there is no lazy loading (so far) in Entity Framework Core and, as you know, the entity class instance does not know the context instance, the encapsulation works only in the context class (see `GetNeighbours()` in Listing A-29). Figure A-18 shows the output.
